Load your battery holder (taking care that the batteries are the right way around, with the negative ends pressing against the springs in the carrier). Use your meter to check the voltage on the wires coming out of the battery carrier. You should have at least 6 volts.

Now select a 2KΩ resistor. Remember, "2KΩ" means "2,000 ohms." If it has colored stripes, they should be red-black-red, meaning 2-0 and two more zeros. Because 2.2K resistors are more common than 2K resistors, you can substitute one of them if necessary. It will be colored red-red-red.

Wire it into the circuit as shown in Figures 1-44 and 1-45, making the connections with alligator clips. You should see the LED glow very dimly.

Now swap out your 2K resistor and substitute a 1K resistor, which will have brown-black-red stripes, meaning 1-0 and two more zeros. The LED should glow more brightly.

Swap out the 1K resistor and substitute a 470Ω resistor, which will have yellow-violet-brown stripes, meaning 4-7 and one more zero. The LED should be brighter still.

This may seem very elementary, but it makes an important point. The resistor blocks a percentage of the voltage in the circuit. Think of it as being like a kink or constriction in a flexible hose. A higher-value resistor blocks more voltage, leaving less for the LED.

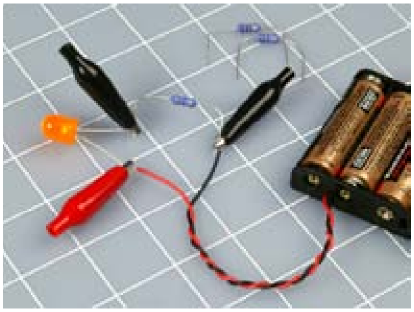

Figure 1-44. *The setup for Experiment 3, showing resistors of 470Ω, 1KΩ, and 2KΩ. Apply alligator clips where shown, to make a secure contact, and try each of the resistors one at a time at the same point in the circuit, while watching the LED.*

6v Battery Pack

Figure 1-45. *Here's how it actually looks, using a large LED. If you start with the highest value resistor, the LED will glow very dimly as you complete the circuit. The resistor drops most of the voltage, leaving the LED with insufficient current to make it shine brightly.*

Cleanup and Recycling

We'll use the batteries and the LED in the next experiment. The resistors can be reused in the future.

Experiment 4: Varying the Voltage

Potentiometers come in various shapes and sizes, but they all do the same thing: they allow you to vary voltage and current by varying resistance. This experiment will enable you to learn more about voltage, amperage, and the relationship between them. You'll also learn how to read a manufacturer's data sheet.

You will need the same batteries, battery carrier, alligator clips, and LED from the last experiment, plus:

- Potentiometer, 2KΩ linear. Quantity: 2. (See Figure 1-46.) Full-sized potentiometers that look like this are becoming less common, as miniature versions are taking their place. I'd like you to use a large one, though, because it's so much easier to work with.
- One extra LED.
- Multimeter.

Look Inside Your Potentiometer

The first thing I want you to do is find out how a potentiometer works. This means you'll have to open it, which is why your shopping list required you to buy two of them, in case you can't put the first one back together again.

Most potentiometers are held together with little metal tabs. You should be able to grab hold of the tabs with your wire cutters or pliers, and bend them up and outward. If you do this, the potentiometer should open up as shown in Figures 1-47 and 1-48.

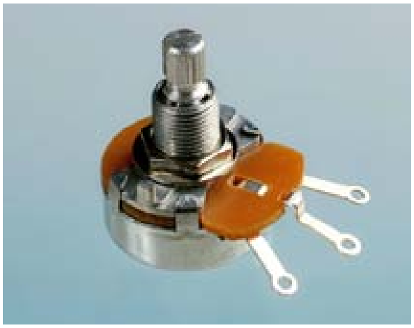

Figure 1-46

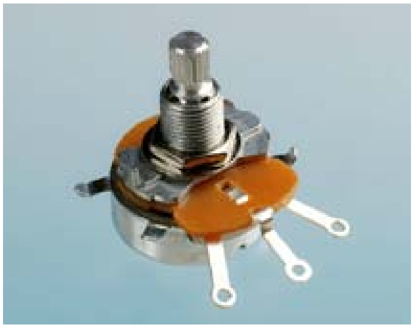

Figure 1-47

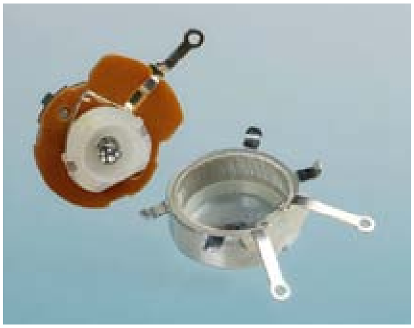

Figure 1-48. *To open the potentiometer, first pry up the four little metal tabs around the edge (you can see one sticking out at the left and another one sticking out at the right in Figure 1-47). Inside is a coil of wire around a flat plastic band, and a pair of springy contacts (the wiper), which conduct electricity to or from any point in the coil when you turn the shaft.*

Depending whether you have a really cheap potentiometer or a slightly more high-class version, you may find a circular track of conductive plastic or a loop of coiled wire. Either way, the principle is the same. The wire or the plastic possesses some resistance (a total of 2K in this instance), and as you turn the shaft of the potentiometer, a wiper rubs against the resistance, giving you a shortcut to any point from the center terminal.

You can try to put it back together, but if it doesn't work, use your backup potentiometer instead.

To test your potentiometer, set your meter to measure resistance (ohms) and touch the probes while turning the potentiometer shaft to and fro, as shown in Figure 1-49.

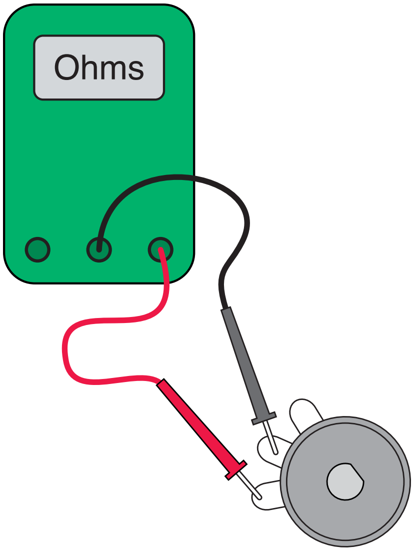

Figure 1-49. *Measure the resistance between these two terminals of the potentiometer while you turn its shaft to and fro.*

Dimming Your LED

Begin with the potentiometer turned all the way counterclockwise, otherwise you'll burn out the LED before we even get started. (A very, very small number of potentiometers increase and decrease resistance in the opposite way to which I'm describing here, but as long as your potentiometer looks like the one in Figure 1-48 after you open it up, my description should be accurate.)

Now connect everything as shown in Figures 1-50 and 1-51, taking care that you don't allow the metal parts of any of the alligator clips to touch each other. Now turn up the potentiometer *very* slowly. You'll notice the LED glowing brighter, and brighter, and brighter—until, oops, it goes dark. You see how easy it is to destroy modern electronics? Throw away that LED. It will never glow again. Substitute a new LED, and we'll be more careful this time.

On your battery pack, this wire may be either blue or black.
Begin with the potentiometer turned all the way counter-clockwise, and then rotate the shaft in the direction of the arrow.
6v Battery Pack

Figure 1-50. *The setup for Experiment 4. Rotating the shaft of the 2K potentiometer varies its resistance from 0 to 2,000Ω. This resistance protects the LED from the full 6 volts of the battery.*

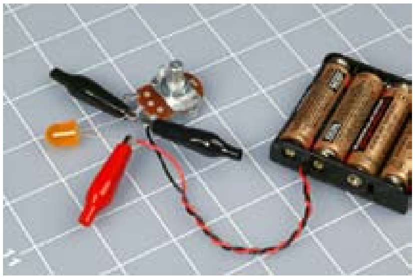

Figure 1-51. *The LED in this photo is dark because I turned the potentiometer up just a little bit too far.*

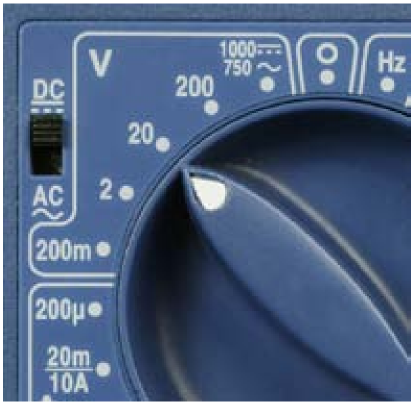

Figure 1-52

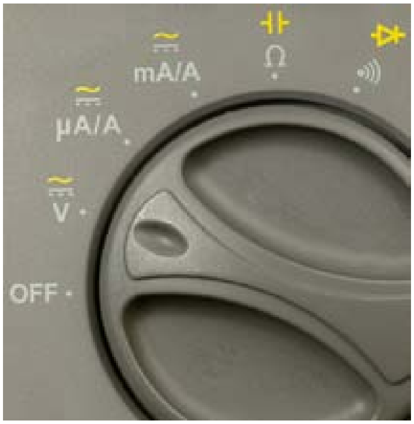

Figure 1-53

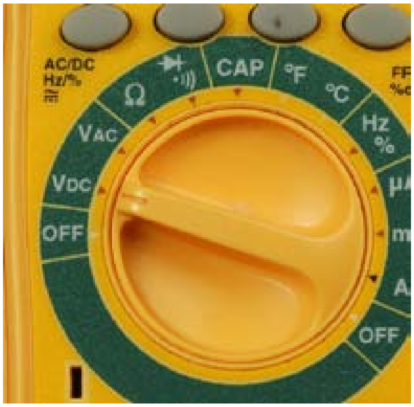

Figure 1-54. *Each meter has a different way to measure volts DC. The manually adjusted meter (top) requires you to move a slider switch to "DC" and then choose the highest voltage you want to measure: In this case, the selected voltage is 20 (because 2 would be too low). Using the autoranging RadioShack meter, you set it to "V" and the meter will figure out which range to use.*

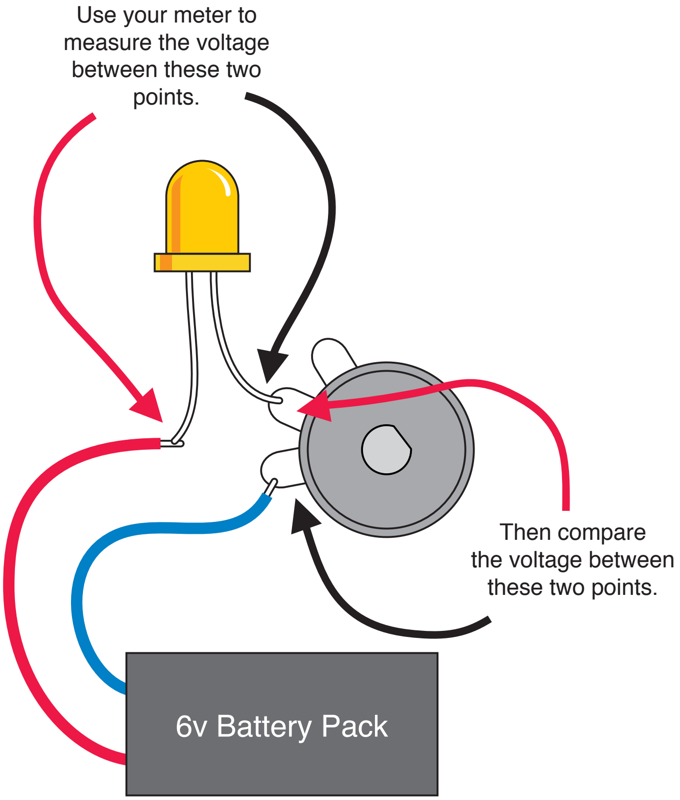
While the batteries are connected to the circuit, set your meter to measure *volts DC* as shown in Figures 1-52 through 1-54. Now touch the probes either side of the LED. Try to hold the probes in place while you turn the potentiometer up a little, and down a little. You should see the voltage pressure around the LED changing accordingly. We call this the *potential difference* between the two wires of the LED.

If you were using a miniature old-fashioned lightbulb instead of an LED, you'd see the potential difference varying much more, because a lightbulb behaves like a "pure" resistor, whereas an LED self-adjusts to some extent, modifying its resistance as the voltage pressure changes.

Now touch the probes to the two terminals of the potentiometer that we're using, so that you can measure the potential difference between them. The potentiometer and the LED share the total available voltage, so when the potential difference (the voltage drop) around the potentiometer goes up, the potential difference around the LED goes down, and vice versa. See Figures 1-55 through 1-57. A few things to keep in mind:

- If you add the voltage drops across the devices in the circuit, the total is the same as the voltage supplied by the batteries.
- You measure voltage relatively, between two points in a circuit.
- Apply your meter like a stethoscope, without disturbing or breaking the connections in the circuit.



Use your meter to measure the voltage between these two points.
Then compare the voltage between these two points.
6v Battery Pack

Figure 1-55. *How to measure voltage in a simple circuit.*

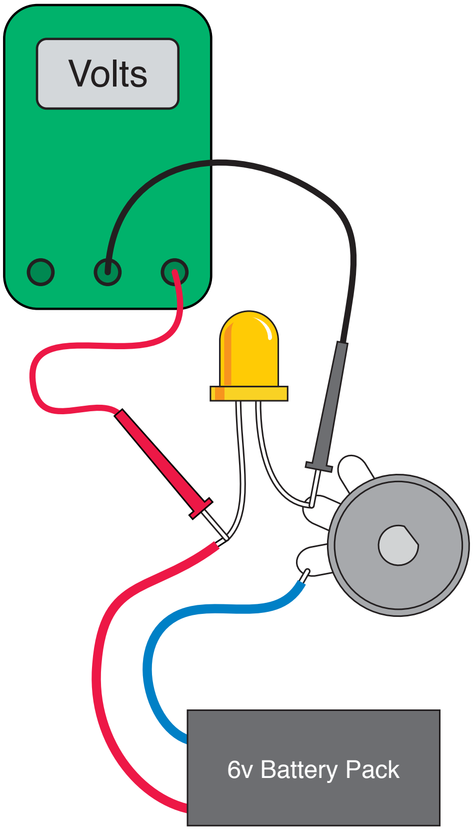


Figure 1-56. *The meter shows how much voltage the LED takes.*

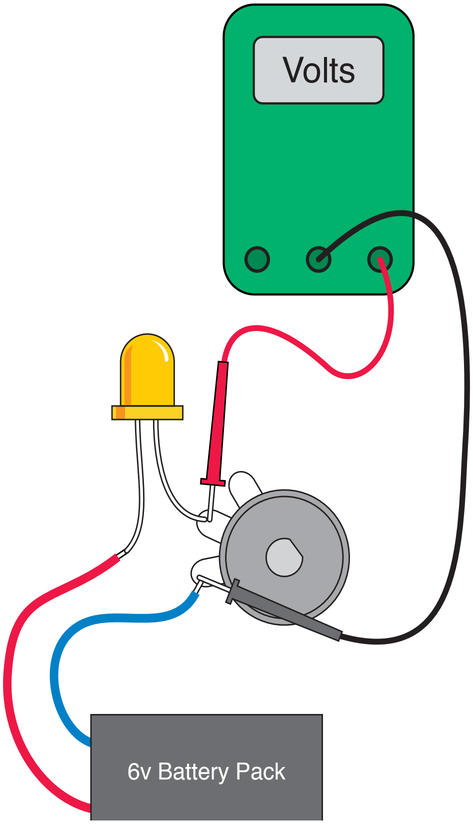

Figure 1-57. *The meter shows how much voltage the potentiometer takes.*

Checking the Flow

Now I want you to make a different measurement. I want you to measure the flow, or current, in the circuit, using your meter set to mA (milliamps). Remember, to measure current:

- You can only measure current when it passes *through* the meter.
- You have to insert your meter into the circuit.
- Too much current will blow the fuse inside your meter.

Make sure you set your meter to measure mA, not volts, before you try this. Some meters require you to move one of your leads to a different socket on the meter, to measure mA. See Figures 1-58 through 1-61.

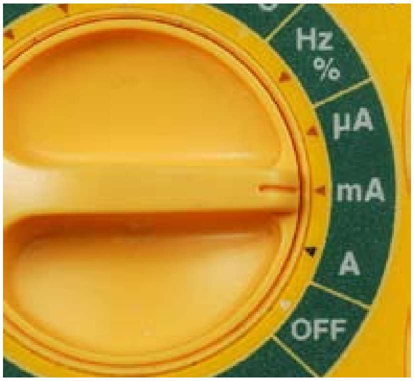

Figure 1-58. *Any meter will blow its internal fuse if you try to make it measure too high an amperage. In our circuit, this is not a risk as long as you keep the potentiometer in the middle of its range. Choose "mA" for milliamps and remember that the meter displays numbers that mean thousandths of an amp.*

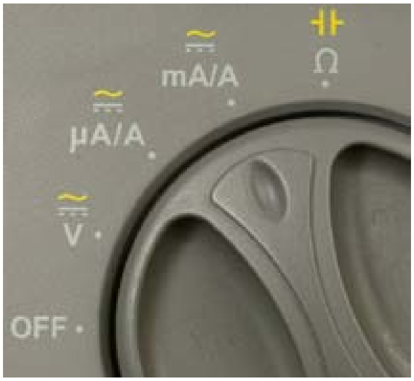

Figure 1-59

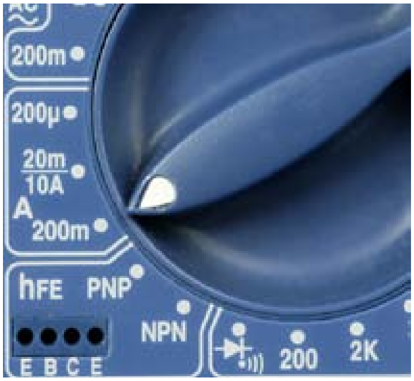

Figure 1-60

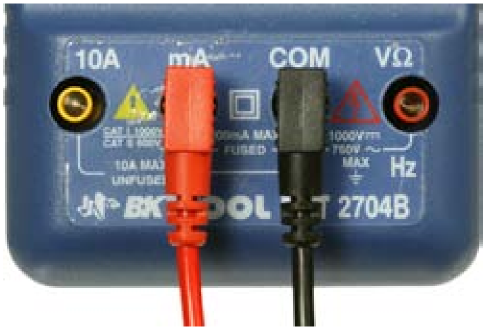

Figure 1-61. *A manual meter such as the one here may require you to shift the red lead to a different socket, to measure milliamps. Most modern meters don't require this until you are measuring higher currents.*

Insert your meter into the circuit, as shown in Figure 1-62. Don't turn the potentiometer more than halfway up. The resistance in the potentiometer will protect your meter, as well as the LED. If the meter gets too much current, you'll find yourself replacing its internal fuse.

As you adjust the potentiometer up and down a little, you should find that the varying resistance in the circuit changes the flow of current—the amperage. This is why the LED burned out in the previous experiment: too much current made it hot, and the heat melts it inside, just like the fuse in the previous experiment. *A higher resistance limits the flow of current, or amperage*.

Now insert the meter in another part of the circuit, as shown in Figure 1-63. As you turn the potentiometer up and down, you should get exactly the same results as with the configuration in Figure 1-64. This is because the current is the same at all points in a similar circuit. *It has to be, because the flow of electrons has no place else to go*.

It's time now to nail this down with some numbers. Here's one last thing to try. Set aside the LED and substitute a 1KΩ resistor, as shown in Figure 1-64. The total resistance in the circuit is now 1KΩ plus whatever the resistance the potentiometer provides, depending how you set it. (The meter also has some resistance, but it's so low, we can ignore it.)

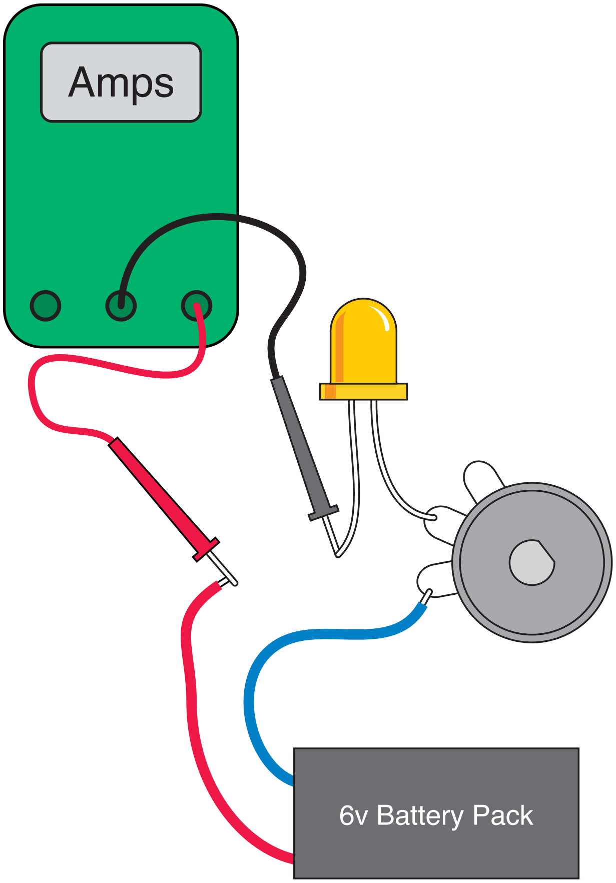

Figure 1-62. *To measure amps, as illustrated here and in Figure 1-63, the current has to pass through the meter. When you increase the resistance, you restrict the current flow, and the lower flow makes the LED glow less brightly.*

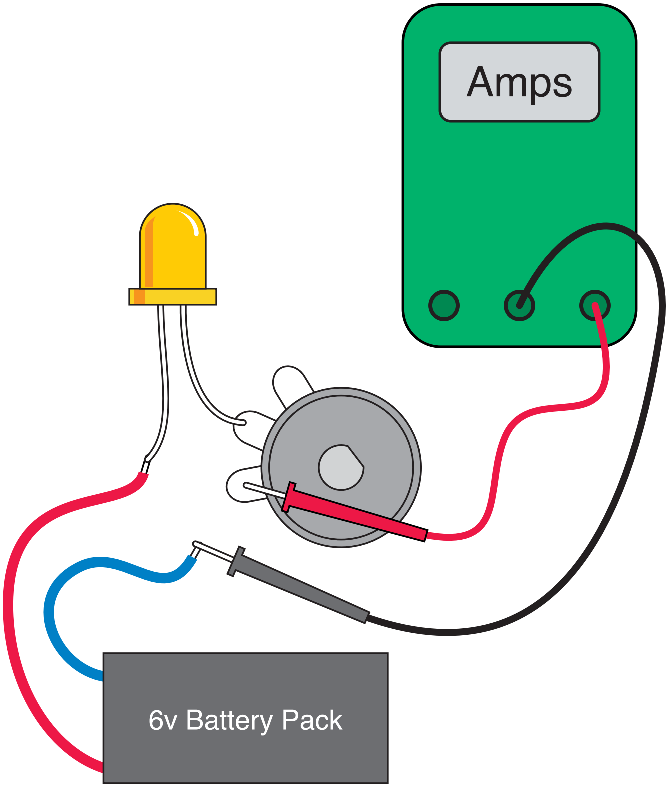

Figure 1-63

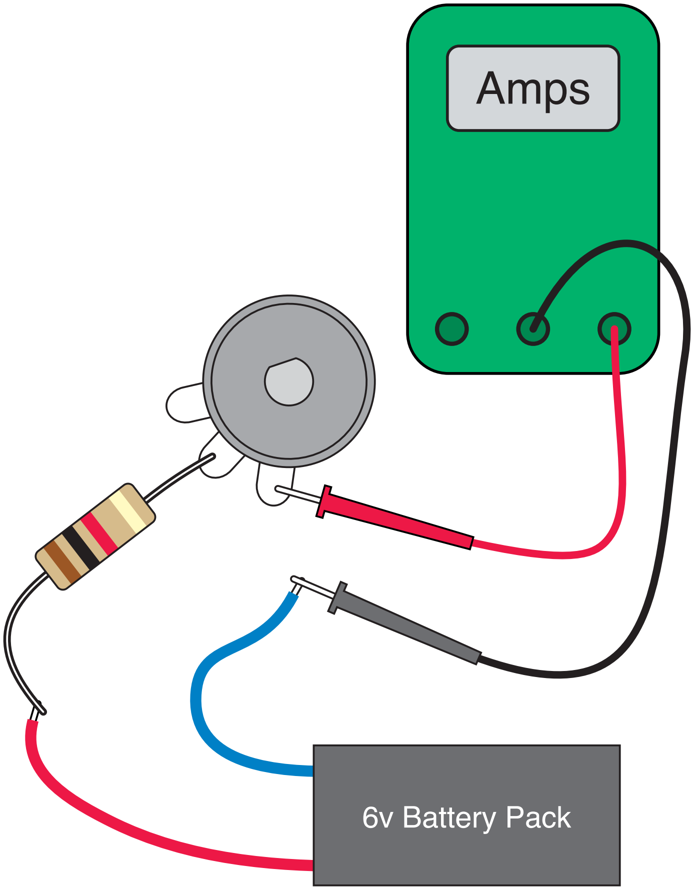

Figure 1-64. *If you substitute a resistor instead of the LED, you can confirm that the current flowing through the circuit varies with the total resistance in the circuit, if the voltage stays the same.*

Turn the potentiometer all the way counterclockwise, and you have a total of 3K resistance in the circuit. Your meter should show about 2 mA flowing. Now turn the potentiometer halfway, and you have about 2K total resistance. You should see about 3 mA flowing. Turn the potentiometer all the way clockwise, so there's a total of 1K, and you should see 6 mA flowing. You may notice that if we multiply the resistance by the amperage, we get 6 each time—which just happens to be the voltage being applied to the circuit. See the following table.

Total resistance	**Current**	**Voltage**
(KΩ)	(mA)	(Volts)
3	2	6
2	3	6
1	6	6

In fact, we could say:

voltage = kilohms × milliamps

But wait a minute: 1K is 1,000 ohms, and 1mA is 1/1,000 of an amp. Therefore, our formula should really look like this:

voltage = (ohms × 1,000) × (amps/1,000)

The two factors of 1,000 cancel out, so we get this:

volts = ohms × amps

This is known as Ohm's Law. See the section, "Fundamentals: Ohm's Law," on the following page.

FUNDAMENTALS

Series and parallel

Before we go any further, you should know how resistance in a circuit increases when you put resistors in series or in parallel. Figures 1-65 through 1-67 illustrate this. Remember:

- Resistors in series are oriented so that one follows the other.
- Resistors in parallel are oriented side by side.

When you put two equal-valued resistors in series, you double the total resistance, because electricity has to pass through two barriers in succession.

When you put two equal-valued resistors in parallel, you divide the total resistance by two, because you're giving the electricity two paths which it can take, instead of one.

In reality we don't normally need to put resistors in parallel, but we often put other types of components in parallel. Lightbulbs in your house, for instance, are all wired that way. So, it's useful to understand that resistance in a circuit goes down if you keep adding components in parallel.

circuit resistance
12mA current

Figure 1-67. *When two resistors are in parallel, each is exposed to the full voltage, so each of them takes 6 volts. The electricity can now flow through both at once, so the total resistance of the circuit is half as much as before. According to Ohm's Law, the circuit draws v/R = 6/500 = 0.012 amps = 12mA of current.*

FUNDAMENTALS

Ohm's Law

For reasons I'll explain in a moment, amps are normally abbreviated with the letter I. V stands for volts and R stands for resistance in ohms (because the omega symbol, Ω, is not easily generated from most keyboards). Using these symbols, you can write Ohm's Law in three different ways:

$$V = I \times R$$

$$I = V/R$$

$$R = V/I$$

Remember, V is a *difference* in voltage between two points in a simple circuit, R is the resistance in ohms *between* the same two points, and I is the current in amps flowing *through* the circuit between the two points.

Letter I is used because originally current was measured by its *inductance*, meaning the ability to induce magnetic effects. It would be much less confusing to use A for amps, but unfortunately it's too late for that to happen.

Using Ohm's Law

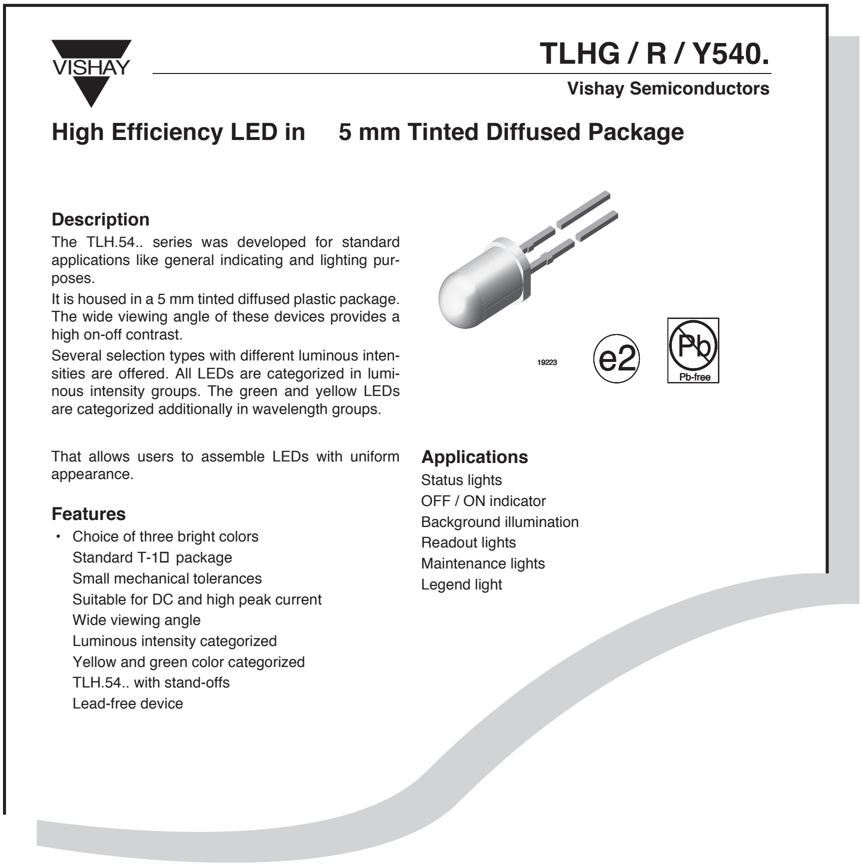
Ohm's Law is extremely useful. For example, it helps us to figure out whether a component can be used safely in a circuit. Instead of stressing the component until we burn it out, we can predict whether it will work.

For instance, the first time you turned the potentiometer, you didn't really know how far you could go until the LED burned out. Wouldn't it be useful to know precisely what resistance to put in series with an LED, to protect it adequately while providing as much light as possible?

How to Read a Data Sheet

Like most information, the answer to this question is available online.

Here's how you find a manufacturer's data sheet (Figure 1-68). First, find the component that you're interested in from a mail-order source. Next, Google the part number and manufacturer's name. Usually the data sheet will pop up as the first hit. A source such as *Mouser.com* makes it even easier by giving you a direct link to manufacturers' data sheets for many products.



VISHAY

TLHG / R / Y540.

Vishay Semiconductors

High Efficiency LED in 5 mm Tinted Diffused Package

Description

The TLH.54.. series was developed for standard applications like general indicating and lighting purposes.

It is housed in a 5 mm tinted diffused plastic package. The wide viewing angle of these devices provides a high on-off contrast.

Several selection types with different luminous intensities are offered. All LEDs are categorized in luminous intensity groups. The green and yellow LEDs are categorized additionally in wavelength groups.

That allows users to assemble LEDs with uniform appearance.

Features

- Choice of three bright colors
  Standard T-1□ package
  Small mechanical tolerances
  Suitable for DC and high peak current
  Wide viewing angle
  Luminous intensity categorized
  Yellow and green color categorized
  TLH.54.. with stand-offs
  Lead-free device

Applications

Status lights
OFF / ON indicator
Background illumination
Readout lights
Maintenance lights
Legend light

Figure 1-68. *The beginning of a typical data sheet, which includes all relevant specifications for the product, freely available online.*

BACKGROUND

How much voltage does a wire consume?

Normally, we can ignore the resistance in electric wires, such as the little leads of wire that stick out of resistors, because it's trivial. However, if you try to force large amounts of current through long lengths of thin wire, the resistance of the wire can become important.

How important? Once again, we can use Ohm's Law to find out.

Suppose that a very long piece of wire has a resistance of 0.2Ω. And we want to run 15 amps through it. How much voltage will the wire steal from the circuit, because of its resistance?

Once again, you begin by writing down what you know:

$R = 0.2$

$I = 15$

We want to know V, the potential difference, for the wire, so we use the version of Ohm's Law that places V on the left side:

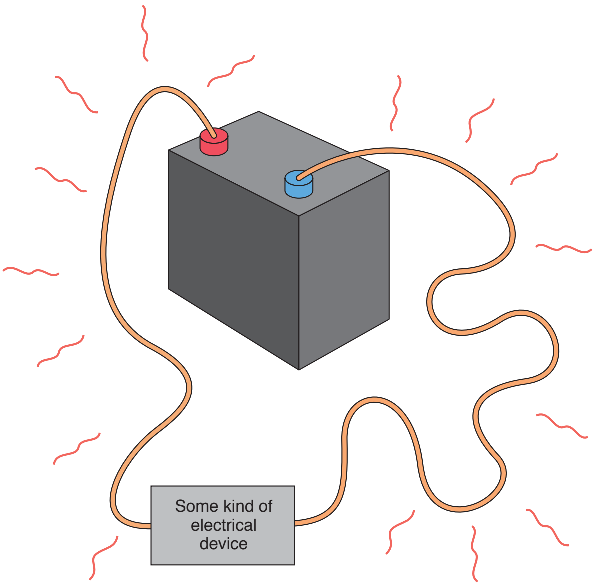
$V = I \times R$

Now plug in the values:

$V = 15 \times 0.2 = 3$ volts

Three volts is not a big deal if you have a high-voltage power supply, but if you are using a 12-volt car battery, this length of wire will take one-quarter of the available voltage.

Now you know why the wiring in automobiles is relatively thick—to reduce its resistance well below 0.2Ω. See Figure 1-69.



Some kind of electrical device

Figure 1-69. *When a 12-volt car battery runs some kind of electrical device through a long piece of thin wire, the resistance of the wire steals some of the voltage and dissipates it as heat.*

BACKGROUND

The origins of wattage

James Watt (Figure 1-70) is known as the inventor of the steam engine. Born in 1736 in Scotland, he set up a small workshop in the University of Glasgow, where he struggled to perfect an efficient design for using steam to move a piston in a cylinder. Financial problems and the primitive state of the art of metal working delayed practical applications until 1776.

Despite difficulties in obtaining patents (which could only be granted by an act of parliament in those times), Watt and his business partner eventually made a lot of money from his innovations. Although he predated the pioneers in electricity, in 1889 (70 years after his death), his name was assigned to the basic unit of electric power that can be defined by multiplying amperes by volts. See the Fundamentals section, "Watt Basics," on page 31.

Figure 1-70. *James Watt's development of steam power enabled the industrial revolution. After his death, he was honored by having his name applied to the basic unit of power in electricity.*

Here's an example. Suppose I want a red LED, such as the Vishay part TLHR5400, which has become such a common item that I can buy them individually for 9 cents apiece. I click the link to the data sheet maintained by the manufacturer, Vishay Semiconductor. Almost immediately I have a PDF page on my screen. This data sheet is for TLHR, TLHG, and TLHY types of LED, which are red, green, and yellow respectively, as suggested by the R, G, and Y in the product codes. I scroll down and look at the "Optical and Electrical Characteristics" section. It tells me that under conditions of drawing a current of 20 mA, the LED will enjoy a "Typ," meaning, typical, "forward voltage" of 2 volts. The "Max," meaning maximum, is 3 volts.

Let's look at one other data sheet, as not all of them are written the same way. I'll choose a different LED, the Kingbright part WP7113SGC. Click on the link to the manufacturer's site, and I find on the second page of the data sheet a typical forward voltage of 2.2, maximum 2.5, and a maximum forward current of 25 mA. I also find some additional information: a maximum reverse voltage of 5 and maximum reverse current of 10 uA (that's microamps, which are 1,000 times smaller than milliamps). This tells us that you should avoid applying excessive voltage to the LED the wrong way around. If you exceed the reverse voltage, you risk burning out the LED. Always observe polarity!

Kingbright also warns us how much heat the LED can stand: 260° C (500° F) for a few seconds. This is useful information, as we'll be putting aside our alligator clips and using hot molten solder to connect electrical parts in the near future. Because we have already destroyed a battery, a fuse, and an LED in just four experiments, maybe you won't be surprised when I tell you that we will destroy at least a couple more components as we test their limits with a soldering iron.

Anyway, now we know what an LED wants, we can figure out how to supply it. If you have any difficulties dealing with decimals, check the Fundamentals section "Decimals," on the next page, before continuing.

How Big a Resistor Does an LED Need?

Suppose that we're use the Vishay LED. Remember its requirements from the data sheet? Maximum of 3 volts, and a safe current of 20mA.

I'm going to limit it to 2.5 volts, to be on the safe side. We have 6 volts of battery power. Subtract 2.5 from 6 and we get 3.5. So we need a resistor that will take 3.5 volts from the circuit, leaving 2.5 for the LED.

The current flow is the same at all places in a simple circuit. If we want a maximum of 20mA to flow through the LED, the same amount of current will be flowing through the resistor.

Now we can write down what we know about the resistor in the circuit. Note that we have to convert all units to volts, amps, and ohms, so that 20mA should be written as 0.02 amps:

V = 3.5 (the potential drop across the resistor)
I = 0.02 (the current flowing through the resistor)

We want to know R, the resistance. So, we use the version of Ohm's Law that puts R on the left side:

$R = V/I$

Now plug in the values:

$R = 3.5/0.02$

Run this through your pocket calculator if you find decimals confusing. The answer is:

$R = 175\Omega$

It so happens that 175Ω isn't a standard value. You may have to settle for 180 or 220Ω, but that's close enough.

Evidently the 470Ω resistor that you used in Experiment 3 was a very conservative choice. I suggested it because I said originally that you could use any LED at all. I figured that no matter which one you picked, it should be safe with 470Ω to protect it.

Cleanup and Recycling

The dead LED can be thrown away. Everything else is reusable.

FUNDAMENTALS

Decimals

Legendary British politician Sir Winston Churchill is famous for complaining about "those damned dots." He was referring to decimal points. Because Churchill was Chancellor of the Exchequer at the time, and thus in charge of all government expenditures, his difficulty with decimals was a bit of a problem. Still, he muddled through in time-honored British fashion, and so can you.

You can also use a pocket calculator—or follow two basic rules.

Doing multiplication: combine the zeros

Suppose you need to multiply 0.04 by 0.005:

1. Count the total number of zeros following both of the decimal points. In this case, three zeros.
2. Multiply the numbers which follow the zeros. In this case, $4 \times 5 = 20$.
3. Write down the result as 0 followed by a decimal point, followed by the number of zeros, followed by the multiplication result. Like this: 0.00020, which is the same as 0.0002.

Doing division: cancel the zeros

Suppose you need to divide 0.006 by 0.0002:

1. Shift the decimal points to the right, in both the numbers, by the same number of steps, until both the numbers are greater than 1. In this case, shift the point four steps in each number, so you get 60 divided by 2.
2. Do the division. The result in this case is 30.

THEORY

Doing the math on your tongue

I'm going to go back to the question I asked in the previous experiment: why didn't your tongue get hot?

Now that you know Ohm's Law, you can figure out the answer in numbers. Let's suppose the battery delivered its rated 9 volts, and your tongue had a resistance of 50K, which is 50,000 ohms. Write down what you know:

$V = 9$

$R = 50{,}000$

We want to know the current, I, so we use the version of Ohm's Law that puts this on the left:

$I = V/R$

Plug in the numbers:

$I = 9/50{,}000 = 0.00018$ amps

Move the decimal point three places to convert to milliamps:

$I = 0.18$ mA

That's a tiny current that will not produce much heat at 9 volts.

What about when you shorted out the battery? How much current made the wires get hot? Well, suppose the wires had a resistance of 0.1 ohms (probably it's less, but I'll start with 0.1 as a guess). Write down what we know:

$V = 1.5$

$R = 0.1$

Once again we're trying to find I, the current, so we use:

$I = V/R$

Plug in the numbers:

$I = 1.5/0.1 = 15$ amps

That's 100,000 times the current that may have passed through your tongue, which would have generated much more heat, even though the voltage was lower.

Could that tiny little battery really pump out 15 amps? Remember that the battery got hot, as well as the wire. This tells us that the electrons may have met some resistance inside the battery, as well as in the wire. (Otherwise, where else did the heat come from?) Normally we can forget about the internal resistance of a battery, because it's so low. But at high currents, it becomes a factor.

I was reluctant to short-circuit the battery through a meter, to try to measure the current. My meter will fry if the current is greater than 10A. However I did try putting other fuses into the circuit, to see whether they would blow. When I tried a 10A fuse, it did not melt. Therefore, for the brand of battery I used, I'm fairly sure that the current in the short circuit was under 10A, but I know it was over 3A, because the 3A fuse blew right away.

The internal resistance of the 1.5-volt battery prevented the current in the short circuit from getting too high. This is why I cautioned against using a larger battery (especially a car battery). Larger batteries have a much lower internal resistance, allowing dangerously high currents which generate explosive amounts of heat. A car battery is designed to deliver literally hundreds of amps when it turns a starter motor. That's quite enough current to melt wires and cause nasty burns. In fact, you can weld metal using a car battery.

Lithium batteries also have low internal resistance, making them very dangerous when they're shorted out. High current can be just as dangerous as high voltage.

FUNDAMENTALS

Watt basics

So far I haven’t mentioned a unit that everyone is familiar with: watts.

A watt is a unit of work. Engineers have their own definition of work—they say that work is done when a person, an animal, or a machine pushes something to overcome mechanical resistance. Examples would be a steam engine pulling a train on a level track (overcoming friction and air resistance) or a person walking upstairs (overcoming the force of gravity).

When electrons push their way through a circuit, they are overcoming a kind of resistance, and so they are doing work, which can be measured in watts. The definition is easy:

watts = volts × amps

Or, using the symbols customarily assigned, these three formulas all mean the same thing:

$W = V \times I$

$V = W/I$

$I = W/V$

Watts can be preceded with an “m,” for “milli,” just like volts:

Number of watts	Usually expressed as	Abbreviated as
0.001 watts	1 milliwatt	1mW
0.01 watts	10 milliwatts	10 mW
0.1 watts	100 milliwatts	100 mW
1 watt	1,000 milliwatts	1W

Because power stations, solar installations, and wind farms deal with much larger numbers, you may also see references to kilowatts (using letter K) and megawatts (with a capital M, not to be confused with the lowercase m used to define milliwatts):

Number of watts	Usually expressed as	Abbreviated as
1,000 watts	1 kilowatt	1 KW
1,000,000 watts	1 megawatt	1 MW

Lightbulbs are calibrated in watts. So are stereo systems. The watt is named after James Watt, inventor of the steam engine. Incidentally, watts can be converted to horsepower, and vice versa.

THEORY

Power assessments

I mentioned earlier than resistors are commonly rated as being capable of dealing with 1/4 watt, 1/2 watt, 1 watt, and so on. I suggested that you should buy resistors of 1/4 watt or higher. How did I know this?

Go back to the LED circuit. Remember we wanted the resistor to drop the voltage by 3.5 volts, at a current of 20 mA. How many watts of power would this impose on the resistor?

Write down what you know:

$V = 3.5$ (the voltage drop imposed by the resistor)

$I = 20\text{mA} = 0.02$ amps (the current flowing through the resistor)

We want to know W, so we use this version of the formula:

$W = V \times I$

Plug in the values:

$W = 3.5 \times 0.02 = 0.07$ watts (the power being dissipated by the resistor)

Because 1/4 watt is 0.25 watts, obviously a 1/4 watt resistor will have about four times the necessary capacity. In fact you could have used a 1/8 watt resistor, but in future experiments we may need resistors that can handle 1/4 watt, and there’s no penalty for using a resistor that is rated for more watts than will actually pass through it.

Experiment 5: Let's Make a Battery

Long ago, before web surfing, file sharing, or cell phones, kids were so horribly deprived that they tried to amuse themselves with kitchen-table experiments such as making a primitive battery by pushing a nail and a penny into a lemon. Hard to believe, perhaps, but true!

This is seriously old-school—but I want you to try it anyway, because anyone who wants to get a feel for electricity should see how easy it is to extract it from everyday objects around us. Plus, if you use enough lemons, you just *might* generate enough voltage to power an LED.

The basic components of a battery are two metal electrodes immersed in an electrolyte. I won't define these terms here (they're explained in the following section "Theory: The nature of electricity"). Right now all you need to know is that lemon juice will be your electrolyte, and copper and zinc will be your electrodes. A penny provides the necessary copper, as long as it is fairly new and shiny. Pennies aren't solid copper anymore, but they are still copper-plated, which is good enough.

To find some metallic zinc, you will have to make a trip to a hardware store, where you should ask for roofing nails. The nails are zinc-plated to prevent them from rusting. Small metal brackets or mending plates also are usually zinc-plated. They should have a slightly dull, silvery look. If they have a mirror-bright finish, they're more likely to be nickel-plated.

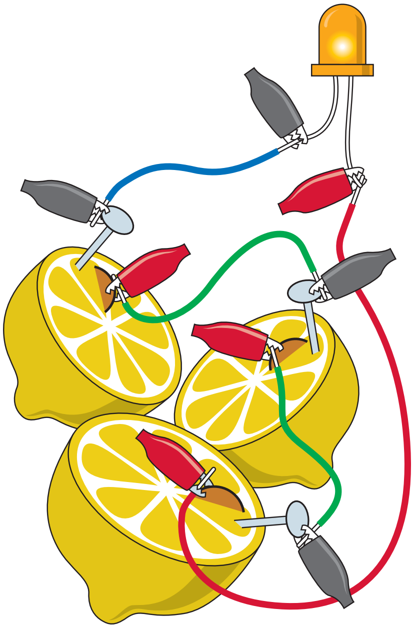


Figure 1-71. *A three-lemon battery. Don't be too disappointed if the LED fails to light up. The lemons have a high electrical resistance, so they can't deliver much current, especially through the relatively small surface area of the nails and the pennies. However, the lemon battery does generate voltage that you can measure with your meter.*

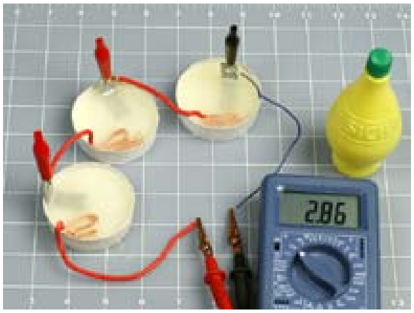

Figure 1-72. *Bottled lemon juice seems to work just as well as fresh lemon juice. I cut the bottoms off three paper cups, inserted a galvanized bracket into each, and used heavyweight stranded copper wire to make the positive electrodes*

Cut a lemon in half, set your multimeter so that it can measure up to 2 volts DC, and hold one probe against a penny while you hold the other probe against a roofing nail (or other zinc-plated object). Now force the penny and the nail into the exposed juicy interior of the lemon, as close to each other as possible, but not actually touching. You should find that your meter detects between 0.8 volts and 1 volt.

You can experiment with different items and liquids to see which works best. Immersing your nail and penny in lemon juice that you have squeezed into a shot glass or egg cup may enhance the efficiency of your battery, although you'll have a harder time holding everything in place. Grapefruit juice and vinegar will work as substitutes for lemon juice.

To drive a typical LED, you need more than 1 volt. How to generate the extra electrical pressure? By putting batteries in series, of course. In other words, more lemons! (Or more shot glasses or egg cups.) You'll also need lengths of wire to connect multiple electrodes, and this may entail skipping ahead to Chapter 2, where I describe how to strip insulation from hookup wire. Figures 1-71 and 1-72 show the configuration.

If you set things up carefully, making sure than none of the electrodes are touching, you may be able to illuminate your LED with two or three lemon-juice batteries in series. (Some LEDs are more sensitive to very low currents than others. Later in the book I'll be talking about very-low-current LEDs. If you want your lemon-juice battery to have the best chance of working, you can search online for low-current LEDs and buy a couple.)

THEORY

The nature of electricity

To understand electricity, you have to start with some basic information about atoms. Each atom consists of a nucleus at the center, containing protons, which have a positive charge. The nucleus is surrounded by electrons, which carry a negative charge.

Breaking up the nucleus of an atom requires a lot of energy, and can also liberate a lot of energy—as happens in a nuclear explosion. But persuading a couple of electrons to leave an atom (or join an atom) takes very little energy. For instance, when zinc reacts chemically with an acid, it can liberate electrons. This is what happens at the zinc electrode of the chemical battery in Experiment 5.

The reaction soon stops, as electrons accumulate on the zinc electrode. They feel a mutual force of repulsion, yet they have nowhere to go. You can imagine them like a crowd of hostile people, each one wanting the others to leave, and refusing to allow new ones to join them, as shown in Figure 1-73.

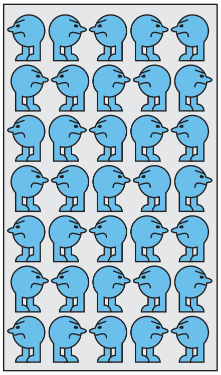

Figure 1-73. *Electrons on an electrode have a bad attitude known as mutual repulsion.*

Now consider what happens when a wire connects the zinc electrode, which has a surplus of electronics, to another electrode, made from a different material, that has a shortage of electrons. The electrons can pass through the wire very easily by jumping from one atom to the next, so they escape from the zinc electrode and run through the wire, propelled by their great desire to get away from each other. See Figure 1-74. This mutual force of propulsion is what creates an electrical current.

Now that the population of electrons on the zinc electrode has been reduced, the zinc-acid reaction can continue, replacing the missing electrodes with new ones—which promptly imitate their predecessors and try to get away from each other by running away down the wire. The process continues until the zinc-acid reaction grinds to a halt, usually because it creates a layer of a compound such as zinc oxide, which won't react with acid and prevents the acid from reacting with the zinc underneath. (This is why your zinc electrode may have looked sooty when you pulled it out of the acidic electrolyte.)

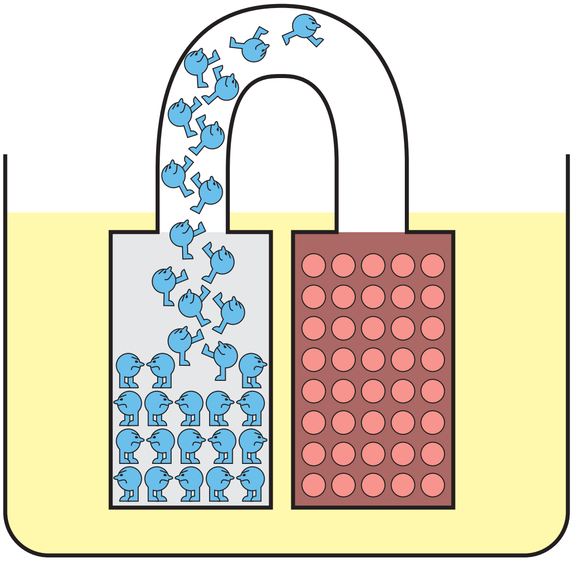

Figure 1-74. *As soon as we open up a pathway from a zinc electrode crowded with electrons to a copper electrode, which contains "holes" for the electrons, their mutual repulsion makes them try to escape from each other to their new home as quickly as possible.*

This description applies to a "primary battery," meaning one that is ready to generate electricity as soon as a connection between its terminals allows electrons to transfer from one electrode to the other. The amount of current that a primary battery can generate is determined by the speed at which chemical reactions inside the battery can liberate electrons. When the raw metal in the electrodes has all been used up in chemical reactions, the battery can't generate any more electricity and is dead. It cannot easily be recharged, because the chemical reactions are not easily reversible, and the electrodes may have oxidized.

In a rechargeable battery, also known as a secondary battery, a smarter choice of electrodes and electrolyte does allow the chemical reactions to be reversed.

How much current is being generated in your lemon battery? Set your meter to measure milliamps, and connect it between the nail and the penny. I measured about 2mA, but got 10mA when I used some #10 stranded copper wire instead of a penny and a large mending plate instead of a roofing nail, immersed in a cup of grapefruit juice. When a larger surface area of metal makes better contact with the electrolyte, you get a greater flow of current. (Don't ever connect your meter to measure amps directly between the terminals of a real battery. The current will be too high, and can blow the fuse inside your meter.)

What's the internal resistance of your lemon? Put aside the copper and zinc electrodes and insert your nickel-plated meter probes into the juice. I got a reading of around 30K when both probes were in the same segment of the lemon, but 40K or higher if the probes were in different segments. Is the resistance lower when you test liquid in a cup?

Here are a couple more questions that you may wish to investigate. For how long will your lemon battery generate electricity? And why do you think your zinc-plated electrode becomes discolored after it has been used for a while?

Electricity is generated in a battery by an exchange of ions, or free electrons, between metals. If you want to know more about this, check the section "Theory: The nature of electricity" on the previous page.

Cleanup and Recycling

The hardware that you immersed in lemons or lemon juice may be discolored, but it is reusable. Whether you eat the lemons is up to you.

BACKGROUND

Positive and negative

If electricity is a flow of electrons, which have a negative charge, why do people talk as if electricity flows from the positive terminal to the negative terminal of a battery?

The answer lies in a fundamental embarrassment in the history of research into electricity. For various reasons, when Benjamin Franklin was trying to understand the nature of electric current by studying phenomena such as lightning during thunderstorms, he believed he observed a flow of "electrical fluid" from positive to negative. He proposed this concept in 1747.

In fact, Franklin had made an unfortunate error that remained uncorrected until after physicist J. J. Thomson announced his discovery of the electron in 1897, 150 years later. Electricity actually flows from an area of greater negative charge, to some other location that is "less negative"—that is, "more positive." In other words, electricity is a flow of negatively charged particles. In a battery, they originate from the negative terminal and flow to the positive terminal.

You might think that when this fact was established, everyone should have discarded Franklin's idea of a flow from positive to negative. But when an electron moves through a wire, you can still think of an equal positive charge flowing in the opposite direction. When the electron leaves home, it takes a small negative charge with it; therefore, its home becomes a bit more positive. When the electron arrives at its destination, its negative charge makes the destination a bit less positive. This is pretty much what would happen if an imaginary positive particle traveled in the opposite direction. Moreover, all of the mathematics describing electrical behavior are still valid if you apply them to the imaginary flow of positive charges.

As a matter of tradition and convenience we still retain Ben Franklin's erroneous concept of flow from positive to negative, because it really makes no difference. In the symbols that represent components such as diodes and transistors, you will actually find arrows reminding you which way these components should be placed—and the arrows all point from positive to negative, even though that's not the way things really work at all! Ben Franklin would have been surprised to learn that although most lightning strikes occur when a negative charge in clouds discharges to neutralize a positive charge on the ground, some forms of lightning are actually a flow of electrons from the negatively charged surface of the earth, up to a positive charge in the clouds. That's right: someone who is "struck by lightning" may be hurt by *emitting* electrons rather than by receiving them, as shown in Figure 1-75.

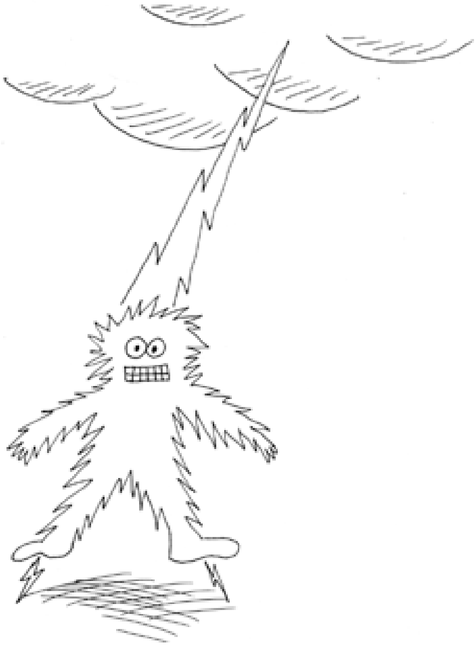

Figure 1-75. *In some weather conditions, the flow of electrons during a lightning strike can be from the ground, through your feet, out of the top of your head, and up to the clouds. Benjamin Franklin would have been surprised.*

THEORY

Basic measurements

Electrical potential is measured by adding up the charges on individual electrons. The basic unit is the *coulomb*, equal to the total charge on about 6,250,000,000,000,000,000 electrons.

If you know how many electrons pass through a piece of wire each second, this establishes the flow of electricity, which can be expressed in amperes. In fact 1 ampere can be defined as 1 coulomb per second. Thus:

1 ampere = 1 coulomb/second
= about 6.25 quintillion electrons/second

There's no way to "see" the number of electrons running through a conductor (Figure 1-76), but there are indirect ways of getting at this information. For instance, when an electron goes running through a wire, it creates a wave of electromagnetic force around it. This force can be measured, and we can calculate the amperage from that. The electric meter installed at your home by the utility company functions on this principle.

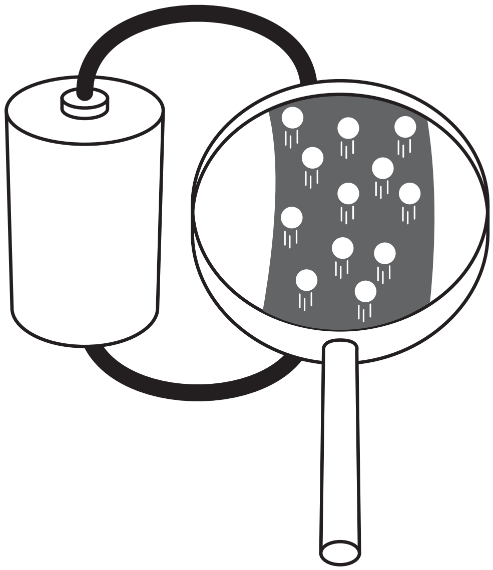

Figure 1-76. *If you could look inside an electric wire with a sufficiently powerful magnifying device, and the wire happened to be carrying 1 ampere of electron flow at the time, you might hope to see about 6.25 quintillion electrons speeding past each second.*

If electrons are just moving freely, they aren't doing any work. If you had a loop of wire of zero resistance, and you kick-started a flow of electrons somehow, they could just go buzzing around forever. (This is what happens inside a superconductor—almost.)

Under everyday conditions, even a copper wire has some resistance. The force that we need to push electrons through it is known as "voltage," and creates a flow that can create heat, as you saw when you shorted out a battery. (If the wire that you used had zero resistance, the electricity running through it would not have created any heat.) We can use the heat directly, as in an electric stove, or we can use the electrical energy in other ways—to run a motor, for instance. Either way, we are taking energy out of the electrons, to do some work.

One volt can be defined as the amount of pressure that you need to create a flow of 1 ampere, which does 1 watt of work. As previously defined, 1 watt = 1 volt × 1 ampere, but the definition actually originated the other way around:

1 volt = 1 watt/1 ampere

It's more meaningful this way, because a watt can be defined in nonelectrical terms. Just in case you're interested, we can work backward through the units of the metric system like this:

1 watt = 1 joule/second
1 joule = a force of 1 newton acting through 1 meter
1 newton = the force required to accelerate 1 kilogram by 1 meter per second, each second

On this basis, the electrical units can all be anchored with observations of mass, time, and the charge on electrons.

Practically Speaking

For practical purposes, an intuitive understanding of electricity can be more useful than the theory. Personally I like the water analogies that have been used for decades in guides to electricity. Figure 1-77 shows a tall tank half full of water, with a hole punched in it near the bottom. Think of the tank as being like a battery. The height of the water is comparable to voltage. The volume of flow through the hole, per second, is comparable to amperage. The smallness of the hole is comparable to resistance. See Figure 1-79 on the next page.

Where's the wattage in this picture? Suppose we place a little water wheel where it is hit by the flow from the hole. We can attach some machinery to the water wheel. Now the flow is doing some work. (Remember, wattage is a measurement of work.)

Maybe this looks as if we're getting something for nothing, extracting work from the water wheel without putting any energy back into the system. But remember, the water level in the tank is falling. As soon as I include some helpers hauling the waste water back up to the top of the tank (in Figure 1-78), you see that we have to put work in to get work out.

Similarly, a battery may seem to be giving power out without taking anything in, but the chemical reactions inside it are changing pure metals into metallic compounds, and the power we get out of a battery is enabled by this change of state. If it's a rechargeable battery, we have to push power back into it to reverse the chemical reactions.

Going back to the tank of water, suppose we can't get enough power out of it to turn the wheel. One answer could be to add more water. The height of the water will create more force. This would be the same as putting two batteries end to end, positive to negative, in series, to double the voltage. See Figure 1-80. As long as the resistance in the circuit remains the same, greater voltage will create more amperage, because amperage = voltage/resistance.

What if we want to run two wheels instead of one? We can punch a second hole in the tank, and the force (voltage) will be the same at each of them. However, the water level in the tank will drop twice as fast. Really, we'd do better to build a second tank, and here again the analogy with a battery is good. If you wire two batteries side by side, in parallel, you get the same voltage, but for twice as long. The two batteries may also be able to deliver more current than if you just used one. See Figure 1-81.

Summing up:

- Two batteries in series deliver twice the voltage.
- Two batteries in parallel can deliver twice the current.

All right, that's more than enough theory for now. In the next chapter, we'll continue with some experiments that will build on the foundations of knowledge about electricity, to take us gradually toward gadgets that can be fun and useful.

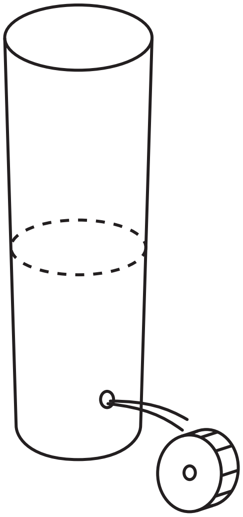

Figure 1-77. *If you want to get work out of a system...*

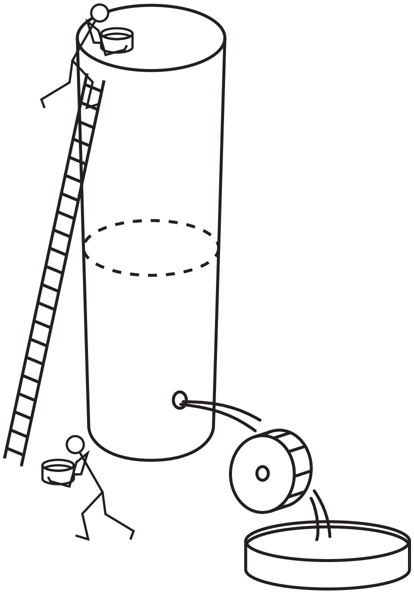

Figure 1-78. *. . . somehow or other you have to put work back into it.*

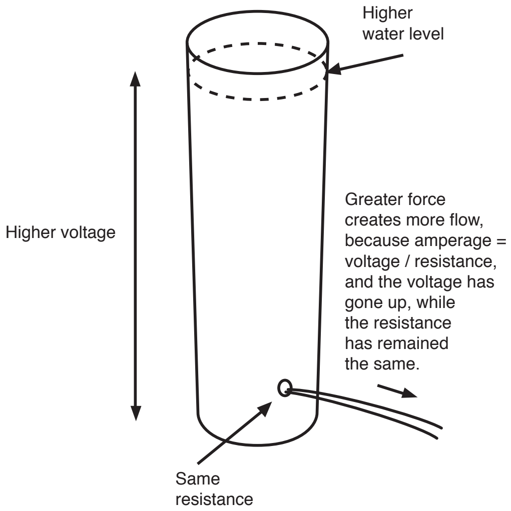

Higher water level
Higher voltage
Greater force creates more flow, because amperage = voltage / resistance, and the voltage has gone up, while the resistance has remained the same.
Same resistance

1.5 volts
for twice as long

Figure 1-81. *Two equal batteries that are wired in parallel will deliver the same voltage for twice as long as one.*

2

Switching Basics and More

The concept of switching is fundamental in electronics, and I'm not just talking about power switches. By "switching," I mean using one flow of electricity to switch, or control, another. This is such an important principle that no digital device can exist without it.

Today, switching is mostly done with semiconductors. Before I deal with them, I'll back up and illustrate the concept by introducing you to relays, which are easier to understand, because you can see what's going on inside them. And before I get to relays, I'll deal with everyday on/off switches, which may seem very simple—but we have to nail down the basics.

Also in this chapter, I'll deal with capacitance, because capacitance and resistance are fundamental to electronic circuits. By the end of the chapter, you should have a basic grounding in electronics and be able to build the noise-making section of a simple intrusion alarm. This will be your first circuit that does something genuinely useful!

IN THIS CHAPTER

Shopping List: Experiments 6 Through 11
Experiment 6: Very Simple Switching
Experiment 7: Relay-Driven LEDs
Experiment 8: A Relay Oscillator
Experiment 9: Time and Capacitors
Experiment 10: Transistor Switching
Experiment 11: A Modular Project

Shopping List: Experiments 6 Through 11

As in the previous shopping list, you should visit the various online suppliers for availability and pricing of components and devices. Manufacturers seldom sell small numbers of parts directly. Check the appendix for a complete list of URLs for all the companies mentioned here.

Devices

- Power supply/universal AC adapter, 3 to 12 volts at 1A (1,000 mA). See Figure 2-1. Part number 273-029 from RadioShack, part PH-62092 by Philips, or similar.
- Breadboard suitable for integrated circuits. Quantity: 1. See Figures 2-2 and 2-3. Part 276-002 from RadioShack, model 383-X1000 made by PSP, part 923252-I by 3M, or similar. A breadboard that has screw terminals mounted beside it will be a little easier to use but more expensive than one that does not have terminals.

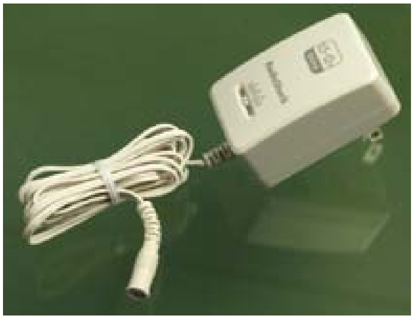

Figure 2-1. *This AC adapter delivers DC from 3 to 12 volts, and is ideal for electronics projects.*

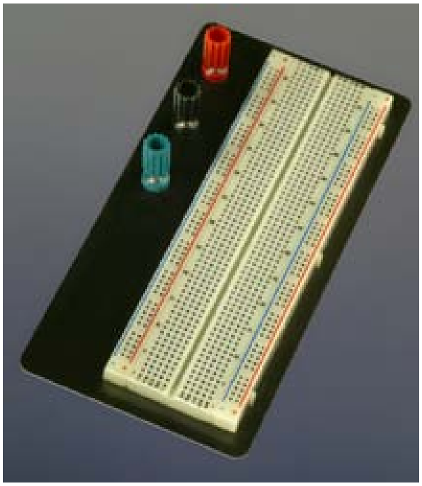

Figure 2-2. *This "breadboard" for quickly constructing electronic circuits has a metal base, and screw terminals for attaching wires from a power supply.*

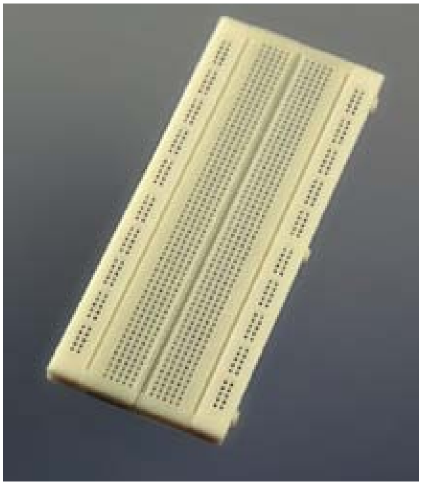

Figure 2-3. *A breadboard without screw terminals is almost as convenient, and is cheaper.*

Tools

Wire strippers

Ideal model 45-121 wire strippers for 16- to 26-gauge wire, or similar. See Figure 2-4. (The "gauge" of the wire tells you how thick it is. A higher gauge means a thinner wire. In this book, we will mainly be using thin wire of 20- to 24-gauge.)

You may also consider the Kronus Automatic Wire Strippers, part 64-2981 from RadioShack, or GB Automatic Wire Strippers, part SE-92 from Amazon.com. See Figure 2-5.

The Kronus and GB wire strippers are functionally identical. The advantage of their design is that it enables you to strip insulation from a wire with one hand. But they do not work well on really thin wire.

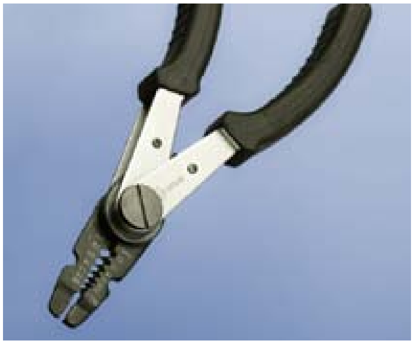

Figure 2-4. *To use these wire strippers, insert a piece of insulated wire in the appropriate-sized hole between the jaws, grip the handles, and pull a section of insulation away. See page 45.*

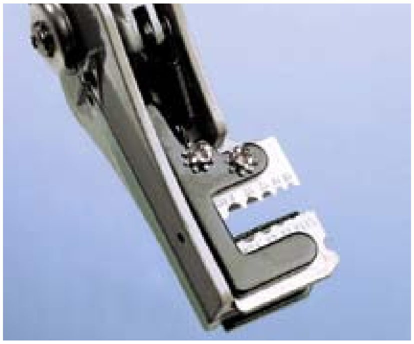

Figure 2-5. *These automatic wire strippers enable one-handed operation, but are not suitable for very small wire diameters. See page 44.*

Supplies

Hookup wire

Solid-conductor, 22-gauge, minimum 25 feet of each color. See Figure 2-6. Part 278-1222 from RadioShack, catalog item 9948T17 from McMaster-Carr, or check eBay for deals.

It's easy to buy the wrong kind of wire. You need solid-core wire, which has a single conductor inside the plastic insulation, not stranded, which has multiple, thinner conductors. See Figures 2-7 and 2-8. You're going to be pushing wires into little holes in a "breadboard," and stranded wire won't let you do this. You will also have problems if you buy wire thicker than 22-gauge. Remember: the lower the gauge number, the thicker the wire.

For a little extra money, you can buy an assortment of precut sections of wire, with ends stripped and ready for use. Try catalog item JW-140 (jumper wire assortment) from All Electronics or search eBay for "breadboard wire." See Figure 2-9.

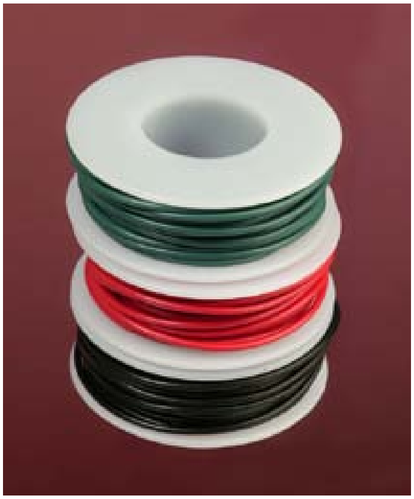

Figure 2-6. *Using hookup wire with different colors of plastic insulation will help you to distinguish one wire from another in your circuits.*

Patch cords

Patch cords are not strictly necessary but very convenient. You don't want audio or video patch cords, which have a plug on each end; you want wires with alligator clips on each end, also sometimes referred to as "test leads." Try catalog item 461-1176-ND from Digi-Key or catalog item MTL-10 from All Electronics. See Figure 2-10.

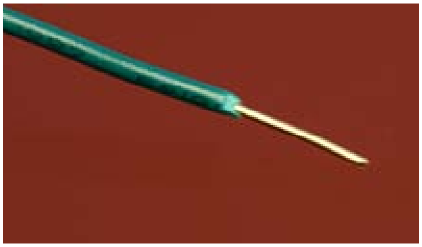

Figure 2-7. *Solid-conductor wire of 22 or 24 gauge is suitable for most of the experiments in this chapter.*

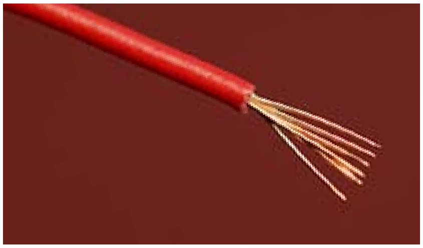

Figure 2-8. *Stranded is more flexible, but cannot be used easily with breadboards.*

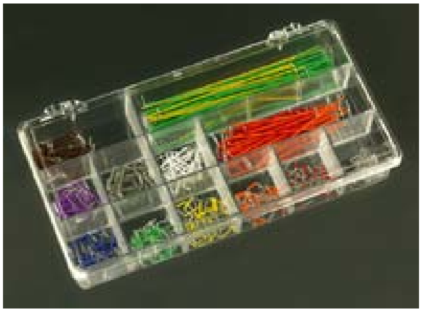

Figure 2-9. *Precut wires with stripped ends can save a lot of time and trouble—if you don't mind paying a little extra.*

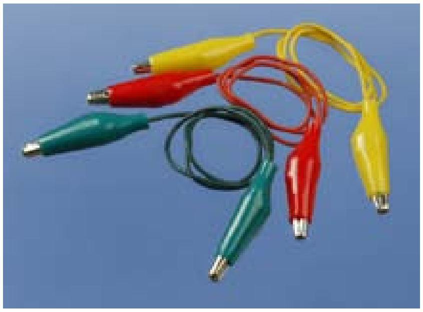

Figure 2-10. *Patch cords, sometimes known as test leads, consist of wires preattached to alligator clips. This is another of those little luxuries that reduces the hassle factor in hobby electronics.*

Components

Pushbutton

Momentary-on, SPST, sometimes referred to as OFF-(ON) or (ON)-OFF type. Must be PCB- or PC-mount, meaning is extremely small with thin spiky contacts on the bottom. Quantity: 1. See Figure 2-11.

Examples are part number AB11AP by NKK, part MPA103B04 by Alcoswitch, or part EP11SD1CBE by C&K. If you have a choice, buy the cheapest, as we're going to switch very low current.

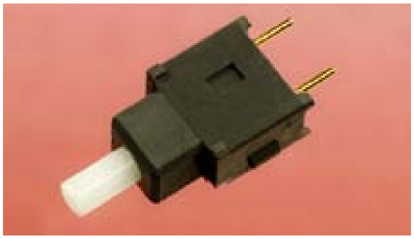

Figure 2-11. *The terminals protruding from this tiny pushbutton are spaced 0.2 inches apart, making it ideal for the "breadboard" that you'll be using.*

Switches

Toggle switch, single-pole, double-throw (SPDT), sometimes referred to as ON-ON type. Quantity: 2. See Figure 2-12.

Model S302T-RO by NKK is ideal; it has screw terminals that will eliminate the need for alligator clips. Other options are catalog item MTS-4PC from All Electronics or part 275-603 from RadioShack.

We won't be switching large currents or high voltages, so the exact type of switch is unimportant. However, the terminals on larger-size switches are spaced wider apart, which makes them easier to deal with.

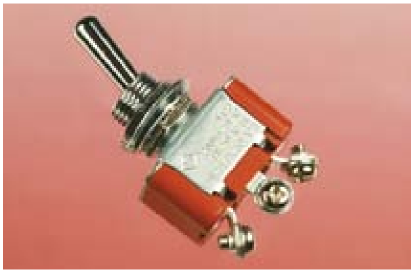

Figure 2-12. *This relatively large toggle switch made by NKK has screw terminals, which will reduce the inconvenience of attaching it to hookup wire.*

Relays

DPDT, nonlatching, 12v DC. Quantity: 2.

It's important to get the right kind of relay—one whose configuration matches the pictures I'll be using. Look for parts FTR-F1CA012V or FTR-F1CD012V by Fujitsu, G2RL-24-DC12 by Omron, or OMI-SH-212D by Tyco. Avoid substitutions.

Potentiometer

1 megohm linear potentiometer, Part number 271-211 from RadioShack, part number 24N-1M-15R-R from Jameco, or similar.

Transistors

NPN transistor, general-purpose, such as 2N2222 by STMicroelectronics, part PN2222 by Fairchild, or part 2N2222 from RadioShack. Quantity: 4. See Figure 2-13.

2N6027 programmable unijunction transistor manufactured by On Semiconductor or Motorola. Quantity: 4.

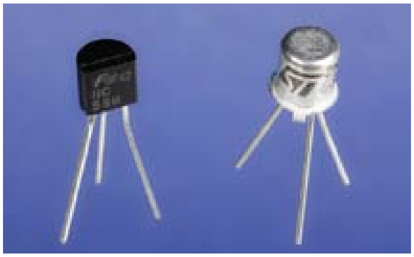

Figure 2-13. *Transistors are commonly sold either in little metal cans or sealed into little lumps of plastic. For our purposes, the packaging makes no difference.*

Capacitors

Electrolytic capacitors, assorted. Must be rated for a minimum of 25 volts and include at least one capacitor of 1,000 µF (microfarads). If you search on eBay, make sure you find *electrolytic* capacitors. If they're rated for higher voltages, that's OK, although they will be physically larger than you need. See Figure 2-14.

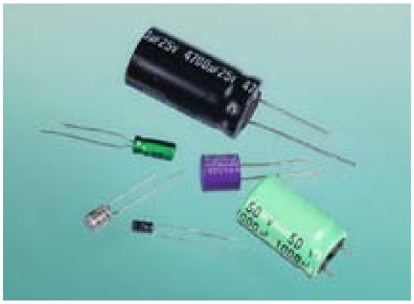

Figure 2-14. *An assortment of electrolytic capacitors.*

Ceramic capacitors, assorted. Make sure you get at least one rated at 0.0047 µF (which can also be written as 47 nF). See Figure 2-15.

Resistors

If you bought only a minimal selection for experiments 1 through 5, now's the time to buy a larger assortment, so that you won't be stuck needing the one value that you don't have. 1/4-watt minimum.

Loudspeaker

Any 8Ω, 1-inch miniature loudspeaker such as part 273-092 from RadioShack. See Figure 2-16.

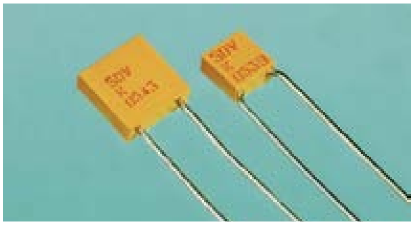

Figure 2-15. *Ceramic capacitors mostly look like this, although many of them are round or bead-shaped instead of square. The packaging shape is unimportant to us.*

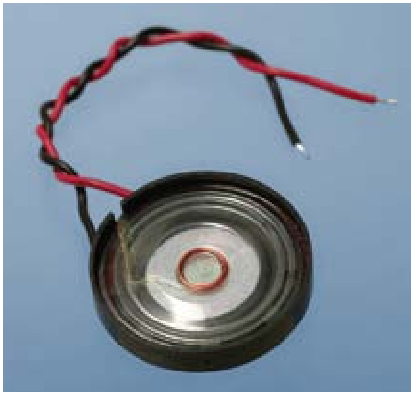

Figure 2-16. *This miniature loudspeaker, just over 1 inch in diameter, is useful for verifying audio output direct from transistor circuits.*

Experiment 6: Very Simple Switching

You will need:

- AA batteries. Quantity: 4.
- Battery carrier for 4 AA batteries. Quantity: 1.
- LED. Quantity: 1.
- Toggle switches, SPDT. Quantity: 2. See Figure 2-12.
- 220Ω or similar value resistor, 1/4-watt minimum. Quantity: 1.
- Alligator clips. Quantity: 8.
- Wire or patch cords. See Figure 2-10, shown previously.
- Wire cutters and wire strippers if you don't use patch cords. See Figure 2-4, shown previously.

In Experiment 3, you illuminated an LED by attaching a battery, and switched it off by removing the battery. For greater convenience our circuits should have proper switches to control power, and while I'm dealing with the general topic of switches, I'm going to explore all the varieties, using a circuit to suggest some possibilities.

Assemble the parts as shown in Figures 2-17 and 2-18. The long lead on the LED must connect with the resistor, because that is the more positive side of the circuit.

You'll notice that you have to include a couple lengths of wire. I suggest green wire to remind you that these sections are not connected directly to positive or to negative power. But you can use any color you like. You can also substitute patch cords, if you have them. However, learning to strip insulation from pieces of wire is a necessary skill, so let's deal with that now.

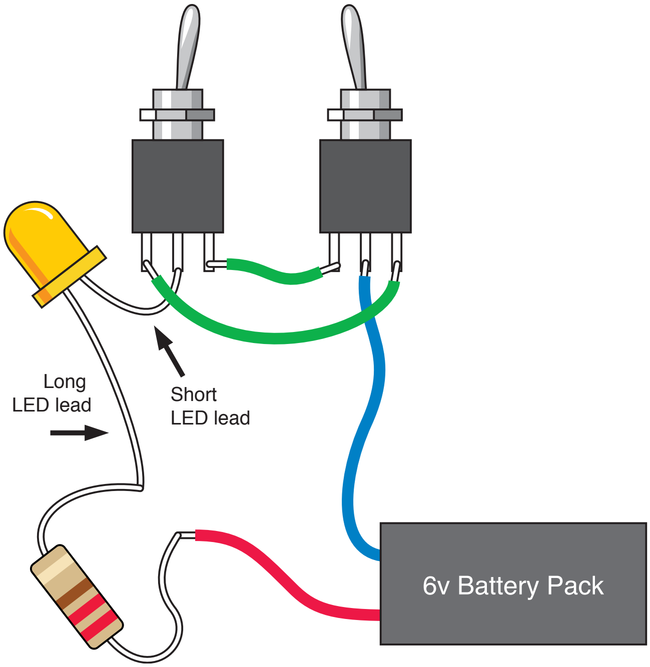

Figure 2-17. *If the LED is on, flipping either of the switches will turn it off. If the LED is off, either of the switches will turn it on. Use alligator clips to attach the wires to each other, and to the switches if your switches don't have screw terminals. Be careful that the clips don't touch each other.*

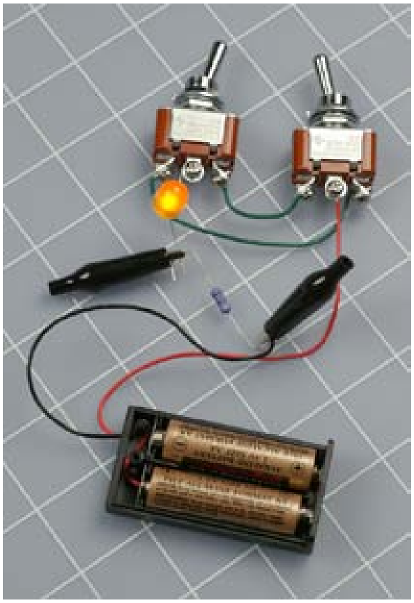

Figure 2-18. *Full-size toggle switches with screw terminals make it easy to hook up this simple circuit.*

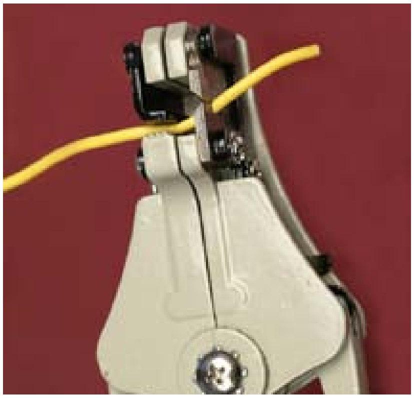

Figure 2-19. *Using automatic wire strippers, when you squeeze the handles the jaw on the left clamps the wire, the sharp grooves on the right bite into the insulation. Squeeze harder and the jaws pull away from each other, stripping the insulation from the wire.*

Tools

If automatic wire strippers (Figure 2-19) don't grip skinny 22-gauge wire very effectively, try the Ideal brand of wire strippers shown back in Figure 2-4, or use plain and simple wire cutters as shown in Figure 2-20. When using wire cutters, you hold the wire in one hand and apply the tool in your other hand, squeezing the handles with moderate pressure—just enough to bite into the insulation, but not so much that you chop the wire. Pull the wire down while you pull the cutters up, and with a little practice you can rip the insulation off to expose the end of the wire.

Macho hardware nerds may use their teeth to strip insulation from wires. When I was younger, I used to do this. I have two slightly chipped teeth to prove it. Really, it's better to use the right tool for the job.

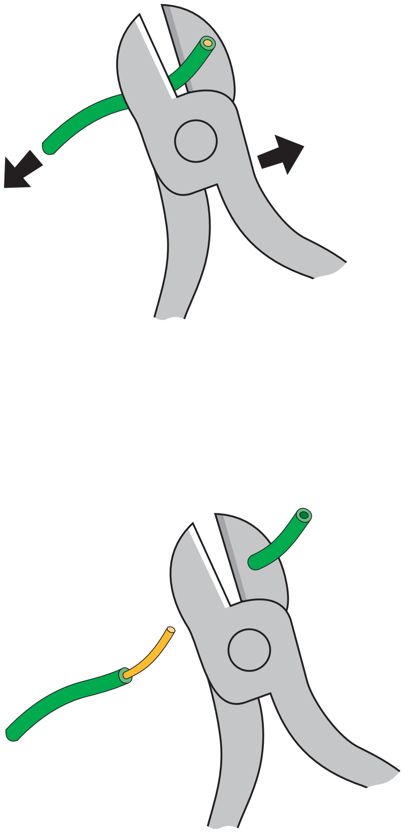

Figure 2-20. *To remove insulation from the end of a thin piece of wire, you can also use wire cutters. This takes a little practice.*

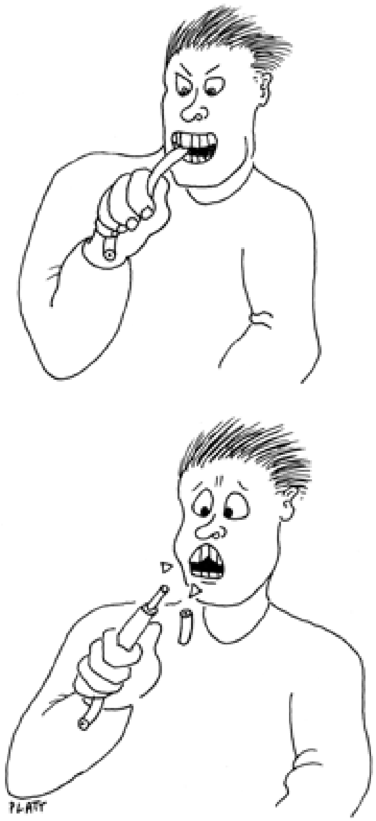

Figure 2-21. *Those who tend to misplace tools, and feel too impatient to search for them, may feel tempted to use their teeth to strip insulation from wire. This may not be such a good idea.*

Connection Problems

Depending on the size of toggle switches that you are using, you may have trouble fitting in all the alligator clips to hold the wires together. Miniature toggle switches, which are more common than the full-sized ones these days, can be especially troublesome (see Figure 2-22). Be patient: fairly soon we'll be using a breadboard, which will eliminate alligator clips almost completely.

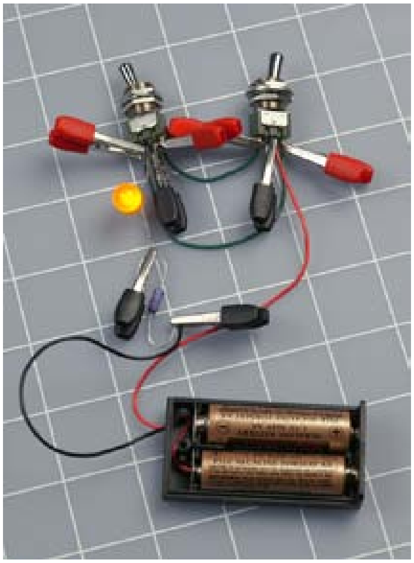

Figure 2-22. *Miniature toggle switches can be used—ideally, with miniature alligator clips—but watch out for short circuits.*

Testing

Make sure that you connect the LED with its long wire toward the positive source of power (the resistor, in this case). Now flip either of the toggle switches. If the LED was on, it will go off, and if it was off, it will go on. Flip the other toggle switch, and it will have the same effect. If the LED does not go on at all, you've probably connected it the wrong way around. Another possibility is that two of your alligator clips may have shorted out the battery.

Assuming your two switches do work as I described them, what's going on here? It's time to nail down some basic facts.

FUNDAMENTALS

All about switches

When you flip the type of toggle switch that you used in Experiment 6, it connects the center terminal with one of the outer terminals. Flip the switch back, and it connects the center terminal with the other outer terminal, as shown in Figure 2-23.

The center terminal is called the pole of the switch. Because you can flip, or throw, this switch to make two possible connections, it is called a *double-throw switch*. As mentioned earlier, a single-pole, double-throw switch is abbreviated *SPDT*.

Some switches are on/off, meaning that if you throw them in one direction they make a contact, but in the other direction, they make no contact at all. Most of the light switches in your house are like this. They are known as *single-throw switches*. A single-pole, single-throw switch is abbreviated *SPST*.

Some switches have two entirely separate poles, so you can make two separate connections simultaneously when you flip the switch. These are called *double-pole switches*. Check the photographs in Figures 2-24 through 2-26 of old-fashioned "knife" switches (which are still used to teach electronics to kids in school) and you'll see the simplest representation of single and double poles, and single and double throws. Various toggle switches that have contacts sealed inside them are shown in Figure 2-27.

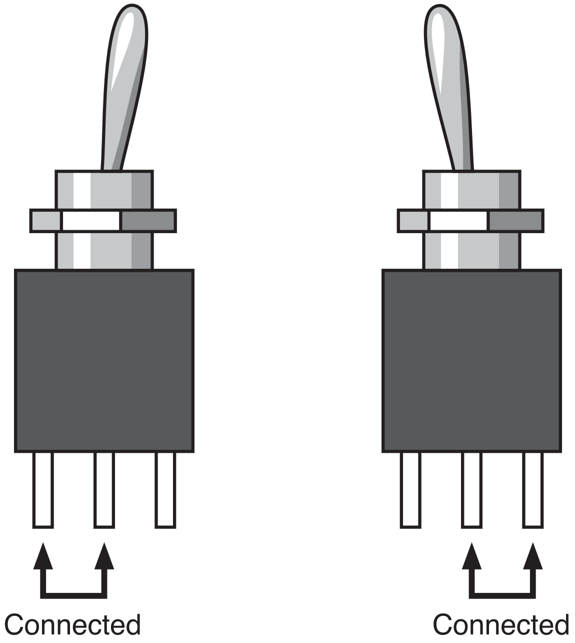

Figure 2-23. *The center terminal is the pole of the switch. When you flip the toggle, the pole changes its connection.*

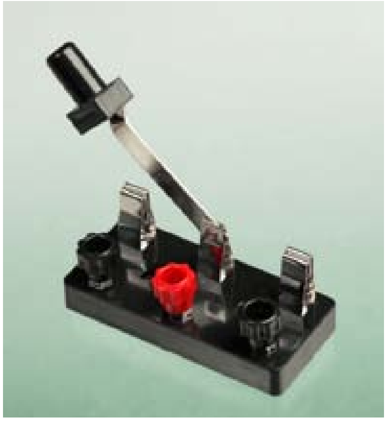

Figure 2-24. *This primitive-looking single-pole, double-throw switch does exactly the same thing as the toggle switches in Figures 2-23 and 2-27.*

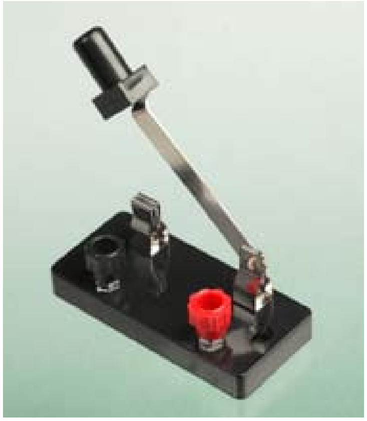

Figure 2-25. *A single-pole, single-throw switch makes only one connection with one pole. Its two states are simply open and closed, on and off.*

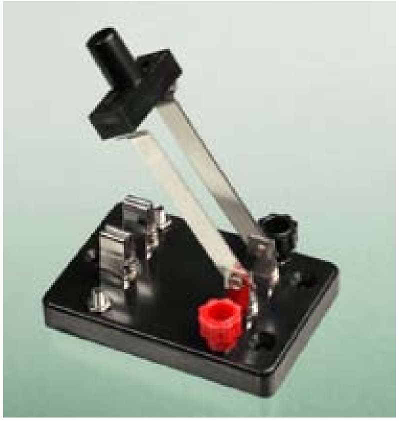

Figure 2-26. *A double-pole, single-throw switch makes two separate on/off connections.*

FUNDAMENTALS

All about switches (continued)

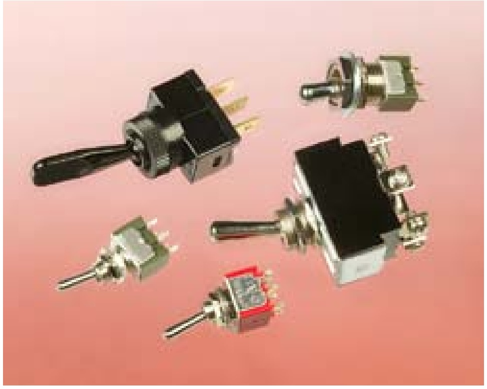

Figure 2-27. *These are all toggle switches. Generally, the larger the switch, the more current it can handle.*

To make things more interesting, you can also buy switches that have three or four poles. (Some rotary switches have even more, but we won't be using them.) Also, some double-throw switches have an additional "center off" position.

Putting all this together, I made a table of possible types of switches (Figure 2-28). When you're reading a parts catalog, you can check this table to remind yourself what the abbreviations mean.

	Single Pole	Double Pole	3-Pole	4-Pole
Single Throw	SPST ON-OFF	DPST ON-OFF	3PST ON-OFF	4PST ON-OFF
Double Throw	SPDT ON-ON	DPDT ON-ON	3PDT ON-ON	4PDT ON-ON
Double Throw with Center Off	SPDT ON-OFF-ON	DPDT ON-OFF-ON	3PDT ON-OFF-ON	4PDT ON-OFF-ON

Figure 2-28. *This table summarizes all the various options for toggle switches and pushbuttons.*

Now, what about pushbuttons? When you press a door bell, you're making an electrical contact, so this is a type of switch—and indeed the correct term for it is a momentary switch, because it makes only a momentary contact. Any spring-loaded switch or button that wants to jump back to its original position is known as a momentary switch. We indicate this by putting its momentary state in parentheses. Here are some examples:

- OFF-(ON): Because the ON state is in parentheses, it's the momentary state. Therefore, this is a single-pole switch that makes contact only when you push it, and flips back to make no contact when you let it go. It is also known as a "normally open" momentary switch, abbreviated "NO."
- ON-(OFF): The opposite kind of momentary single-pole switch. It's normally ON, but when you push it, you break the connection. So, the OFF state is momentary. It is known as a "normally closed" momentary switch, abbreviated "NC."
- (ON)-OFF-(ON): This switch has a center-off position. When you push it either way, it makes a momentary contact, and returns to the center when you let it go.

Other variations are possible, such as ON-OFF-(ON) or ON-(ON). As long as you remember that parentheses indicate the momentary state, you should be able to figure out what these switches are.

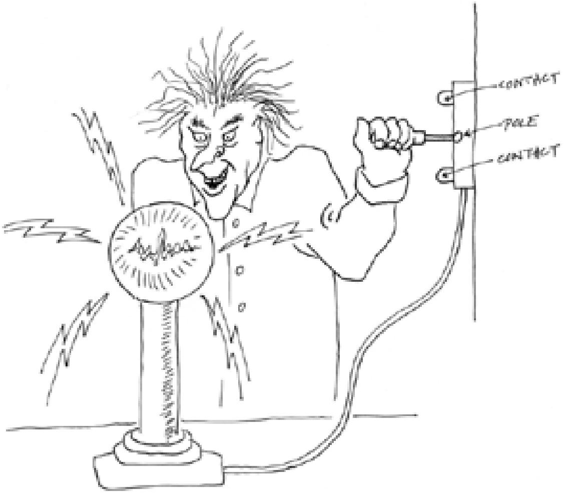

Figure 2-29. *This evil mad scientist is ready to apply power to his experiment. For this purpose, he is using a single-pole, double-throw knife switch, conveniently mounted on the wall of his basement laboratory.*

FUNDAMENTALS

All about switches (continued)

Sparking

When you make and break an electrical connection, it tends to create a spark. Sparking is bad for switch contacts. It eats them until the switch doesn't make a reliable connection anymore. For this reason, you must use a switch that is appropriate for the voltage and amperage that you are dealing with. Electronic circuits generally are low-current, and low-voltage, so you can use almost any switch, but if you are switching a motor, it will tend to suck an initial surge of current that is at least double the rating of the motor when it is running constantly. You should probably use a 4-amp switch to turn a 2-amp motor on and off.

Checking a switch

You can use your meter to check a switch. Doing this helps you find out which contacts are connected when you turn a switch one way or the other. It's also useful if you have a pushbutton and you can't remember whether it's the type that is normally open (you press it to make a connection) or normally closed (you press it to break the connection). Set your meter to measure ohms, and touch the probes to the switch terminals while you work the switch.

This is a hassle, though, because you have to wait while the meter makes an accurate measurement. When you just want to know whether there is a connection, your meter has a "continuity tester" setting. It beeps if it finds a connection, and stays silent if it doesn't. See Figures 2-30 through 2-32 for examples of meters set to test continuity. Figure 2-33 offers an example of a toggle switch being tested for continuity.

Use the continuity-testing feature on your meter only on circuits or components that have no power in them at the time.

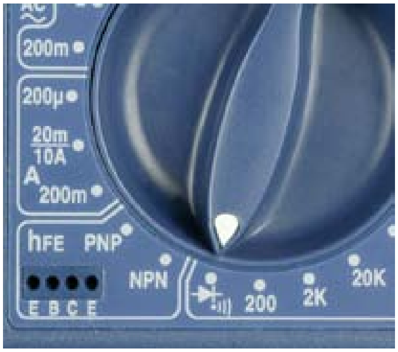

Figure 2-30

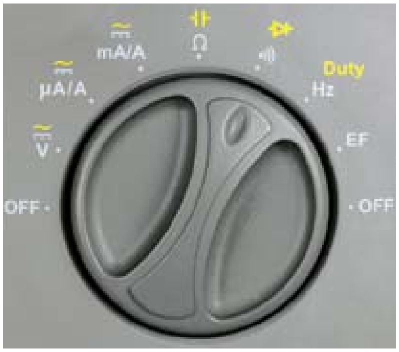

Figure 2-31

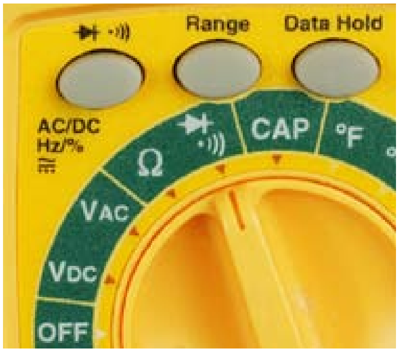

Figure 2-32. *To check a circuit for continuity, turn the dial of your meter to the symbol shown. Only use this feature when there is no power in the component or the circuit that you are testing.*

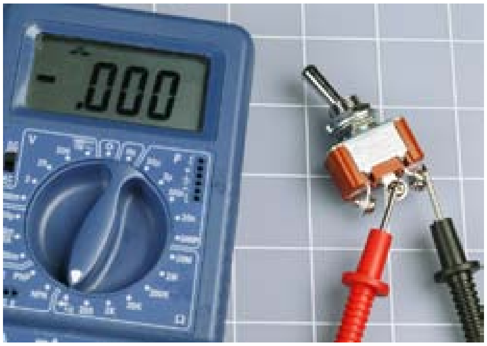

Figure 2-33. *When the switch connects two of its terminals, the meter shows zero resistance between them and will beep if you have set it to verify continuity.*

BACKGROUND

Early switching systems

Switches seem to be such a fundamental feature of our world, and their concept is so simple that it's easy to forget that they went through a gradual process of development and refinement. Primitive knife switches were quite adequate for pioneers of electricity who simply wanted to connect and disconnect electricity to some apparatus in a laboratory, but a more sophisticated approach was needed when telephone systems began to proliferate. Typically, an operator at a "switchboard" needed a way to connect any pair of 10,000 lines on the board. How could it be done?

In 1878, Charles E. Scribner (Figure 2-34) developed the "jack-knife switch," so called because the part of it that the operator held looked like the handle of a jackknife. Protruding from it was a plug, and when the plug was pushed into a socket, it made contact inside the socket. The socket, in fact, was the switch.

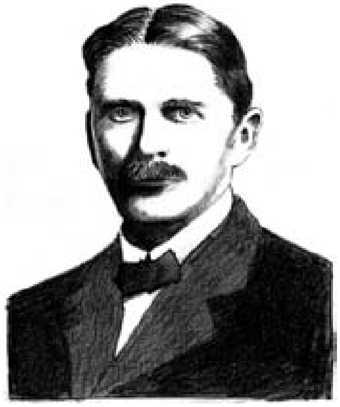

Figure 2-34. *Charles E. Scribner invented the "jack-knife switch" to satisfy the switching needs of telephone systems in the late 1800s. Today's audio jacks still work on the same basis.*[*]

Audio connectors on guitars and amplifiers still work on the same principle, and when we speak of them as being "jacks," the term dates back to Scribner's invention. Switch contacts still exist inside a jack socket.

Today, of course, telephone switchboards have become as rare as telephone operators. First they were replaced with relays—electrically operated switches, which I'll talk about later in this chapter. And then the relays were superceded by transistors, which made everything happen without any moving parts. Before the end of this chapter, you'll be switching current using transistors.

---

[*] The photo on which this drawing is based first appeared in *The History of the Telephone* by Herbert Newton Casson in 1910 (Chicago: A. C. McClurg & Co.).

Introducing Schematics

In Figure 2-35, I've redrawn the circuit from Experiment 6 in a simplified style known as a "schematic." From this point onward, I will be illustrating circuits with schematics, because they make circuits easier to understand. You just need to know a few symbols to interpret them.

Larger versions of all schematics and breadboard photos are available online at this book's website: http://oreilly.com/catalog/9780596153748.

Compare the schematic here with the drawing of the circuit in Figure 2-17. They both show exactly the same thing: Components, and connections between them. The gray rectangles are the switches, the zigzag thing is the resistor, and the symbol with two diagonal arrows is the LED.

The schematic LED symbol includes two arrows indicating that it emits light, because there are some kinds of diodes, which we'll get to later, that don't. The triangle inside the diode symbol always points from positive to negative.

Trace the path that electricity can take through the circuit and imagine the switches turning one way or the other. You should see clearly now why either switch will reverse the state of the LED from on to off or off to on.

This same circuit is used in houses where you have a switch at the bottom of a flight of stairs, and another one at the top, both controlling the same lightbulb. The wires in a house are much longer, and they snake around behind the walls, but because their connections are still the same, they could be represented with the same basic schematic. See Figure 2-36.

A schematic doesn't tell you exactly where to put the components. It just tells you how to join them together. One problem: Different people use slightly different schematic symbols to mean the same thing. Check the upcoming section, "Fundamentals: Basic schematic symbols," for the details.

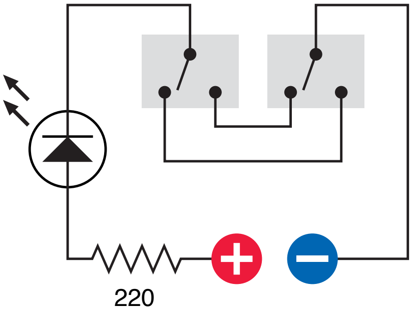

Figure 2-35. *This schematic shows the same circuit as in Figure 2-17 and makes it easier to see how the switches function.*

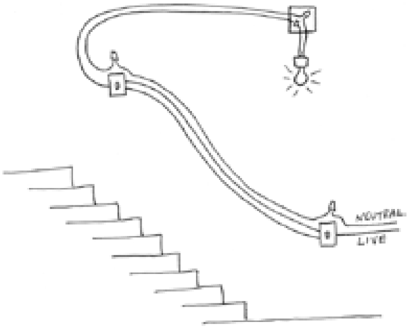

Figure 2-36. *The two-switch circuit shown in Figures 2-17 and 2-35 is often found in house wiring, especially where switches are located at the top and bottom of a flight of stairs. This sketch shows what you might find inside the walls. Wires are joined with "wire nuts" inside boxes that are hidden from everyday view.*

FUNDAMENTALS

Basic schematic symbols

Schematic symbols are like words in a language: they have mutated over the years into a confusing range of variations. A simple on/off (single-pole, single-throw, or SPST) switch, for instance, can be represented by any of the symbols shown in Figure 2-37. They all mean exactly the same thing.

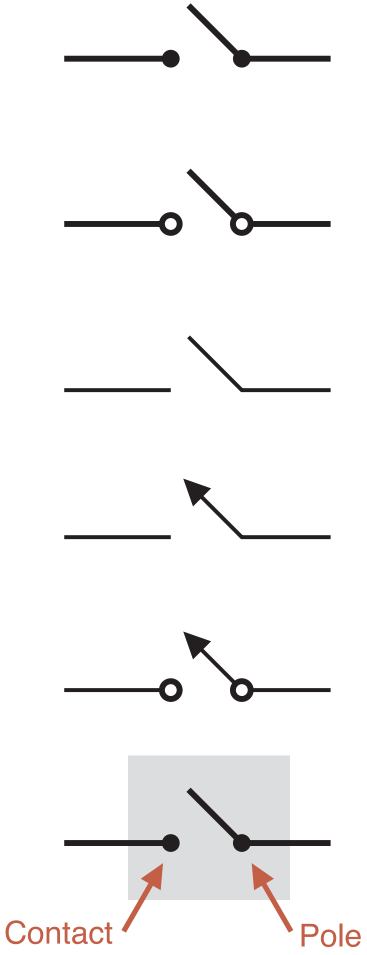

Figure 2-37. *Variations on a theme: Just some of the different styles used to depict a single-pole, single-throw switch in schematic diagrams. The bottom version is the style used in this book.*

Figure 2-38 shows double-pole, double-throw switches. A dotted line indicates a mechanical connection inside the switch, so that when you flip it, you affect both the poles simultaneously. Remember, the poles are electrically isolated from each other.

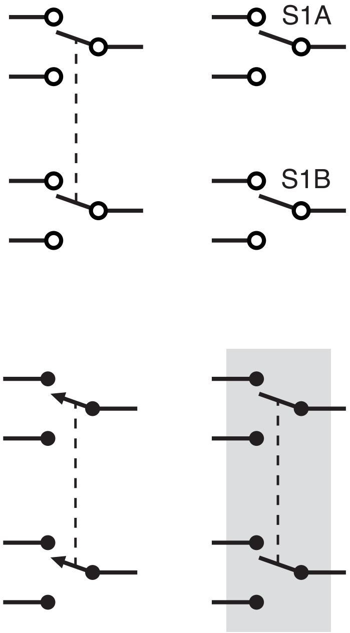

Figure 2-38. *More variations: some different styles for depicting a double-pole, double-throw switch. The style at bottom-right is used in this book.*

Once in a while, you may find a schematic in which switches seem to be scattered around, but the way they are identified (such as S1A, S1B, S1C, and so on) tells you that this is really all one switch with multiple poles.

In the schematics in this book, I'll place a gray rectangle behind each switch. This gray rectangle is not a standard symbol; you won't find it in other books. I'm just including it to remind you that the parts inside are all contained in one package.

A very important stylistic variation in schematics is the way they show whether wires make a connection with each other. Old schematics used to show a little semicircular bump in a wire if it crossed another wire without making a connection. Because modern circuit-drawing software doesn't create this style of schematic, it is no longer often used. The modern style, which you are likely to find if you browse through schematics online, can be summarized like this:

- A dot joining two wires indicates an electrical connection.
- No dot indicates no connection.

FUNDAMENTALS

Basic schematic symbols (continued)

The problem is that this is not very intuitive, especially when you're just beginning to use schematics. When you see two wires crossing, you can easily imagine that they are making a connection, even though there's no dot at the intersection. Therefore, in the interests of clarity, I've chosen to use the old "semicircular bump" style of schematic in this book (see Figure 2-39). It can be summarized like this:

- A dot joining two wires indicates an electrical connection.
- A bump in a wire that crosses another wire indicates no connection.

In this book, you won't find wires crossing each other without either a dot or a bump.

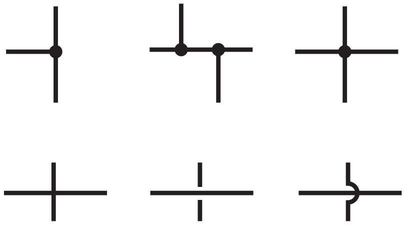

Figure 2-39. *In wiring schematics, a dot always indicates an electrical connection. However, the cross-shaped intersection of wires at top-right is considered bad style because if the dot is accidentally omitted or poorly printed, the intersection can be mistaken for the type shown at bottom left, in which the wires do not make a connection. All three of the configurations in the bottom row indicate no connection, the first example being the most common style, the center example being least common, and the third being the most old-fashioned—although for reasons of clarity, it is used in this book.*

In a battery-powered circuit, you may find a battery symbol, but more often you will find a little note indicating where positive voltage enters the system, while negative is indicated by a "ground" symbol. In fact there may be ground symbols all over the place. You have to remember that when you build a circuit, all the wires leading to grounds must actually be connected together, to the negative side of the voltage supply.

The idea of the ground symbol dates back to the time when electronic gadgets were mounted on a metal chassis, which was connected to the negative side of the power supply. The ground symbol really meant "connect to the chassis." Some variants in the ground symbol are shown in Figure 2-40.

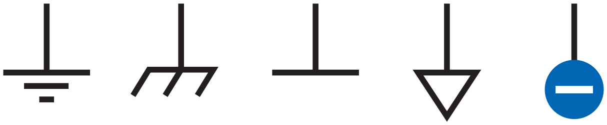

Figure 2-40. *All of these symbols are used to mean the same thing: connect the wire to "ground" or "chassis" or the negative side of the power source. The far-right symbol is used in this book.*

In this book, we have color throughout, so I'll show a red positive and blue negative to clarify where the power is connected, and I won't use ground symbols. Once again, my purpose is to minimize the risk of misunderstandings, because I know how frustrating it is to build a circuit that doesn't work.

A big inconsistency in schematics is the way in which they show resistors. The traditional zigzag symbol has been abandoned in Europe. Instead they use a rectangle with a number inside indicating the number of ohms. See Figure 2-41. The Europeans also changed the way in which decimal points are represented: they omit them as much as possible, because in badly printed schematics, the little dots tend to get lost (or can be confused with dust and dirt). So, a 4.7KΩ resistor will be listed as 4K7, and a 1.2MΩ resistor will be 1M2. I like this notation, so I'm going to be using it myself, but I'll be keeping the zigzag resistor symbol, which remains widely used in the United States.

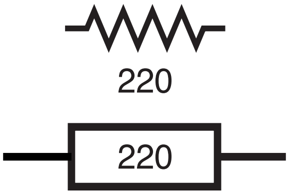

Figure 2-41. *Two styles for depicting a 220Ω resistor. The upper version is traditional, and still used in the United States. The lower version is European.*

FUNDAMENTALS

Basic schematic symbols (continued)

Potentiometers suffer from the same inconsistent style between the United States and Europe, but either way, you'll find an arrow showing where the wiper (usually, the center terminal) touches the resistance. See Figure 2-42. And sometimes LEDs are shown inside circles, and sometimes not. I prefer circles, myself. See Figure 2-46.

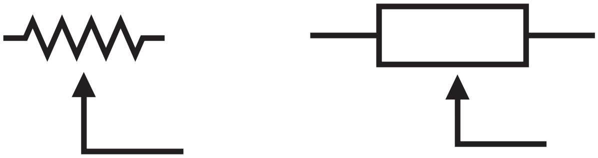

Figure 2-42. *Potentiometer symbols: the left is traditional and used in the United States, the right is European. In both cases the arrow indicates the wiper (usually the center terminal).*

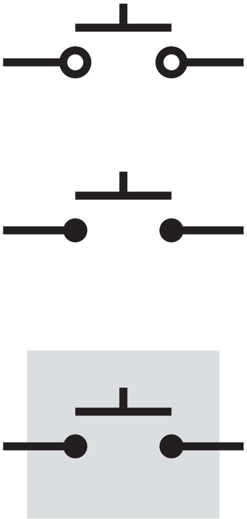

Figure 2-43. *Three ways of indicating a pushbutton switch.*

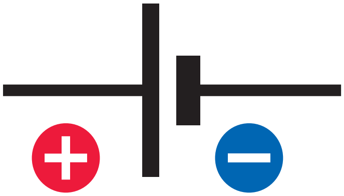

Figure 2-44. *The battery symbol is usually shown without + and – symbols. I've added them for clarity.*

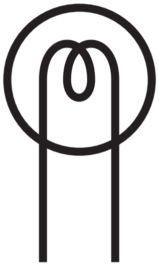

Figure 2-45. *Symbol for an incandescent lightbulb.*

I'll explore other symbol variants later in the book. Meanwhile, the most important things to remember are:

- The positions of components in a schematic are not important.
- The styles of symbols used in a schematic are not important.
- The connections between the components are extremely important.

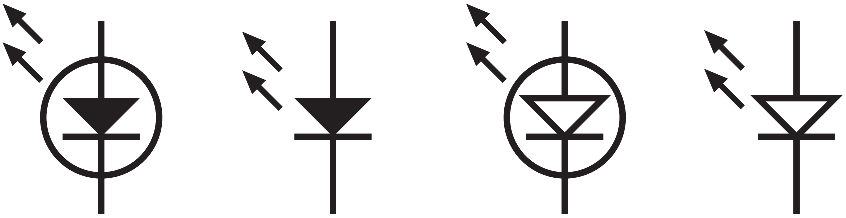

Figure 2-46. *Sometimes an LED is shown with a circle around it; sometimes not. In this book, I will include the circle. The arrows indicate emitted light.*

FUNDAMENTALS

Basic schematic symbols (continued)

For example, the three LED circuits that I have included in Figure 2-47 show components in different positions, using different symbols, but all three circuits function exactly the same way, because their connections are the same. In fact, they all depict the circuit that you built in Experiment 4, shown in Figure 1-50.

Often the symbols in a schematic are placed so that the circuit is most intuitively easy to understand, regardless of how you may build it with actual components. Compare the example in Figure 2-48, showing the two DPDT switches, with the version shown back in Figure 2-35. The previous one looked more like your bench-top version of it, but Figure 2-48 shows the flow of electricity more clearly.

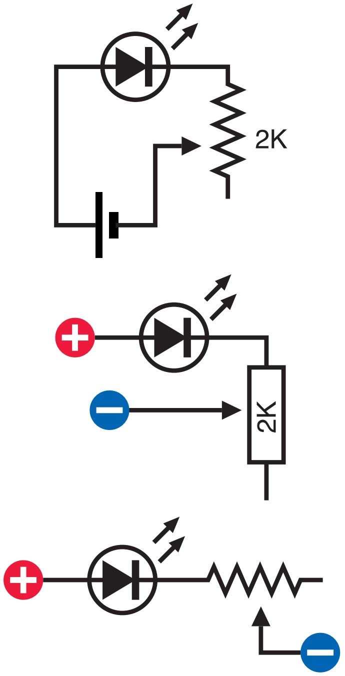

Figure 2-47. *These three schematics all depict the same basic circuit. It's the circuit that you built with the potentiometer in Experiment 4.*

In many schematics, the positive side of the power supply is shown at the top of the diagram, and negative or ground at the bottom. Many people also tend to draw a schematic with an input (such as an audio input, in an amplifier circuit) at the left side, and the output at the right. So, "positive voltage" flows from top to bottom while a signal tends to pass from left to right.

When I was planning this book, initially I drew the schematics to conform with this top-to-bottom, left-to-right convention, but as I started building and testing the circuits, I changed my mind. We use a device known as a "breadboard" to create circuits, and its internal connections require us to lay out components very differently from a typical schematic. When you're starting to learn electronics, it's very confusing to try to rearrange components from a schematic in the configuration that you need for a breadboard.

Therefore, throughout this book, you'll find that I have drawn the schematics to imitate the way you'll wire them on a breadboard. I believe the advantages of doing things this way outweigh the disadvantages of being a little different from the schematic styles that are used elsewhere.

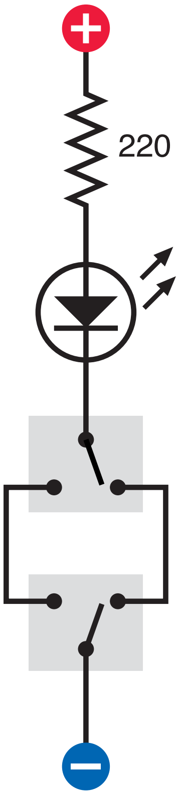

Figure 2-48. *This schematic is just another, clearer, simpler way of showing the circuit that appeared in Figure 2-35.*

Experiment 7: Relay-Driven LEDs

You will need:

- AC adapter, wire cutters and strippers.
- DPDT relay. Quantity: 2.
- LEDs. Quantity: 2.
- Resistor, 680Ω approx. Quantity: 1.
- Pushbutton, SPST. Quantity: 1.
- Hookup wire, 22 gauge, or patch cords.
- Alligator clips. Quantity: 8.
- Utility knife.

The next step in our exploration of switching is to use a remote-controlled switch. By "remote-controlled," I mean one to which you can send a signal to turn it on or off. This kind of switch is known as a *relay*, because it relays an instruction from one part of a circuit to another. Often a relay is controlled by a low voltage or small current, and switches a larger voltage or higher current.

This setup can be cost-effective. When you start your car, for instance, a relatively small, cheap switch sends a small signal down a relatively long, thin, inexpensive piece of wire, to a relay that is near the starter motor. The relay activates the motor through a shorter, thicker, more expensive piece of wire, capable of carrying as much as 100 amps.

Similarly, when you raise the lid on an a top-loading washing machine during its spin cycle, you close a lightweight switch that sends a small signal down a thin wire to a relay. The relay handles the bigger task of switching off the large motor spinning the drum full of wet clothes.

Before you begin this experiment, you need to upgrade your power supply. We're not going to use batteries anymore, because most relays require more than 6 volts, and in any case you should have a power supply that can give you a variety of voltages on demand. The simplest way to achieve this is by using an AC adapter.

First you'll set up the AC adapter. After you have it running, you'll use it to power the relay. Initially the relay will just switch between two LEDs, but then you'll modify the circuit to make the LEDs flash automatically. Finally you'll rebuild the circuit on a breadboard, and say goodbye to alligator clips, for most of the time at least.

Preparing Your AC Adapter

An AC adapter plugs into the wall and converts the high-voltage AC supply in your home into a safe, low DC voltage for electronic devices. Any charger that you use with your cell phone, or iPod, or laptop computer is a special-purpose AC adapter that delivers only one voltage via a specific type of plug. I've asked you to buy a general-purpose adapter that delivers many different voltages, and we're going to begin by getting rid of its plug.

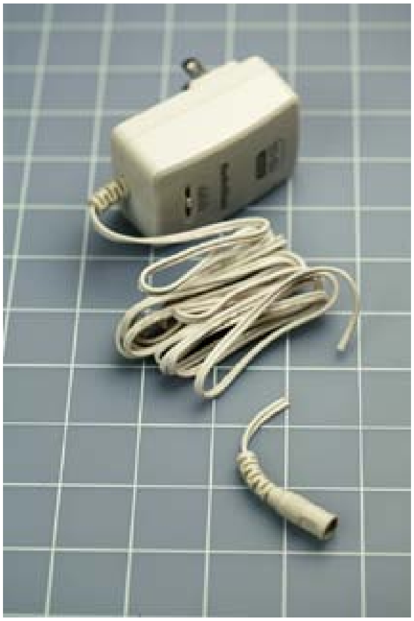

Figure 2-49. *Preparing an AC adapter. First, cut off the little low-voltage plug and throw it away.*

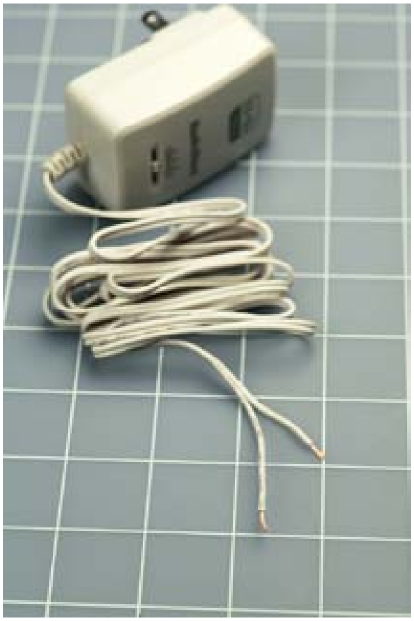

Figure 2-50. *Second, strip the wires, making one shorter than the other to reduce the risk of them touching. Color one of the adapter wires red with a marker, to identify it as the positive one.*

1. It's important to make sure that your AC adapter is not plugged into the wall!
2. Chop off the little plug at the end of its wire. See Figure 2-49.
3. Use a box cutter or utility knife or scissors to make a half-inch cut between the two conductors, and then pull the conductors apart a couple of inches.
4. Use wire cutters to trim one of the conductors shorter than the other, so that after you strip away a little of the insulation, the exposed copper wires cannot easily touch each other. This is a precaution against short-circuiting your AC adapter and burning it out.
5. Strip the two conductors using your wire strippers. Twist the copper strands between finger and thumb so that there are no loose strands sticking out. See Figure 2-50.
6. Make sure that the two wires are not touching each other, and plug your AC adapter into a wall outlet. Set your meter to DC volts and apply the meter probes to the wires from the adapter. If the voltage is preceded with a minus sign, you have the probes the wrong way around. Reverse them and the minus sign should go away. This tells you which wire is positive.
7. Mark the positive wire from the adapter. If the wire has white insulation, you can mark it with a red marker. If it has black insulation, you can tag it with a label. The positive wire will remain positive regardless of which way up you plug the AC adapter into a wall outlet.

The Relay

The type of relay that I want you to use has little spiky legs on the bottom, in a standardized layout. If you buy some other kind of relay, you will have to figure out for yourself which pins are connected to the coil inside, which pins go to the poles of the switch inside it, and which go to the normally closed and normally open contacts. You can check the manufacturer's data sheet for this purpose, but I strongly suggest you use one of the relays mentioned in the shopping list, so that you can follow the instructions here more easily.

I asked you to buy two relays so that you can use one for investigational purposes—meaning that you can break it open and take a look inside. If you do this very, very carefully, the relay should still be usable afterward. If not, well, you still have a spare.

The easiest way to open the relay is with a box cutter or utility knife. Figures 2-52, 2-53, and 2-54 show the technique. Shave the edges of the plastic shell containing the relay, beveling them until you see just a hair-thin opening. Don't go any farther; the parts inside are very, very close to its housing. Now pop the top off. You can use needle-nosed pliers to nibble the rest of the shell away. Read the following section, "Fundamentals: Inside a relay," and then apply power to the relay to see how it works.

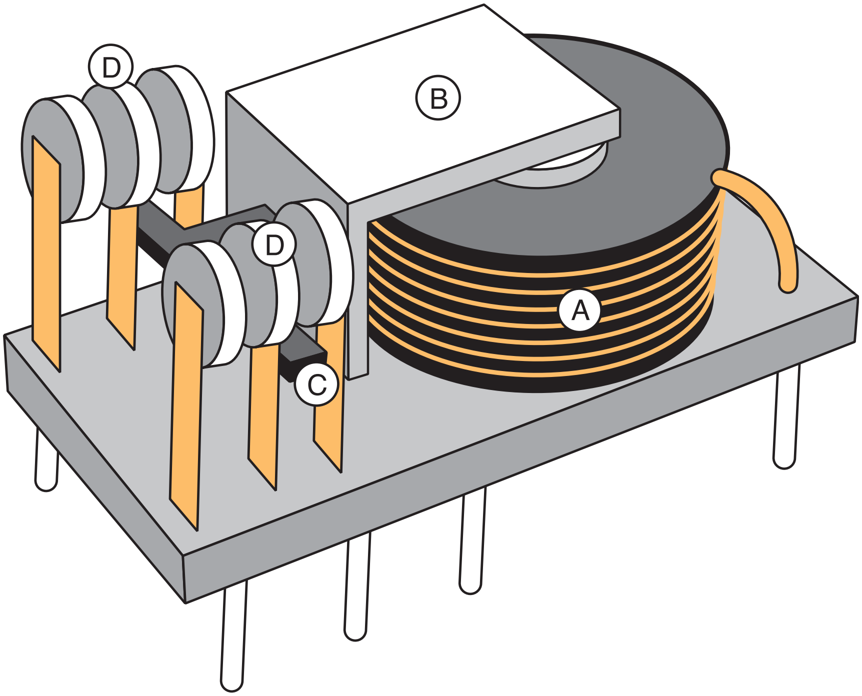

Figure 2-51. *This is one way that the parts inside a relay can be arranged. The coil, A, generates a magnetic attraction pulling lever B downward. A plastic extension, C, pushes outward against flexible metal strips and moves the poles of the relay, D, between the contacts.*

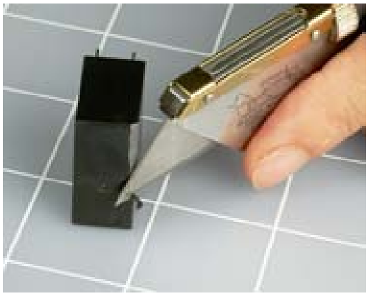

Figure 2-52. *To look inside a sealed relay, shave the top edges of the plastic package with a utility knife til you open a thin crack.*

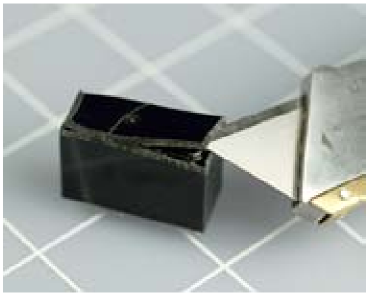

Figure 2-53. *Insert the blade of your knife to pry open the top, then repeat the procedure for the sides.*

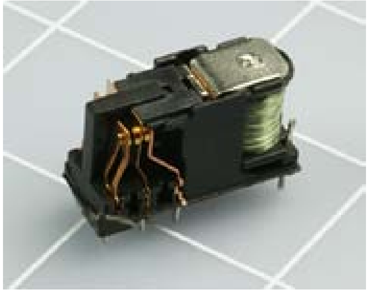

Figure 2-54. *If you are really, really careful, the relay should still work after you open it.*

Figure 2-55

Figure 2-56. *Patience is essential when carving the edges of a relay package in order to open it. Faster methods such as a tomahawk or a flamethrower will satisfy the emotional needs of those with a short attention span, but results may be unpredictable.*

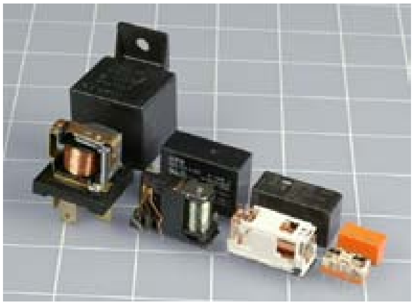

Figure 2-57. *Four assorted 12-volt relays, shown with and without their packages. The automotive relay (far left) is the simplest and easiest to understand, because it is designed without much concern for the size of the package. Smaller relays are more ingeniously designed, more complex, and more difficult to figure out. Usually, but not always, a smaller relay is designed to switch less current than a larger one.*

FUNDAMENTALS

Inside a relay

A relay contains a coil of wire wrapped around an iron core. When electricity runs through the coil, the iron core exerts a magnetic force, which pulls a lever, which pushes or pulls a springy strip of metal, closing two contacts. So as long as electricity runs through the coil, the relay is "energized" and its contacts remain closed.

When the power stops passing through the coil, the relay lets go and the springy strip of metal snaps back into its original position, opening the contacts. (The exception to this rule is a latching relay, which requires a second pulse through a separate coil to flip it back to its original position; but we won't be using latching relays until later in the book.)

Relays are categorized like switches. Thus, you have SPST relays, DPST, SPDT, and so on.

Compare the schematics in Figure 2-58 with the schematics of switches in Figure 2-38. The main difference is that the relay has a coil that activates the switch. The switch is shown in its "relaxed" mode, when no power flows through the coil.

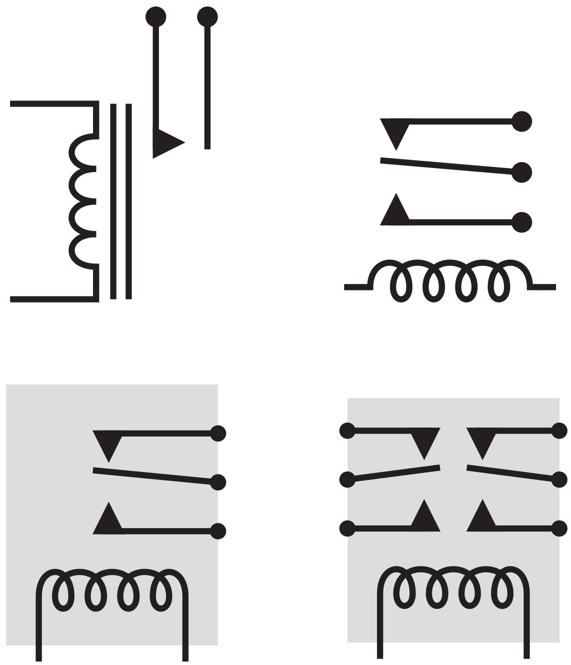

Figure 2-58. *Various ways to show a relay in a schematic. Top left: SPST. Top right and bottom left: SPDT. Bottom right: DPDT. The styles at bottom-left and bottom-right will be used in this book.*

The contacts are shown as little triangles. When there are two poles instead of one, the coil activates both switches simultaneously.

Most relays are nonpolarized, meaning that you can run electricity through the coil in either direction, and the relay doesn't care. You should check the data sheet to make sure, though. Some relay coils work on AC voltage, but almost all low-voltage relays use direct current—a steady flow of electricity, such as you would get from a battery. We'll be using DC relays in this book.

Relays suffer from the same limitations as switches: their contacts will be eroded by sparking if you try to switch too much voltage. It's not worth saving a few dollars by using a relay that is rated for less current or voltage than your application requires. The relay will fail you when you need it most, and may be inconvenient to replace.

Because there are so many different types of relays, read the specifications carefully before you buy one. Look for these basics:

Coil voltage

The voltage that the relay is supposed to receive when you energize it.

Set voltage

The minimum voltage that the relay needs to close its switch. This will be a bit less than the ideal coil voltage.

Operating current

The power consumption of the coil, usually in milliamps, when the relay is energized. Sometimes the power is expressed in milliwatts.

Switching capacity

The maximum amount of current that you can switch with contacts inside the relay. Usually this is for a "resistive load," meaning a passive device such as light bulb. When you use a relay to switch on a motor, the motor takes a big initial surge of current before it gets up to speed. In this case, you should choose a relay rated for double the current that the motor draws when it is running.

Procedure

Turn the relay with its legs in the air and attach wires and LEDs as shown in Figure 2-59, with a 680Ω resistor (a 1K resistor will be OK if you don't have the correct value). Also attach a pushbutton switch. (Your pushbutton switch may look different from the one shown, but as long as it is a SPST pushbutton with two contacts at the bottom, it will work the same way.) When you press the pushbutton, the relay will make the first LED go out and the second LED light up. When you release the pushbutton, the first LED lights up and the second one goes out.

How It Works

Check the schematic in Figure 2-60 and compare it with Figure 2-59. Also see Figure 2-62, which shows how the pins outside the relay make connections inside the relay when its coil is energized, and when it is not energized.

This is a DPDT relay, but we are only using one pole and ignoring the other. Why not buy a SPDT relay? Because I want the pins to be spaced the way they are when you will upgrade this circuit by transferring it onto a breadboard, which will happen very shortly.

On the schematic, I have shown the switch inside the relay in its relaxed state. When the coil is energized, the switch flips upward, which seems counterintuitive, but just happens to be the way that this particular relay is made.

When you're sure you understand how the circuit works, it's time to move on to the next step: making a small modification to get the relay to switch itself on and off, as we'll do in Experiment 8.

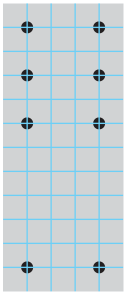

Figure 2-61. *The layout of the pins of the relay, superimposed on a grid of 1/10-inch squares. This is the type of relay that you will need in Experiment 8.*

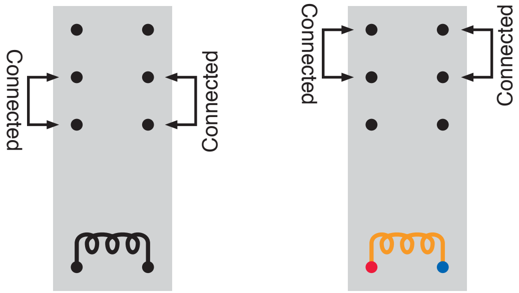

Figure 2-62. *How the relay connects the pins, when it is not energized (left) and when it is energized (right).*

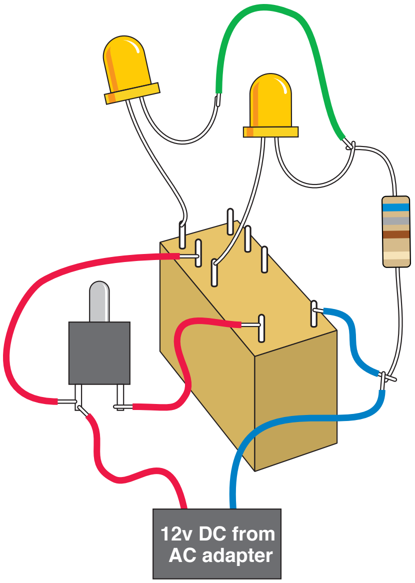

Figure 2-59. *As before, you can use patch cords, if you have them, instead of some of the wired connections shown here.*

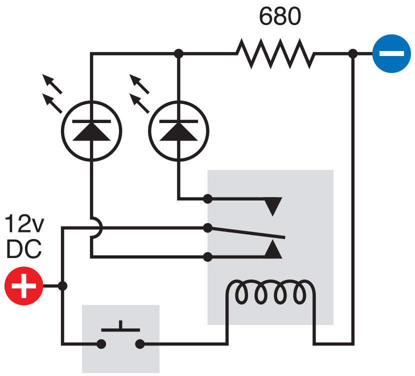

Figure 2-60. *Same circuit, shown in schematic form.*

Larger versions of all schematics and breadboard photos are available online at this book's website: http://oreilly.com/catalog/9780596153748.

Experiment 8: A Relay Oscillator

You will need:

- AC adapter, breadboard, wire, wire cutters and strippers.
- DPDT relay. Quantity: 1.
- LEDs. Quantity: 2.
- Pushbutton, SPST. Quantity: 1.
- Alligator clips. Quantity: 8.
- Resistor, approximately 680Ω. Quantity: 1.
- Capacitor, electrolytic, 1,000 µF. Quantity: 1.

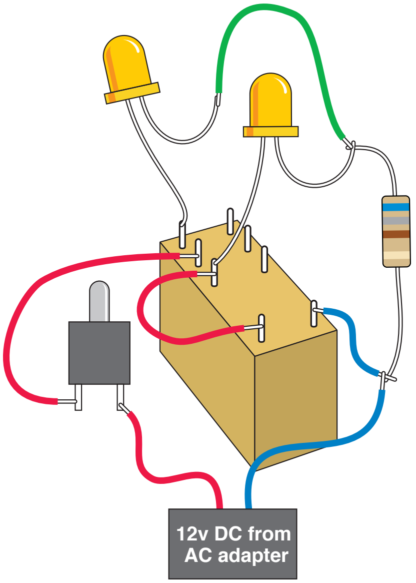

Figure 2-63. *A small revision to the previous circuit causes the relay to start oscillating when power is applied.*

Look at the revised drawing in Figure 2-63 and the revised schematic in Figure 2-64 and compare them with the previous ones. Originally, there was a direct connection from the pushbutton to the coil. In the new version, the power gets to the coil by going, first, through the contacts of the relay.

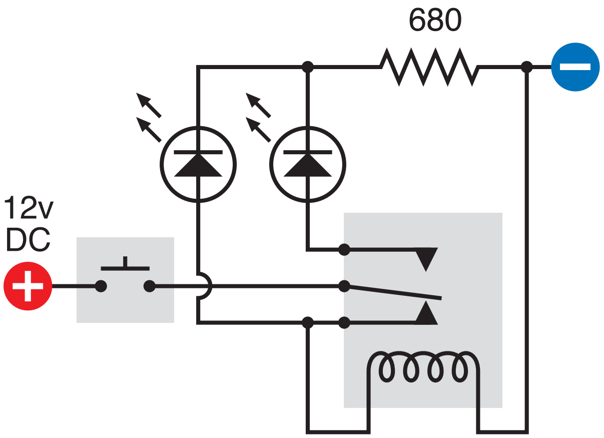

Figure 2-64. *The oscillator circuit shown in schematic form.*

Now, when you press the button, the contacts in their relaxed state feed power to the coil as well as to the lefthand LED. But as soon as the coil is energized, it opens the contacts. This interrupts the power to the coil—so the relay relaxes, and the contacts close again. They feed another pulse of power to the coil, which opens the contacts again, and the cycle repeats endlessly.

Because we're using a very small relay, it switches on and off extremely fast. In fact, it oscillates perhaps 50 times per second (too fast for the LEDs to show what's really happening). Make sure your circuit looks like the one in the diagram, and then press the pushbutton very briefly. You should hear the relay make a buzzing sound. If you have impaired hearing, touch the relay lightly with your finger, and you should feel the relay vibrating.

When you force a relay to oscillate like this, it's liable to burn itself out or destroy its contacts. That's why I asked you to press the pushbutton briefly. To make the circuit more practical, we need something to slow the relay down and prevent it from self-destructing. That necessary item is a capacitor.

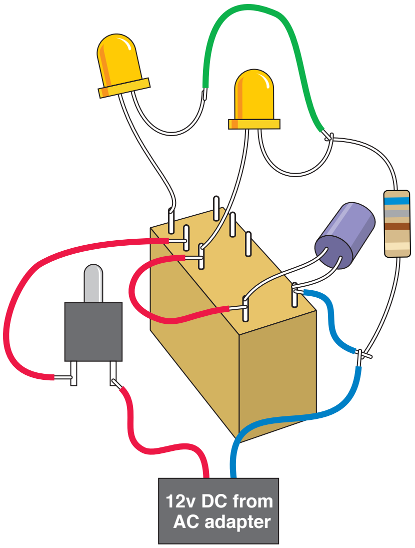
Adding Capacitance

Add a 1,000 µF electrolytic capacitor in parallel with the coil of the relay as shown in the diagram in Figure 2-65 and the schematic in Figure 2-66. Check Figure 2-14 if you're not sure what a capacitor looks like. The 1,000 µF value will be printed on the side of it, and I'll explain what this means a little later.

Make sure the capacitor's *short* wire is connected to the *negative* side of the circuit; otherwise, it won't work. In addition to the short wire, you should find a minus sign on the body of the capacitor, which is there to remind you which side is negative. Electrolytic capacitors are fussy about this.

When you press the button now, the relay should click slowly instead of buzzing. What's happening here?

A capacitor is like a tiny rechargeable battery. It's so small that it charges in a fraction of a second, before the relay has time to open its lower pair of contacts. Then, when the contacts are open, the capacitor acts like a battery, providing power to the relay. It keeps the coil of the relay energized for about one second. After the capacitor exhausts its power reserve, the relay relaxes and the process repeats.



12v DC from AC adapter

Figure 2-65. *Adding a capacitor makes the relay oscillate more slowly.*

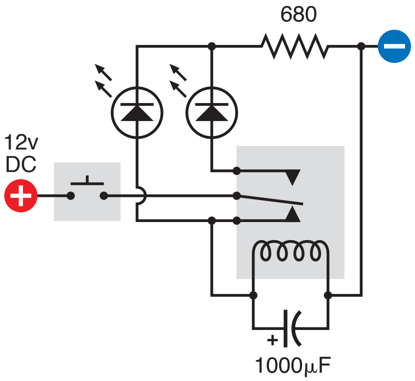


Figure 2-66. *The capacitor appears at the bottom of this schematic diagram.*

FUNDAMENTALS

Farad basics

The Farad is an international unit to measure capacitance. Modern circuits usually require small capacitors. Consequently it is common to find capacitors measured in microfarads (one-millionth of a farad) and even picofarads (one-trillionth of a farad). Nanofarads are also used, more often in Europe than in the United States. See the following conversion table.

0.001 nanofarad	1 picofarad	1 pF
0.01 nanofarad	10 picofarads	10 pF
0.1 nanofarad	100 picofarads	100 pF
1 nanofarad	1,000 picofarads	1,000 pF
0.001 microfarad	1 nanofarad	1 nF
0.01 microfarad	10 nanofarads	10 nF
0.1 microfarad	100 nanofarads	100 nF
1 microfarad	1,000 nanofarads	1,000 nF
0.000001 Farad	1 microfarad	1 µF
0.00001 Farad	10 microfarads	10 µF
0.0001 Farad	100 microfarads	100 µF
0.001 Farad	1,000 microfarads	1,000 µF

(You may encounter capacitances greater than 1,000 microfarads, but they are uncommon.)

FUNDAMENTALS

Capacitor basics

DC current does not flow through a capacitor, but voltage can accumulate very quickly inside it, and remains after the power supply is disconnected. Figures 2-67 and 2-68 may help to give you an idea of what happens inside a capacitor when it is fully charged.

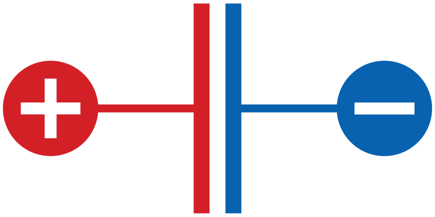

Figure 2-67. *When DC voltage reaches a capacitor, no current flows, but the capacitor charges itself like a little battery. The positive and negative charges are equal and opposite.*

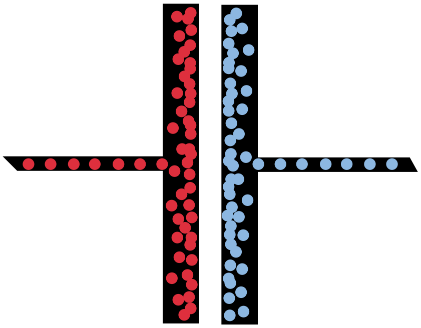

Figure 2-68. *You can imagine positive "charge particles" accumulating on one side of the capacitor and attracting negative "charge particles" to the opposite side.*

In most modern electrolytic capacitors, the plates have been reduced to two strips of very thin, flexible, metallic film, often wrapped around each other, separated by an equally thin insulator. Disc ceramic capacitors typically consist of just a single disc of nonconductive material with metal painted on both sides and leads soldered on.

The two most common varieties of capacitors are ceramic (capable of storing a relatively small charge) and electrolytic (which can be much larger). Ceramics are often disc-shaped and yellow in color; electrolytics are often shaped like miniature tin cans and may be just about any color. Refer back to Figures 2-13 and 2-14 for some examples.

Getting Zapped by Capacitors

If a large capacitor is charged with a high voltage, it can retain that voltage for a long time. Because the circuits in this book use low voltages, you don't have to be concerned about that danger here, but if you are reckless enough to open an old TV set and start digging around inside (which I do not recommend), you may have a nasty surprise. An undischarged capacitor can kill you as easily as if you stick your finger into an electrical outlet. Never touch a large capacitor unless you really know what you're doing.

FUNDAMENTALS

Capacitor basics (continued)

Ceramic capacitors have no polarity, meaning that you can apply negative voltage to either side of them. Electrolytics do have polarity, and won't work unless you connect them the right way around.

The schematic symbol for a capacitor has two significant variants: with two straight lines (symbolizing the plates inside a capacitor), or with one straight line and one curved line, as shown in Figure 2-69. When you see a curved line, that side of the capacitor should be more negative than the other. The schematic symbol may also include a + sign. Unfortunately, some people don't bother to draw a curved plate on a polarized capacitor, yet others draw a curved plate even on a nonpolarized capacitor.

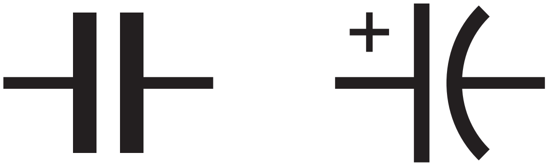

Figure 2-69. *The generic schematic for a capacitor is on the left. The version on the right indicates a polarized capacitor which requires its left plate to be "more positive" than its right plate. The plus sign is often omitted.*

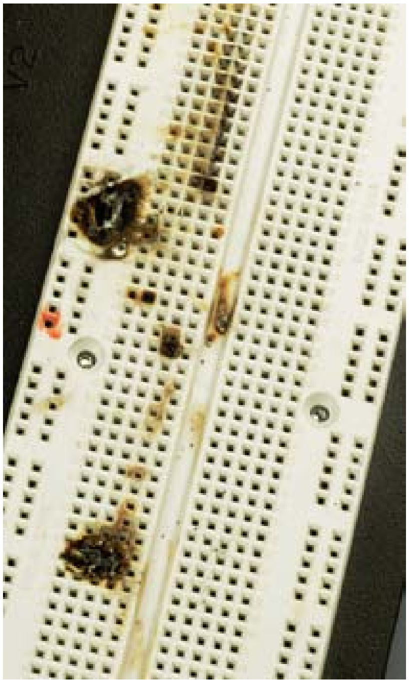

Figure 2-70. *A tantalum capacitor was plugged into this breadboard, accidentally connected the wrong way around to a power source capable of delivering a lot of current. After a minute or so of this abuse, the capacitor rebelled by popping open and scattering small flaming pieces, which burned their way into the plastic of the breadboard. Lesson learned: observe polarity!*

Capacitor Polarity

You must connect an electrolytic capacitor so that its longer wire is more positive than its shorter wire. The shell of the capacitor is usually marked with a negative sign near the shorter wire.

Some capacitors may behave badly if you don't observe their polarity. One time I connected a tantalum capacitor to a circuit, using a power supply able to deliver a lot of current, and was staring at the circuit and wondering why it wasn't working when the capacitor burst open and scattered little flaming fragments of itself in a 3-inch radius. I had forgotten that tantalum capacitors can be fussy about positive and negative connections. Figure 2-70 shows the aftermath.

BACKGROUND

Michael Faraday and capacitors

The earliest capacitors consisted of two metal plates with a very small gap between them. The principle of the thing was simple:

- If one plate was connected to a positive source, the positive charges attracted negative charges onto the other plate.
- If one plate was connected to a negative source, the negative charges attracted positive charges onto the other plate.

Figures 2-67 and 2-68, shown previously, convey the basic idea.

The electrical storage capacity of a capacitor is known as its *capacitance*, and is measured in farads, named after Michael Faraday (Figure 2-71), another of the pantheon of electrical pioneers. He was an English chemist and physicist who lived from 1791 to 1867.

Although Faraday was relatively uneducated and had little knowledge of mathematics, he had an opportunity to read a wide variety of books while working for seven years as a bookbinder's apprentice, and thus was able to educate himself. Also, he lived at a time when relatively simple experiments could reveal fundamental properties of electricity. Thus he made major discoveries including electromagnetic induction, which led to the development of electric motors. He also discovered that magnetism could affect rays of light.

His work earned him numerous honors, and his picture was printed on English 20-pound bank notes from 1991 through 2001.

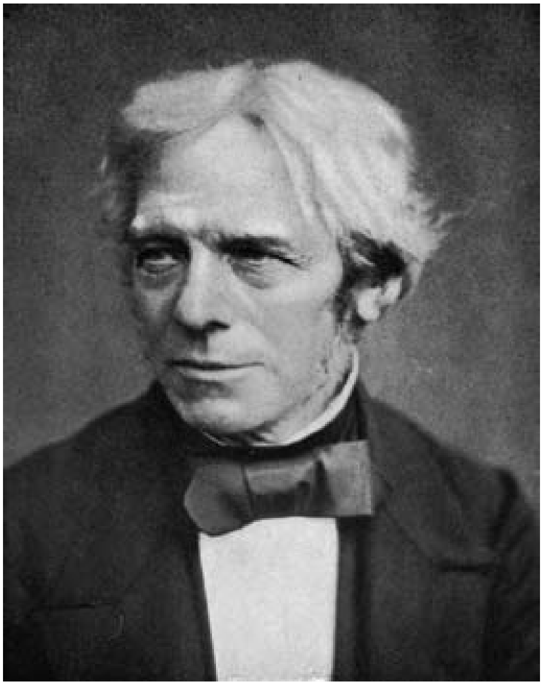

Figure 2-71. *Michael Faraday*

Breadboarding the Circuit

I promised to free you in time from the frustrations of alligator clips, and that time has come. Please turn your attention to the block of plastic with lots of little holes in it that I asked you to buy. For reasons that I do not know, this is called a *breadboard*. When you plug components into the holes, hidden metal strips inside the breadboard connect the components for you, allowing you to set up a circuit, test it, and modify it very easily. Afterward you can pull the components off the breadboard and put them away for future experiments.

Without a doubt, breadboarding is the most convenient way to test something before you decide whether you want to keep it.

Almost all breadboards are designed to be compatible with integrated circuit chips (which we will be using in Chapter 4 of this book). The chip straddles an empty channel in the center of the breadboard with rows of little holes either side—usually five holes per row. You insert other components into these holes.

In addition, the breadboard should have columns of holes running down each side. These are used to distribute positive and negative power.

Take a look at Figures 2-72 and 2-73, which show the upper part of a typical breadboard seen from above, and the same breadboard seen as if with X-ray vision, showing the metal strips that are embedded behind the holes.

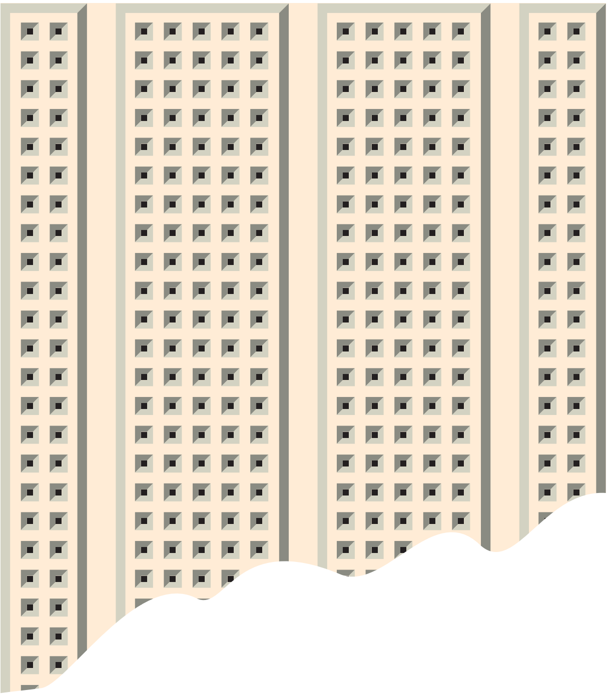

Figure 2-72. *A typical breadboard. You can plug components into the holes to test a circuit very quickly.*

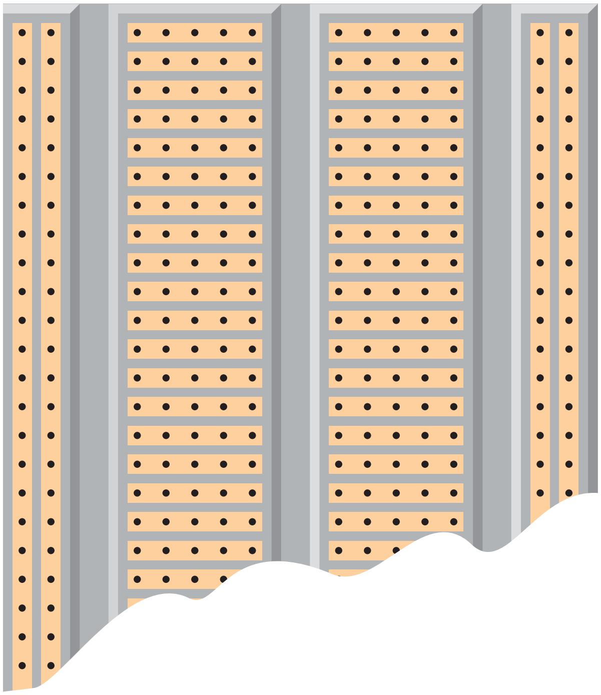

Figure 2-73. *This X-ray-vision view of the breadboard reveals the copper strips that are embedded in it. The strips conduct electricity from one component to another.*

Important note: some breadboards divide each vertical column of holes, on the left and the right, into two separate upper and lower sections. Use your meter's continuity testing feature to find out if your breadboard conducts power along its full length, and add jumper wires to link the upper and lower half of the breadboard if necessary.

Figure 2-74 shows how you can use the breadboard to replicate your oscillating relay circuit. To make this work, you need to apply the positive and negative power from your AC adapter. Because the wire from your AC adapter is almost certainly stranded, you'll have difficulty pushing it into the little holes. A way around this is to set up a couple of pieces of bare 22-gauge wire, and use them as terminals to which you clip the wire from the adapter, as in Figure 2-75. (Yes, you still need just a couple of alligator clips for this purpose.) Alternatively, you can use a breadboard with power terminals built into it, which is more convenient.

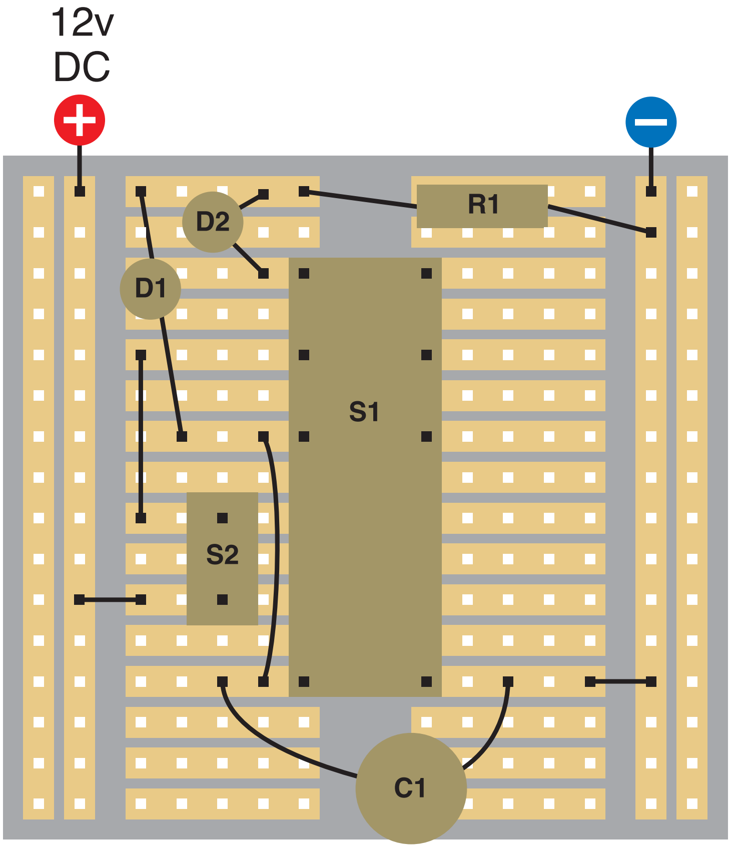

Figure 2-74. *If you place the components on your breadboard in the positions shown, they will create the same circuit that you built from wire and alligator clips in Experiment 8. Component values:*

D1, D2: Light-emitting diodes
S1: DPDT relay
S2: SPST momentary switch
C1: Electrolytic capacitor, 1,000 µF
R1: Resistor, 680Ω minimum

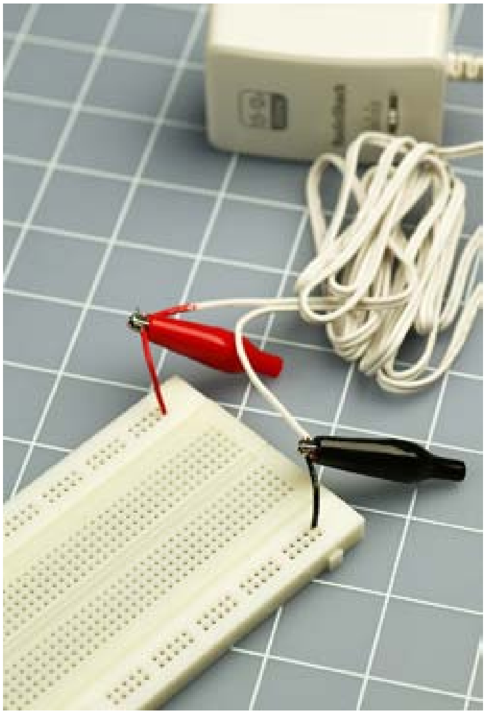

Figure 2-75. *If your breadboard doesn't have screw terminals, insert two short pieces of solid-core wire with stripped ends and then attach the stranded wires from the adapter using alligator clips.*

You'll need some more 22-gauge wire, or some precut hookup wire, to supply the power to your components, which are plugged into the breadboard as shown in Figures 2-76 and 2-77. If you get all the connections right, the circuit should function the same way as before.

The geometry of the metal connecting strips in the breadboard often forces you to connect components in a roundabout way. The pushbutton, for instance, supplies power to the pole of the relay but cannot be connected directly opposite, because there isn't room for it.

Remember that the strips inside the breadboard that don't have any wires or components plugged into them are irrelevant; they don't do anything.

I'll include some suggested breadboard layouts for circuits as you continue through this book, but eventually you'll have to start figuring out breadboard layouts for yourself, as this is an essential part of hobby electronics.

Larger versions of all schematics and breadboard photos are available online at this book's website: http://oreilly.com/catalog/9780596153748.

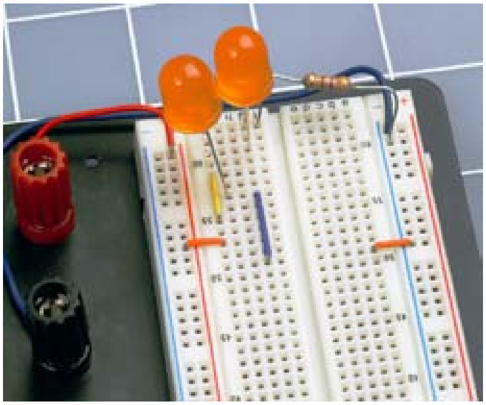

Figure 2-76. *Two oversized LEDs, one resistor, and the necessary jumper wires have been added to the breadboard.*

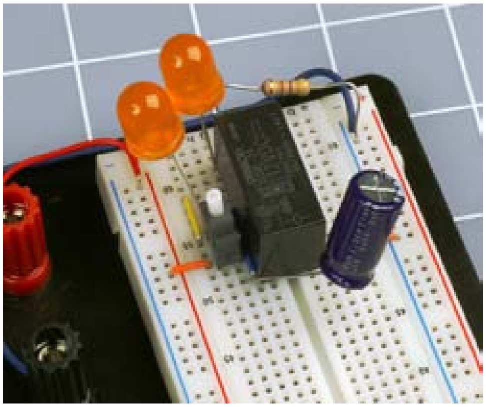

Figure 2-77. *Now the pushbutton, relay, and capacitor have been added to complete the circuit shown in the diagram and the schematic. When the pushbutton is pressed, the relay oscillates and the LEDs flash.*

Experiment 9: Time and Capacitors

You will need:

- AC adapter, breadboard, wire, wire cutters, and strippers.
- Multimeter.
- Pushbutton, SPST. Quantity: 1.
- Resistors and electrolytic capacitors, assorted.

In Experiment 8, when you put a capacitor in parallel with the coil of the relay, the capacitor charged almost instantly before discharging itself through the relay coil. If you add a resistor in series with a capacitor, the capacitor will take longer to charge. By making a capacitor take longer to charge, you can measure time, which is a very important concept.

Clean the components off your breadboard and use it to set up the very simple circuit shown in Figure 2-78, where C1 is a 1,000 µF capacitor, R1 is a 100K resistor, R2 is a 100Ω resistor, and S1 is the pushbutton that you used previously. Set your meter to measure volts DC, place the probes around the capacitor, and hold down the pushbutton. You should see the meter counting upward as the voltage accumulates on the capacitor. (This is easier with a meter that doesn't have autoranging, because you won't have to wait while the meter figures out which range to apply.) Resistor R1 slows the charging time for the capacitor.

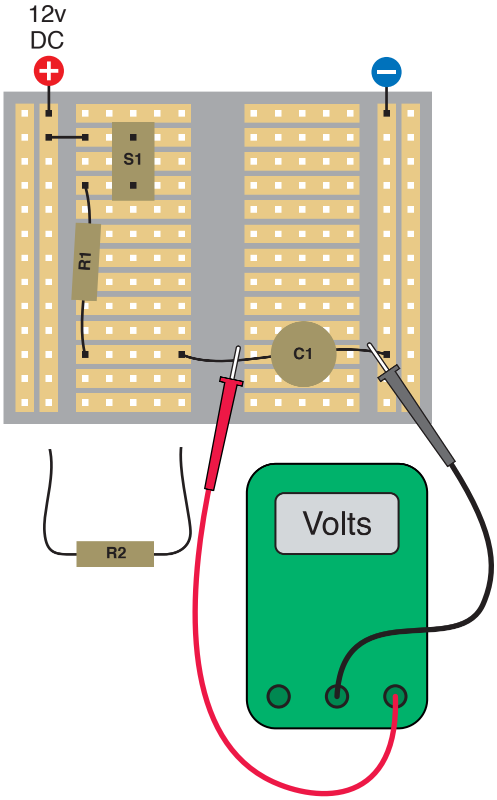

Figure 2-78. *Watch the voltage building up on the capacitor while you hold down the pushbutton. Substitute other values for R1, discharge the capacitor by touching R2 across it, and then repeat your measurement process.*

S1: Momentary pushbutton, OFF (ON)
R1: 100K initially
R2: 100Ω
C1: 1,000 µF

Release the pushbutton, set aside your meter, and discharge the capacitor by touching R2 across it for a second or two. Now substitute a 50K resistor for R1, and repeat the measurement. The meter should count upward almost twice as fast as before.

Voltage, Resistance, and Capacitance

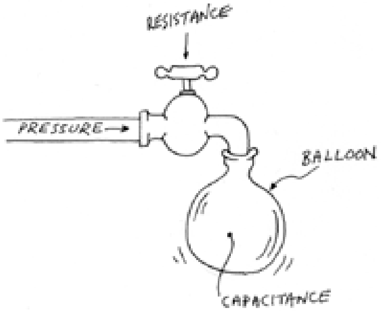

Figure 2-79. *When the faucet is closed half-way, the balloon will take longer to fill, but will still contain as much water and as much pressure in the end.*

Think of the resistor as a faucet, and the capacitor as a balloon that you are trying to fill with water. When you screw down the faucet until only a trickle comes through, the balloon will take longer to fill. But a slow flow of water will still fill the balloon completely if you wait long enough, and (assuming the balloon doesn't burst) the process ends when the pressure inside the balloon is equal to the water pressure in the pipe supplying the faucet. See Figure 2-79.

Similarly, in your circuit, if you wait long enough, eventually the voltage across the capacitor should reach the same value as the voltage of the power supply. In a 12-volt circuit, the capacitor should eventually acquire 12 volts (although "eventually" may take longer than you think).

This may seem confusing, because earlier you learned that when you apply voltage at one end of a resistor, you get less voltage coming out than you have going in. Why should a resistor deliver the full voltage when it is paired with a capacitor?

Forget the capacitor for a moment, and remember how you tested just two 1K resistors. In that situation, each resistor contained half the total resistance of the circuit, so each resistor dropped half the voltage. If you held the negative probe of your meter against the negative side of your power supply and touched the positive probe to the center point between the two resistors, you would measure 6 volts. Figure 2-80 illustrates this.

Now, suppose you remove one of the 1K resistors and substitute a 9K resistor. The total resistance in the circuit is now 10K, and therefore the 9K resistor drops 90% of the 12 volts. That's 10.8 volts. You should try this and check it with your meter. (You are unlikely to find a 9K resistor, because this is not a standard value. Substitute the nearest value you can find.)

Now suppose you remove the 9K resistor and substitute a 99K resistor. Its voltage drop will be 99% of the available voltage, or 11.88 volts. You can see where this is heading: the larger the resistor, the larger its contribution to voltage drop.

However, I noted previously that a capacitor blocks DC voltage completely. It can accumulate an electrical charge, but no current passes through it. Therefore, a capacitor behaves like a resistor that has infinite resistance to DC current.

(Actually the insulation inside the capacitor allows a little bit of "leakage," but a perfect capacitor would have infinite resistance.)

The value of any resistor that you put in series with the capacitor is trivial by comparison. No matter how high the value of the resistor is, the capacitor still provides much more resistance in the circuit. This means that the capacitor steals almost the complete voltage drop in the circuit, and the voltage difference between one end of the resistor and the other will be zero (assuming that we ignore little imperfections in the components). Figure 2-80 may help to clarify this concept.

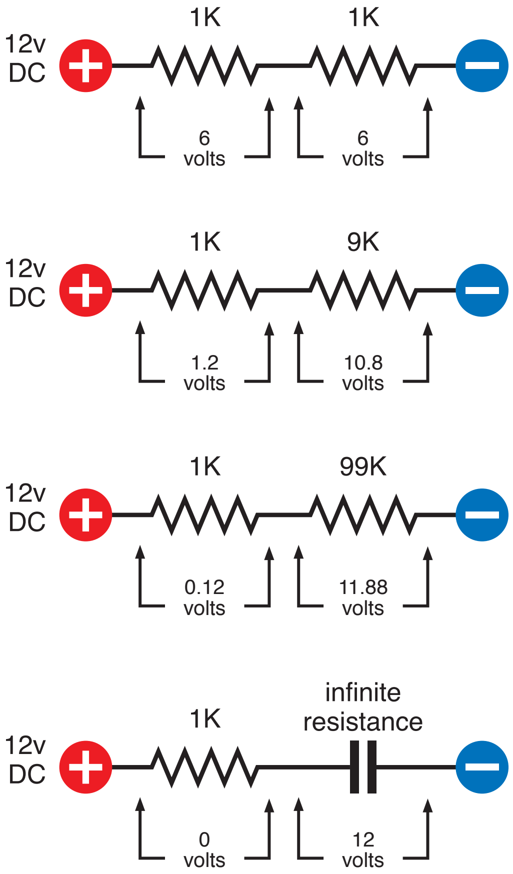

Figure 2-80. *When two resistances are in series, the larger one drops the voltage more than the smaller one. If the larger resistance becomes infinite (as in the case of a capacitor), the smaller one no longer has any measurable contribution to the voltage drop, and the voltage is almost exactly the same at both ends.*

You should try this using real resistors and capacitors—although if you do, you will run into a little problem. When you use your meter in its "DC volts" mode, it diverts a little of the current in the circuit—just a tiny taste—in the process of measuring it. The meter steals such a small amount, it doesn't affect the reading significantly when you are checking voltage across a resistor. The internal resistance of the meter is higher than the values of most resistors. However, remember that the internal resistance of a capacitor is almost infinite. Now the internal resistance of the meter becomes significant. Because you can never have an ideal meter, any more than you can have an ideal capacitor or resistor, your meter will always interfere with the circuit slightly, and you will get only an approximate indication.

If you try to measure the voltage on a capacitor that has been charged but is now not connected to anything else, you'll see the number slowly falling, as the capacitor discharges itself through the meter.

THEORY

The time constant

You may be wondering if there's a way to predict exactly how much time it takes for various capacitors to charge, when they are paired with various resistors. Is there a formula to calculate this?

Of course, the answer is yes, but the way we measure it is a bit tricky, because a capacitor doesn't charge at a constant rate. It accumulates the first volt very quickly, the second volt not quite as quickly, the third volt even less quickly—and so on. You can imagine the electrons accumulating on the plate of a capacitor like people walking into an auditorium and looking for a place to sit. The fewer seats that are left, the longer people take to find them.

The way we describe this is with something called a "time constant." The definition is very simple:

$$TC = R \times C$$

where TC is the time constant, and a capacitor of C farads is being charged through a resistor of R ohms.

Going back to the circuit you just tested, try using it again, this time with a 1K resistor and the 1,000 μF capacitor. We have to change those numbers to farads and ohms before we can put them in the formula. Well, 1,000 μF is 0.001 farads, and 1K is 1,000 ohms, so the formula looks like this:

$$TC = 1{,}000 \times 0.001$$

In other words, TC = 1—a lesson that could not be much easier to remember:

> ***A 1K resistor in series with a 1,000 μF capacitor has a time constant of 1.***

Does this mean that the capacitor will be fully charged in 1 second? No, it's not that simple. TC, the time constant, is the time it takes for a capacitor to acquire *63%* of the voltage being supplied to it, if it starts with zero volts.

(Why 63%? The answer to that question is too complicated for this book, and you'll have to read about time constants elsewhere if you want to know more. Be prepared for differential equations.) Here's a formal definition for future reference:

> TC, the time constant, is the time it takes for a capacitor to acquire 63% of the difference between its current charge and the voltage being applied to it. When TC=1, the capacitor acquires 63% of its full charge in 1 second. When TC=2, the capacitor acquires 63% of its full charge in 2 seconds. And so on.

What happens if you continue to apply the voltage? History repeats itself. The capacitor accumulates *another* 63% of the *remaining* difference between its current charge, and the voltage being applied to it.

Imagine someone eating a cake. In his first bite he's ravenously hungry, and eats 63% of the cake in one second. In his second bite, not wanting to seem too greedy, he takes just another 63% of the cake that is left—and because he's not feeling so hungry anymore, he requires the same time to eat it as he took to eat the first bite. In his third bite, he takes 63% of what still remains, and still takes the same amount of time. And so on. He is behaving like a capacitor eating electricity (Figure 2-81).

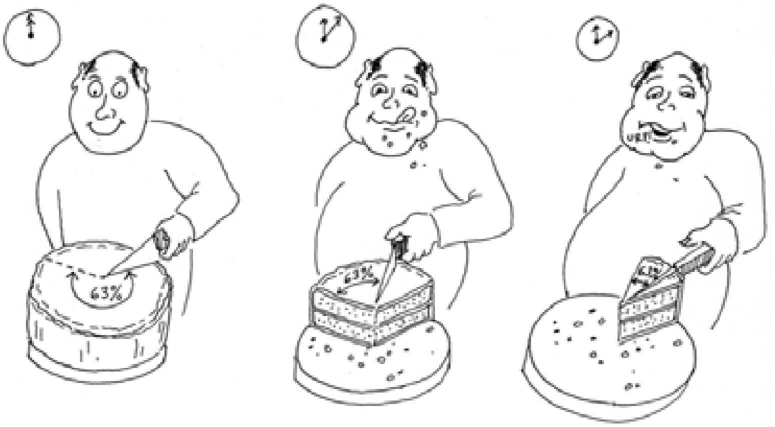

Figure 2-81. *If our gourmet always eats just 63% of the cake still on the plate, he "charges up" his stomach in the same way that a capacitor charges itself. No matter how long he keeps at it, his stomach is never completely filled.*

THEORY

The time constant (continued)

The cake eater will always have a few crumbs to eat, because he never takes 100% of the remainder. Likewise, the capacitor will never acquire a full charge. In a perfect world of perfect components, this process would continue for an infinite time.

In the real world, we say rather arbitrarily:

> After 5 × TC the capacitor will be so nearly fully charged, we won't care about the difference.

In the table is a calculation (rounded to two decimal places) showing the charge accumulating on a capacitor in a 12-volt circuit where the time constant is 1 second.

Here's how to understand the table. V1 is the current charge on the capacitor. Subtract this from the supply voltage (12 volts) to find the difference. Call the result V2. Now take 63% of V2, and add this to the current charge (V1) and call the result V4. This is the new charge that the capacitor will have after 1 second, so we copy it down to the next line in the table, and it becomes the new value for V1.

Now we repeat the same process all over again. Figure 2-82 shows this in graphical form. Note that after 5 seconds, the capacitor has acquired 11.92 volts, which is 99% of the power supply voltage. This should be close enough to satisfy anyone's real-world requirements.

If you try to verify these numbers by measuring the voltage across the capacitor as it charges, remember that because your meter steals a little current, there will be a small discrepancy that will increase as time passes. For practical purposes, the system works well enough.

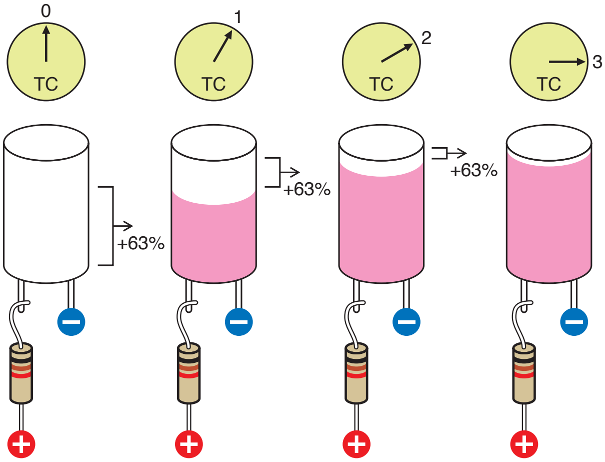

Figure 2-82. *A capacitor starts with 0 volts. After 1 time constant it adds 63% of the available voltage. After another time constant, it adds another 63% of the remaining voltage difference, and so on.*

Time in secs	V1: Charge on capacitor	V2: 12 – V1	V3: 63% of V2	V4: V1 + V3
0	0.00	12.00	7.56	7.56
1	7.56	4.44	2.80	10.36
2	10.36	1.64	1.03	11.39
3	11.39	0.61	0.38	11.77
4	11.77	0.23	0.15	11.92
5	11.92			

Experiment 10: Transistor Switching

You will need:

- AC adapter, breadboard, wire, and meter.
- LED. Quantity: 1.
- Resistors, various.
- Pushbutton, SPST. Quantity: 1.
- Transistor, 2N2222 or similar. Quantity: 1.

A transistor can switch a flow of electricity, just like a relay. But it's much more sensitive and versatile, as this first ultra-simple experiment will show.

We'll start with the 2N2222 transistor, which is the most widely used semiconductor of all time (it was introduced by Motorola in 1962 and has been in production ever since).

First, you should get acquainted with the transistor. Because Motorola's patents on the 2N2222 ran out long ago, any company can manufacture their own version of it. Some versions are packaged in a little piece of black plastic; others are enclosed in a little metal "can." (See Figure 2-83.) Either way, it contains a piece of silicon divided into three sections known as the collector, the base, and the emitter. I'll describe their function in more detail in a moment, but initially you just need to know that in this type of transistor, the collector receives current, the base controls it, and the emitter sends it out.

Use your breadboard to set up the circuit shown in Figure 2-85. Be careful to get the transistor the right way around! (See Figure 2-84.) For the three brands I have mentioned in the shopping list, the flat side should face right, if the transistor is packaged in black plastic, or the little tab should face toward the lower left, if the transistor is packaged in metal.

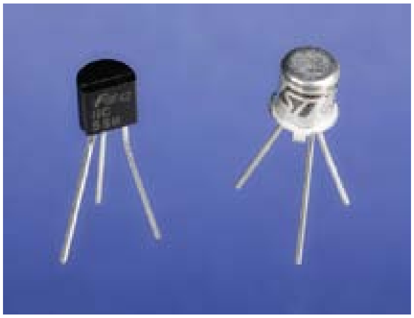

Figure 2-83. *A typical transistor is packaged either in a little metal can or a molded piece of black plastic. The manufacturer's data sheet tells you the identities of the three wire leads, relative to the flat side of a black plastic transistor or the tab that sticks out of a metal-can transistor.*

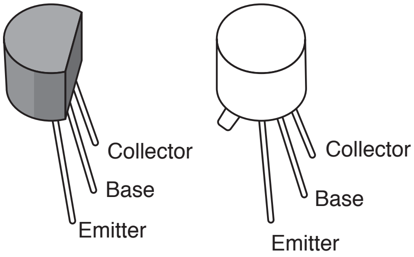

Figure 2-84. *The 2N2222 transistor may be packaged in either of these formats. Left: RadioShack or Fairchild. Right: STMicroelectronics (note the little tab sticking out at the lower-left side). If you use a different brand, you'll have to check the manufacturer's data sheet. Insert the transistor in your breadboard with the flat side facing right, as seen from above, or the tab pointing down and to the left, seen from above.*

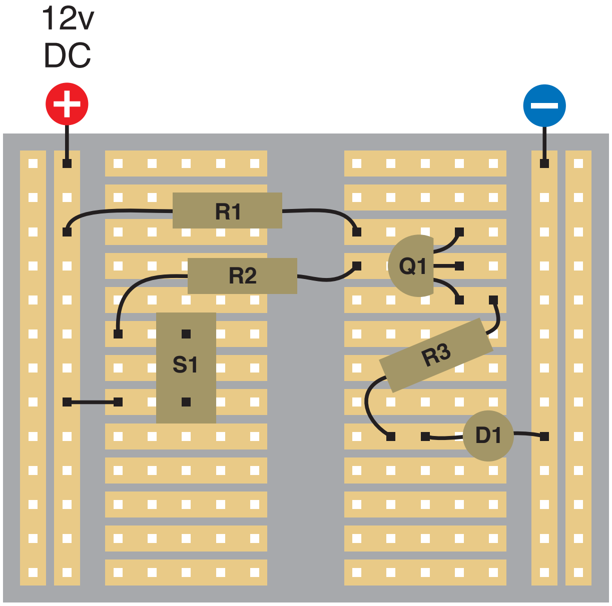

Figure 2-85. *The transistor blocks voltage that reaches it through R1. But when pushbutton S1 is pressed, this tells the transistor to allow current to pass through it. Note that transistors are always identified with letter Q in wiring diagrams and schematics.*

S1: Pushbutton, momentary, OFF (ON)
R1: 180Ω
R2: 10K
R3: 680Ω
Q1: 2N2222 or similar
D1: LED

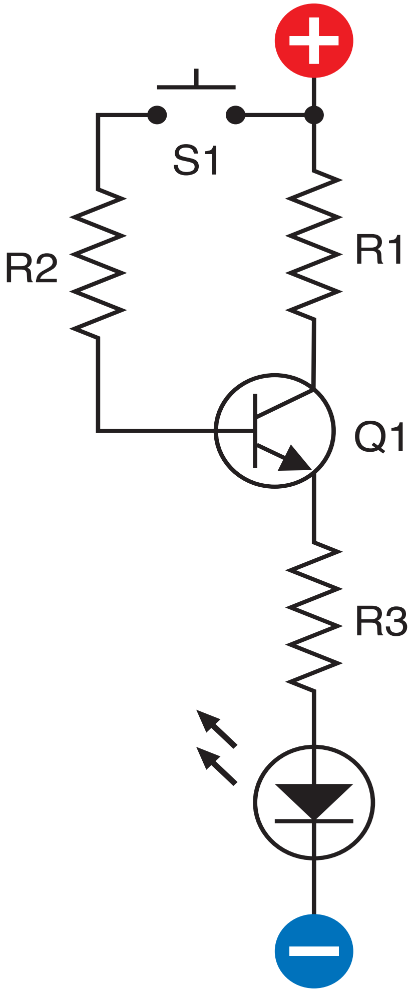

Figure 2-86. *This shows the same circuit as the breadboard diagram in Figure 2-85.*

Initially, the LED should be dark. Now press the pushbutton and the LED should glow brightly. Electricity is following two paths here. Look at the schematic in Figure 2-86, which shows the same circuit more clearly. I've shown positive at the top and negative at the bottom (the way most schematics do it) because it helps to clarify the function of this particular circuit. If you view the schematic from the side, the similarity with the breadboard layout is easier to see.

Through R1, voltage reaches the top pin (the collector) of the transistor. The transistor only lets a tiny trickle of it pass through, so the LED stays dark. When you press the button, voltage is also applied along a separate path, through R2 to the middle pin (the base) of the transistor. This tells the transistor to open its solid-state switch and allow current to flow out through its third pin (the emitter), and through R3, to the LED.

You can use your meter in volts DC mode to check the voltage at points in the circuit. Keep the negative probe from the meter touching the negative voltage source while you touch the positive probe to the top pin of the transistor, the middle pin, and the bottom pin. When you press the button, you should see the voltage change.

Fingertip Switching

Now here's something more remarkable. Remove R2 and the pushbutton, and insert two short pieces of of wire as shown in Figure 2-87. The upper piece of wire connects with the positive voltage supply; the lower piece connects with the middle pin of the transistor (its base). Now touch the tip of your finger to the two wires. Once again, the LED should glow, although not as brightly as before. Lick the tip of your finger, try again, and the LED should glow more brightly.

Never Use Two Hands

The fingertip switching demo is safe if the electricity passes just through your finger. You won't even feel it, because it's 12 volts DC from a power supply of 1 amp or less. But it's not a good idea to put the finger of one hand on one wire, and the finger of your other hand on the other wire. This would allow the electricity to pass through your body. Although the chance of hurting yourself this way is extremely small, you should never allow electricity to run through you from one hand to the other. Also, when touching the wires, don't allow them to penetrate your skin.

Your finger is conducting positive voltage to the base of the transistor. Even though your skin has a high resistance, the transistor still responds. It isn't just switching the LED on and off; it is *amplifying the current* applied to its base. This is an essential concept: *a transistor amplifies any changes in current that you apply to its base*.

Check Figure 2-88 to see more clearly what's happening.

If you studied the section "Background: Positive and negative" in Chapter 1, you learned that there is really no such thing as positive voltage. All we really have is negative voltage (created by the pressure of free electrons) and an absence of negative voltage (where there are fewer free electrons). But because the idea of a flow of electricity from positive to negative was so widely believed before the electron was discovered, and because the inner workings of a transistor involve "holes" which are an absence of electrons and can be thought of as positive, we can still pretend that electricity flows from positive to negative. See the following section, "Essentials: All about NPN and PNP transistors," for more details.

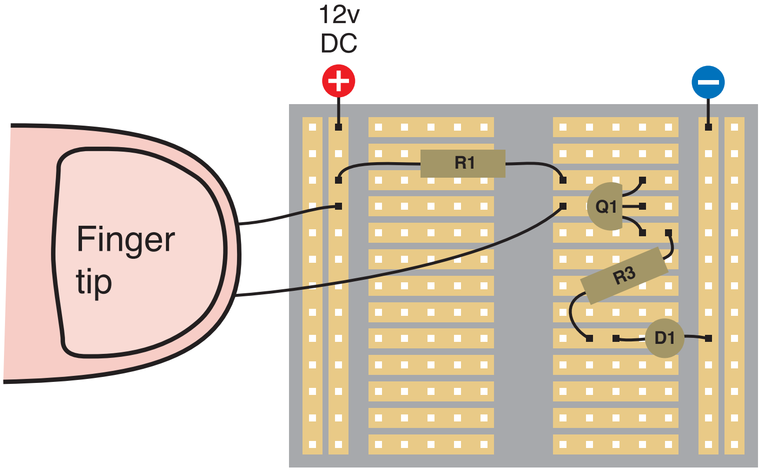

Figure 2-87

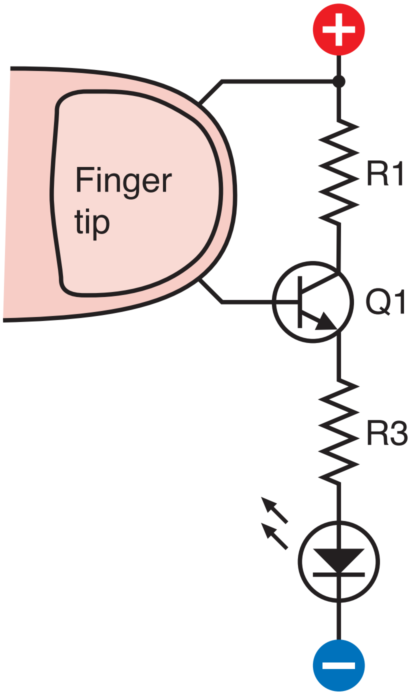

Figure 2-88. *These two diagrams show the same components as before, with a fingertip substituted for R2. Although only a trickle of voltage now reaches the base of the transistor, it's enough to make the transistor respond.*

ESSENTIALS

All about NPN and PNP transistors

A transistor is a semiconductor, meaning that sometimes it conducts electricity, and sometimes it doesn't. Its internal resistance varies, depending on the power that you apply to its base.

NPN and PNP transistors are bipolar semiconductors. They contain two slightly different variants of silicon, and conduct using both polarities of carriers—holes and electrons.

The NPN type is a sandwich with P-type silicon in the middle, and the PNP type is a sandwich with N-type silicon in the middle. If you want to know more about this terminology, and the behavior of electrons when they try to cross an NP junction or a PN junction, you'll have to read a separate source on this subject. It's too technical for this book. All you need to remember is:

- All bipolar transistors have three connections: Collector, Base, and Emitter, abbreviated as C, B, and E on the manufacturer's data sheet, which will identify the pins for you.
- NPN transistors are activated by *positive* voltage on the base relative to the emitter.
- PNP transistors are activated by *negative* voltage on the base relative to the emitter.

In their passive state, both types block the flow of electricity between the collector and emitter, just like an SPST relay in which the contacts are normally open. (Actually a transistor allows a tiny bit of current known as "leakage.")

You can think of a bipolar transistor as if it contains a little button inside, as shown in Figures 2-89 and 2-90. When the button is pressed, it allows a large current to flow. To press the button, you inject a much smaller current into the base by applying a small voltage to the base. In an NPN transistor, the control voltage is positive. In a PNP transistor, the control voltage is negative.

NPN transistor basics

- To start the flow of current from collector to emitter, apply a relatively positive voltage to the base.
- In the schematic symbol, the arrow points from base to emitter and shows the direction of positive current.
- The base must be at least 0.6 volts "more positive" than the emitter, to start the flow.
- The collector must be "more positive" than the emitter.

PNP transistor basics

- To start the flow of current from emitter to collector, apply a relatively negative voltage to the base.
- In the schematic symbol, the arrow points from emitter to base and shows the direction of positive current.
- The base must be at least 0.6 volts "more negative" than the emitter, to start the flow.
- The emitter must be "more positive" than the collector.

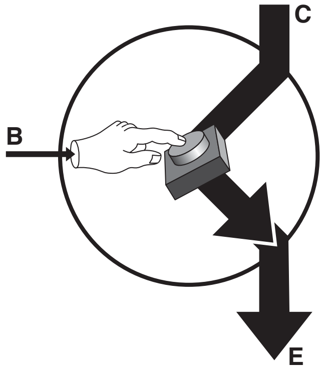

Figure 2-89. *You can think of a bipolar transistor as if it contains a button that can connect the collector and the emitter. In an NPN transistor, a small positive potential presses the button.*

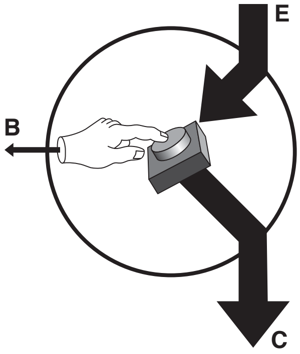

Figure 2-90. *In a PNP transistor, a small negative potential has the same effect. The arrows point in the direction of "positive current flow."*

ESSENTIALS

All about NPN and PNP transistors (continued)

All-transistor basics

- Never apply a power supply directly across a transistor. You can burn it out with too much current.
- Protect a transistor with a resistor, in the same way you would protect an LED.
- Avoid reversing the connection of a transistor between positive and negative voltages.
- Sometimes an NPN transistor is more convenient in a circuit; sometimes a PNP happens to fit more easily. They both function as switches and amplifiers, the only difference being that you apply a relatively positive voltage to the base of an NPN transistor, and a relatively negative voltage to the base of a PNP transistor.
- PNP transistors are used relatively seldom, mainly because they were more difficult to manufacture in the early days of semiconductors. People got into the habit of designing circuits around NPN transistors.
- Remember that bipolar transistors amplify current, not voltage. A small fluctuation of current through the base enables a large change in current between emitter and collector.
- Schematics sometimes show transistors with circles around them, and sometimes don't. In this book, I'll use circles to draw attention to them. See Figures 2-91 and 2-92.
- Schematics may show the emitter at the top and the collector at the bottom, or vice versa. The base may be on the left, or on the right, depending on what was most convenient for the person drawing the schematic. Be careful to look carefully at the arrow in the transistor to see which way up it is, and whether it is NPN or PNP. You can damage a transistor by connecting it incorrectly.
- Transistors come in various different sizes and configurations. In many of them, there is no way to tell which wires connect to the emitter, the collector, or the base, and some transistors have no part numbers on them. Before you throw away the packaging that came with a transistor, check to see whether it identifies the terminals.
- If you forget which wire is which, some multimeters have a function that will identify emitter, collector, and base for you. Check your multimeter instruction booklet for more details.

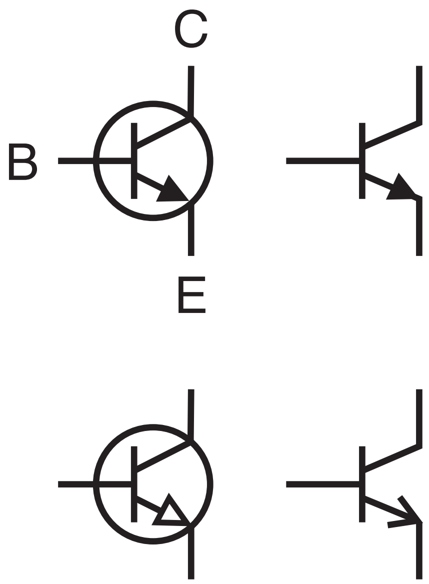

Figure 2-91. *The symbol for an NPN transistor always has an arrow pointing from its base to its emitter. Some people include a circle around the transistor; others don't bother. The style of the arrow may vary. But the meaning is always the same. The top-left version is the one I use in this book.*

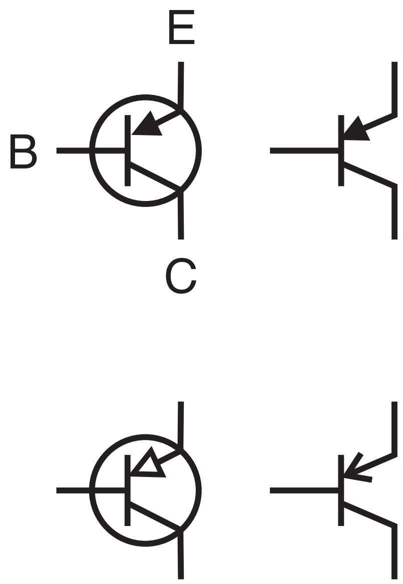

Figure 2-92. *The symbol for a PNP transistor always has an arrow pointing from its emitter to its base. Some people include a circle around the transistor; others don't bother. The style of the arrow may vary. But the meaning is always the same. The top-left version is the one I use in this book.*

BACKGROUND

Transistor origins

Though some historians trace the origins of the transistor back to the invention of diodes (which allow electricity to flow in one direction while preventing reversal of the flow), there's no dispute that the first working transistor was developed at Bell Laboratories in 1948 by John Bardeen, William Shockley, and Walter Brattain (Figure 2-93).

Shockley was the leader of the team, who had the foresight to see how potentially important a solid-state switch could be. Bardeen was the theorist, and Brattain actually made it work. This was a hugely productive collaboration—until it succeeded. At that point, Shockley started maneuvering to have the transistor patented exclusively under his own name. When he notified his collaborators, they were—naturally—unhappy about this idea.

A widely circulated publicity photograph didn't help, in that it showed Shockley sitting at the center in front of a microscope, as if he had done the hands-on work, while the other two stood behind him, implying that they had played a lesser role. In fact Shockley, as the supervisor, was seldom present in the laboratory where the real work was done.

The productive collaboration quickly disintegrated. Brattain asked to be transferred to a different lab at AT&T. Bardeen moved to the University of Illinois to pursue theoretical physics. Shockley eventually left Bell Labs and founded Shockley Semiconductor in what was later to become Silicon Valley, but his ambitions outstripped the capabilities of the technology of his time. His company never manufactured a profitable product.

Eight of Shockley's coworkers in his company eventually betrayed him by quitting and establishing their own business, Fairchild Semiconductor, which became hugely successful as a manufacturer of transistors and, later, integrated circuit chips.

Figure 2-93. *Photographs provided by the Nobel Foundation show, left to right, John Bardeen, William Shockley, and Walter Brattain. For their collaboration in development of the world's first working transistor in 1948, they shared a Nobel prize in 1956.*

ESSENTIALS

Transistors and relays

One limitation of NPN and PNP transistors is that they are naturally "off" until you turn them "on." They behave like a normally open pushbutton, which conducts electricity only for as long as you hold it down. They don't normally behave like a normal on switch, which stays on until you apply a signal to turn it off.

A relay offers more switching options. It can be normally open, normally closed, or it can contain a double-throw switch, which gives you a choice of two "on" positions. It can also contain a double-pole switch, which makes (or breaks) two entirely separate connections when you energize it. Single-transistor devices cannot provide the double-throw or double-pole features, although you can design more complex circuits that emulate this behavior.

Here's a list of transistor and relay characteristics.

	Transistor	Relay
Long-term reliability	Excellent	Limited
Configurable for DP and DT switching	No	Yes
Ability to switch large currents	Limited	Good
Able to switch alternating current (AC)	Usually not	Yes
Can be triggered by alternating current (AC)	Usually not	Optional
Suitability for miniaturization	Excellent	Very limited
Sensitive to heat	High	Moderate
Ability to switch at high speed	Excellent	Limited
Price advantage for low-voltage low-current	Yes	No
Price advantage for high-voltage high-current	No	Yes
Current leakage when "off"	Yes	No

The choice between relays or transistors will depend on each particular application.

THEORY

See the current

If you want to get a more precise understanding of how a transistor works, you should try this little test. It shows the precise behavior and limits of the 2N2222 transistor that you used in the previous experiment.

I've said that in an NPN transistor, the collector should always be more positive than the emitter and that the base should have a potential somewhere between those two voltages. Figure 2-94 shows this rather vague relationship. Now I want to substitute some numbers for these general statements.

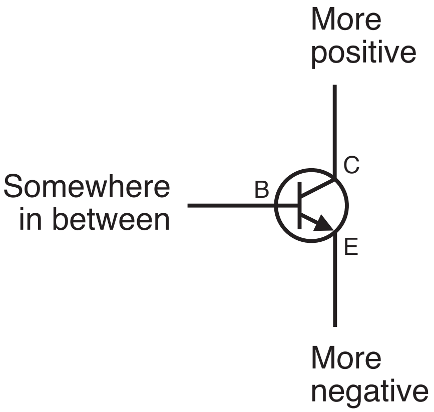

Figure 2-94. *The proper functioning of an NPN transistor requires you to maintain these voltage relationships.*

Take a look at the schematic in Figure 2-95, and check the component values. Notice that the total resistance above the transistor, from R1 + R2, is the same as the total resistance below it, from R3 + R4. Therefore the potential on the base of the transistor should be halfway between the two extremes—until you use potentiometer P1 to adjust the voltage of the base of the transistor up and down.

The two 180Ω resistors, R1 and R3, protect the transistor from passing excessive current. The two 10K resistors, R2 and R4, protect the base when the potentiometer is turned all the way up or all the way down.

I would like you to see what the transistor is doing by measuring the amperage flowing into the base at the position marked A1, and the total amperage flowing out through the emitter at the position marked A2. To do this, it would be really helpful if you had two meters. As that may be impractical, the breadboard diagrams in Figures 2-96 and 2-97 show how you can swap one meter between the two locations.

Remember that to measure milliamps, you have to pass electricity through the meter. This means that the meter must be inserted into the circuit, and whenever you remove the meter, you have to remake the connection where the meter was. The breadboard diagram shows how you can do this. Fortunately, it's very easy to remove and replace wires in a breadboard. Where wires are connected to the potentiometer, you may need to revert to using alligator clips.

Begin with the potentiometer turned about halfway through its range. Measure at A1 and A2. Turn the potentiometer up a bit, and measure current at the two locations again. Following is a table showing some actual readings I obtained at those two locations, using two digital meters simultaneously.

Milliamps passing through location A1	Milliamps passing through location A2
0.01	1.9
0.02	4.9
0.03	7.1
0.04	9.9
0.05	12.9
0.06	15.5
0.07	17.9
0.08	19.8
0.09	22.1
0.10	24.9
0.11	26.0
0.12	28.3

There's a very obvious relationship. The current emerging from the emitter of the transistor, through location A2, is about 24 times the current passing through location A1, into the base. The ratio of current coming out from the emitter of an NPN transistor to current going into the base is known as the *beta value* for a transistor. The beta value expresses the transistor's amplifying power.

It's a very constant ratio, until you push it a little too far. Above 0.12 mA, this particular transistor becomes "saturated," meaning that its internal resistance cannot go any lower.

THEORY

See the current (continued)

In my little experiment, I found that the maximum current at A2 was 33mA. A simple calculation using Ohm's Law showed me that this meant the transistor's internal resistance was near zero. This is why you should protect a transistor with some additional resistance in the circuit. If you don't, its low internal resistance would allow a huge current flow that would immediately burn it out.

What about the other end of its range? When it passes only 1.9 mA, the transistor has an internal resistance of around 6,000Ω. The conclusion is that depending how much current you apply to this transistor, its internal resistance varies between zero and 6,000Ω, approximately.

So much for the theory. Now what can we do with a transistor that's fun, or useful, or both? We can do Experiment 11!

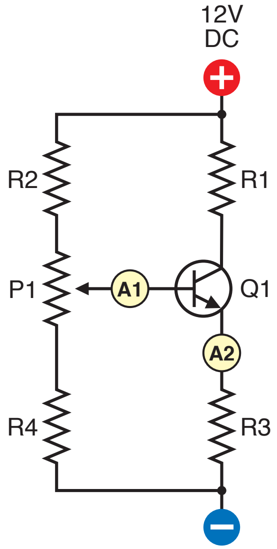

Figure 2-95. *This is basically the same as the previous circuit, with a potentiometer added and the LED removed. Component values:*

R1: 180Ω
R2: 10K
R3: 180Ω
R4: 10K
P1: 1M linear potentiometer
Q1: 2N2222 transistor

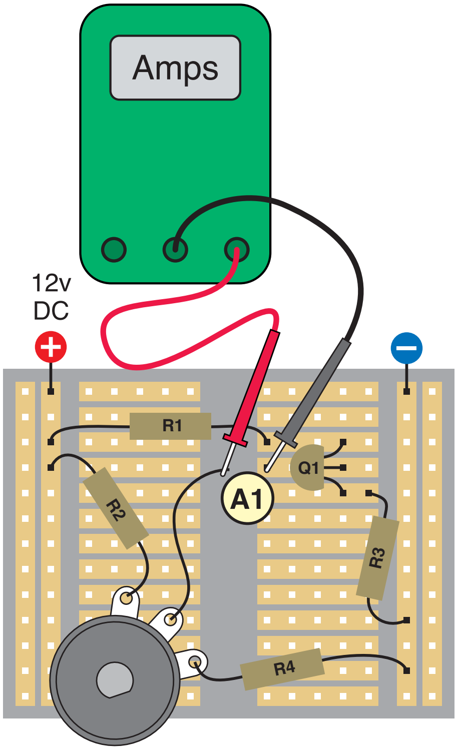

Figure 2-96. *The meter is measuring current flowing from the potentiometer into the base of the transistor at position A1 (see Figure 2-95).*

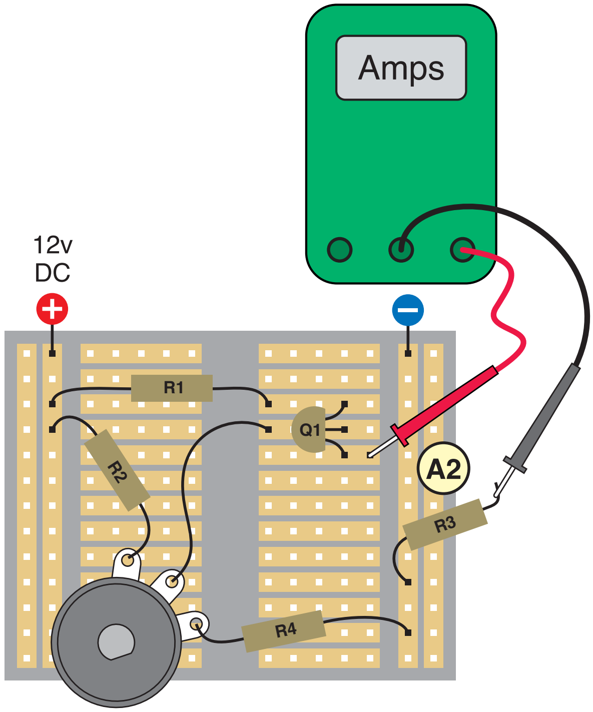

Figure 2-97. *One end of resistor R3 has been unplugged from the breadboard so that the meter now measures current flowing out through the emitter of the transistor, into R3, at position A2.*

Experiment 11: A Modular Project

You will need:

- AC adapter, breadboard, wire, and meter.
- LED. Quantity: 1.
- Resistors, various.
- Capacitors, various.
- Transistor, 2N2222 or similar. Quantity: 2.
- 2N6027 programmable unijunction transistor (PUT). Quantity: 2.
- Miniature 8Ω loudspeaker. Quantity: 1.

So far, I've described small circuits that perform very simple functions. Now it's time to show how modules can be combined to create a device that does a bit more.

The end product of this experiment will be a circuit that makes a noise like a small siren, which could be used in an intrusion alarm. You may or may not be interested in owning an alarm, but the four-step process of developing it is important, because it shows how individual clusters of components can be persuaded to communicate with each other.

I'll begin by showing how to use a transistor to make a solid-state version of the oscillating circuit that you built with a relay in Experiment 8. The relay, you may remember, was wired in such a way that the coil received power through the contacts of the relay. As soon as the coil was energized, it opened the contacts, thus cutting off its own power. As soon as the contacts relaxed they restored the power, and the process repeated itself.

There's no way to do this with a single bipolar transistor. You actually need two of them, switching each other on and off, and the way that this works is quite hard to understand. An easier option is to use a different thing known as a programmable unijunction transistor, or PUT.

Unijunction transistors were developed during the 1950s, but fell into disuse when simple silicon chips acquired the ability to perform the same kinds of functions, more accurately and more cheaply. However, the so-called programmable unijunction transistor is still widely available, often used in applications such as lamp dimmers and motor controllers. Because its primary use is in generating a stream of pulses, it's ideal for our purposes.

If you put together the components shown in Figure 2-98, the LED should start flashing as soon as you apply power.

Note that this circuit will work on 6 volts. You won't damage anything if you run it with 12 volts, but as we continue adding pieces to it, you'll find that it actually performs better at 6 volts than at 12. If you read the next section, "Essentials: All about programmable unijunction transistors," you'll find out how the circuit works.

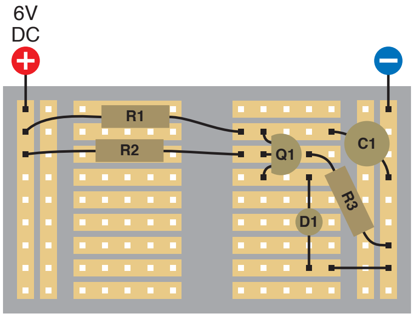

Figure 2-98. *Assemble these components, apply power, and the LED should start flashing.*

R1: 470K
R2: 15K
R3: 27K
C1: 2.2 µF electrolytic capacitor
D1: LED
Q1: 2N6027 programmable unijunction transistor

ESSENTIALS

All about programmable unijunction transistors

The schematic symbol for a programmable unijunction transistor, or PUT, looks very different from the symbol for a bipolar transistor, and its parts are named differently, too. Nevertheless, it does have a similar function as a solid-state switch. The symbol and the names of the three connections are shown in Figure 2-99.

Note that this is a rare case (maybe the only one in the whole of electronics!) in which you won't run into confusing variations of the basic schematic symbol. A PUT always seems to look the way I've drawn it here. Personally I think it would be clearer if we added a circle around it, but no one seems to do that, so I won't, either.

The 2N6027 is probably the most common PUT, and seems to be standardized in its packaging and pin-outs. I've only seen it in a plastic module rather than a little tin can. Figure 2-100 shows the functions of the leads if your 2N6027 is manufactured by Motorola or On Semiconductor. If you have one from another source, you should check the data sheet.

Note that the flat side of the plastic module faces the opposite way around compared with the 2N2222 bipolar transistor, when the two devices are functioning similarly.

The PUT blocks current until its internal resistance drops to allow flow from the "anode" to the "cathode." In this way, it seems very similar to an NPN transistor, but there's a big difference in the circumstances that cause the PUT to lower its resistance. The voltage at the anode determines when the PUT allows current to flow.

Suppose you start with, say, 1 volt at the anode. Slowly, you increase this voltage. The transistor blocks it until the anode gets close to 6 volts. Suddenly this pressure breaks down the resistance and current surges from the anode to the cathode. If the voltage goes back down again, the transistor reverts to its original state and blocks the flow.

I've included another version of the "finger on the button" drawing to convey this concept. The voltage on the anode is itself responsible for pushing the button that opens the pathway to the cathode. See Figure 2-101.

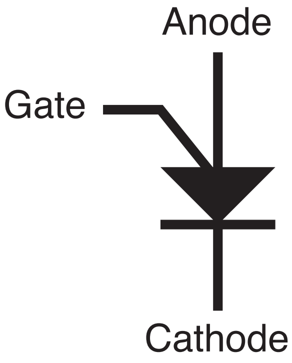

Figure 2-99. *The schematic symbol for a PUT.*

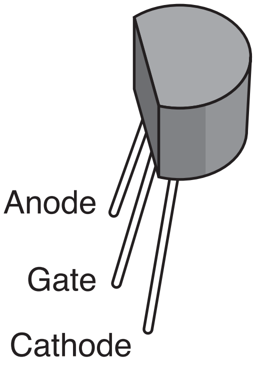

Figure 2-100. *In PUTs manufactured by On Semiconductor and Motorola, the leads have these functions.*

ESSENTIALS

All about programmable unijunction transistors (continued)

This may cause you to wonder what the function of the gate is. You can think of it as “assisting” the finger on the button. In fact, the gate is the “programmable” part of a PUT. By choosing a voltage for the gate, you establish the threshold point when current starts to flow.

Here’s a simple take-home summary:

- The anode has to be more positive than the cathode, and the gate should be between those two extremes.
- If anode voltage increases above a threshold point, current bursts through and flows from the anode to the cathode.
- If anode voltage drops back down below the threshold, the transistor stops the flow.
- The voltage you apply to the gate determines how high the threshold is.
- The gate voltage is adjusted with two resistors, shown as R1 and R2 in the simple schematic in Figure 2-102. Typically, each resistor is around 20K. The PUT is protected from full positive voltage by R3, which can have a high value, 100K or greater, because very little current is needed to bias the transistor.
- You add your input signal in the form of positive voltage at the anode. When it exceeds the threshold, it flows out of the cathode and can work some kind of output device.

The only remaining question is how we make a PUT oscillate, to create a stream of on/off pulses. The answer is the capacitor that you included in the circuit that you breadboarded at the beginning of Experiment 11.

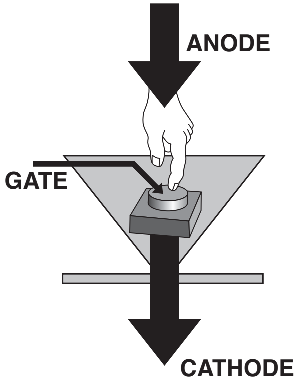

Figure 2-101. *When voltage at the anode of a PUT crosses a threshold (determined by a preset voltage at the gate), current breaks through and surges from the anode to the cathode. In this sense, the anode voltage acts as if it presses a button itself to open a connection inside the PUT, with some assistance from control voltage at the gate.*

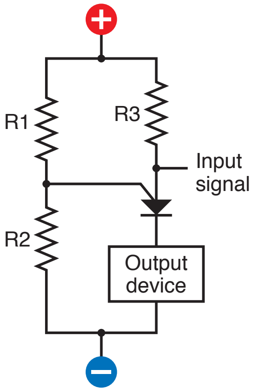

Figure 2-102. *This simple schematic shows how a PUT is used. R1 and R2 determine the voltage at the gate, which sets the threshold point for the input at the anode. Above the threshold, current flows from anode to cathode.*

Step 1: Slow-Speed Oscillation

Figure 2-103 is a schematic version of the previous PUT breadboard circuit shown in Figure 2-98, drawn so that the layout looks as much like the breadboard as possible.

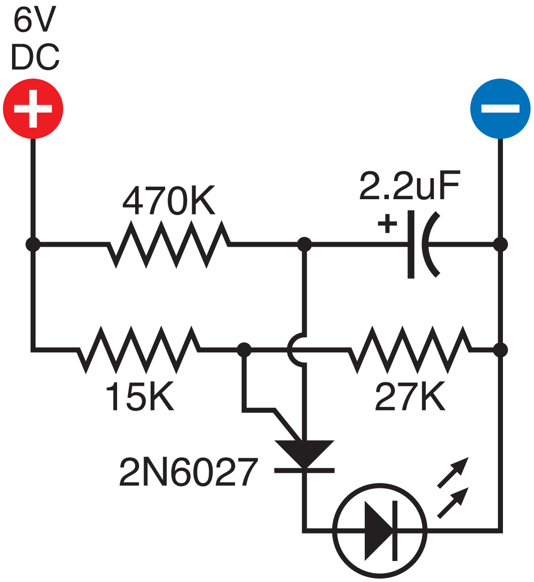

Figure 2-103. *This makes it easier to see what's happening in the breadboard version.*

The 15K resistor and 27K resistor establish the voltage at the gate. The 470K resistor supplies the anode of the PUT, but the PUT begins in its "off" condition, blocking the voltage. So the voltage starts to charge the 2.2 μF capacitor.

You may remember that a resistor slows the rate at which a capacitor accumulates voltage. The bigger the resistor and/or the larger the capacitor, the longer the capacitor takes to reach a full charge. In this circuit, the capacitor takes about half a second to get close to 6 volts.

But notice that the PUT is connected directly with the capacitor. Therefore, whatever voltage accumulates on the capacitor is also experienced by the PUT. As the voltage gradually increases, finally it reaches the threshold, which flips the PUT into its "on" state. The capacitor immediately discharges itself through the PUT, through the LED (which flashes), and from there to the negative side of the power supply.

The surge depletes the capacitor. The voltage drops back down, and the PUT returns to its original state. Now the capacitor has to recharge itself all over again, until the whole process repeats itself.

If you substitute a 22 μF capacitor, the charge/discharge cycle should take about 10 times as long, which will give you time to measure it. Set your meter to measure volts DC and place its probes on either side of the capacitor. You can actually watch the charge increasing until it reaches the threshold, at which point the capacitor discharges and the voltage drops back down again.

So now we have an oscillator. What's next?

Step 2: Beyond the Persistence of Vision

If you substitute a much smaller capacitor, it will charge much more quickly, and the LED will flash faster. Suppose you use a capacitor of 0.0047 µF (which can also be expressed as 47 nanofarads, or 47 nF). This seems like an odd number, but it's a standard value for a capacitor. This will reduce the capacitance by a factor of more than 500, and therefore the LED should flash about 500 times as fast, which should be about 1,000 times per second. The human eye cannot detect such rapid pulses. The human ear, however, can hear frequencies up to 10,000 per second and beyond. If we substitute a miniature loudspeaker for the LED, we should be able to hear the oscillations.

Figure 2-104 shows how I'd like you to make this happen. Please leave your original, slow-flashing circuit untouched, and make a duplicate of it farther down the breadboard, changing a couple of component values as indicated. In the schematic in Figure 2-105, the new part of the circuit is in solid black, while the previous section is in gray.

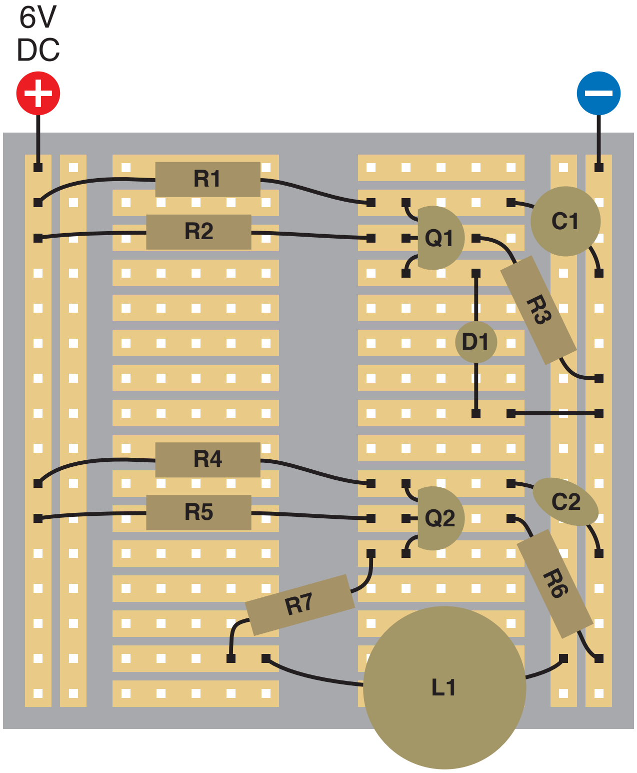

Figure 2-104. *The extra components which have been added at the lower half of the breadboard have the same functions as the components at the top, but some values are slightly different:*

R4: 470K
R5: 33K
R6: 27K
R7: 100Ω
C2: 0.0047 µF
Q2: 2N6027
L1: 8Ω 1-inch loudspeaker

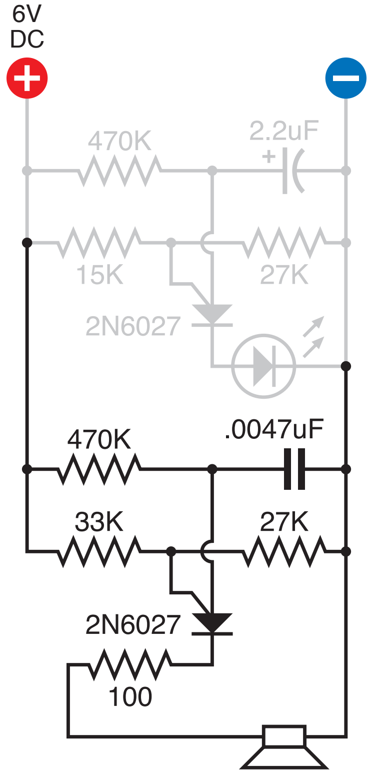

Figure 2-105. *The previous section that you built is shown in gray. Just add the new section in black.*

I want you to keep the slow-flashing circuit separately, untouched, because I have an idea to make use of it a little later. You can leave the LED blinking.

The loudspeaker should be wired in series with a 100Ω resistor to limit the current that flows out of the PUT. The loudspeaker doesn't have any polarity, even though it is fitted with a red wire and a black wire. You can connect it either way around.

Initially, you may be disappointed, because the circuit will not seem to be doing anything. However, if you place your ear very, very close to the loudspeaker, and if you wired the circuit correctly, you should hear a faint buzz, like a mosquito. Obviously, this isn't loud enough to serve any practical purpose. We need to make it louder. In other words, we need to amplify it.

Maybe you remember that the 2N2222, which you played with previously, can function as an amplifier. So let's try using that.

Step 3: Amplification

Disconnect the loudspeaker and its 100Ω series resistor. Then add the 2N2222, which is linked with the output from the PUT via a 1K resistor to protect it from excessive current. See Figure 2-107.

The emitter of the 2N2222 is connected to ground, and the collector is supplied through the loudspeaker and its 100Ω series resistor. This way, small fluctuations in the output from the PUT are sensed by the base of the 2N2222 which converts them into bigger fluctuations between the collector and the emitter, which draw current through the loudspeaker. Check the schematic in Figure 2-108.

Now the sound should be louder than an insect buzz, but still not really loud enough to be useful. What to do?

Well—how about if we add another 2N2222? Bipolar transistors can be placed in series, so that the output from the first one goes to the base of the second one. The 24:1 amplification of the first one is multiplied by another 24:1, giving a total amplification of more than 500:1.

There are limits to this technique. The 2N2222 can only conduct so much current before getting overloaded, and excess amplification can cause distortion. But when I built this circuit, I used a meter to verify that we're still within the design limits of a 2N2222, and for this project, I don't care whether the sound is slightly distorted.

BACKGROUND

Mounting a loudspeaker

The diaphragm or cone of a loudspeaker is designed to radiate sound, but as it oscillates to and fro, it emits sound from its back side as well as its front side. Because the sounds are opposite in phase, they tend to cancel each other out.

The perceived output from a loudspeaker can increase dramatically if you add a horn around it in the form of a tube to separate the output from the front and back of the speaker. For a miniature 1-inch loudspeaker, you can bend and tape a file card around it. See Figure 2-106.

Better still, mount it in a box so that the box absorbs the sound from the rear of the loudspeaker. For purposes of these simple experiments, I won't bother to go into the details of vented enclosures and bass-reflex designs.

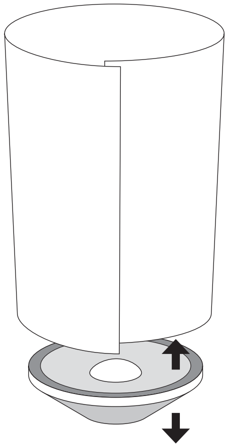

Figure 2-106. *A loudspeaker emits sound from its bottom surface as well as its top surface. To increase the perceived audio volume, use a cardboard tube to separate the two sound sources, or mount the speaker in a small box.*

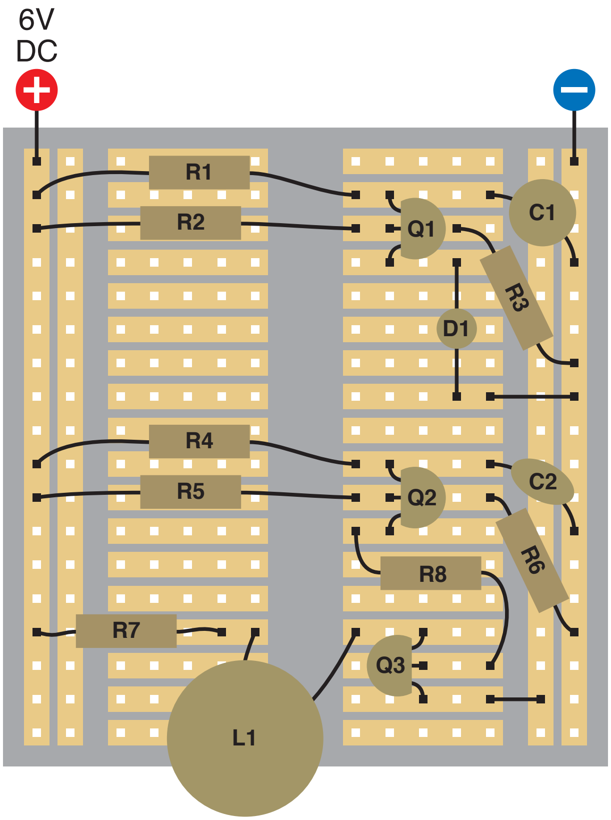

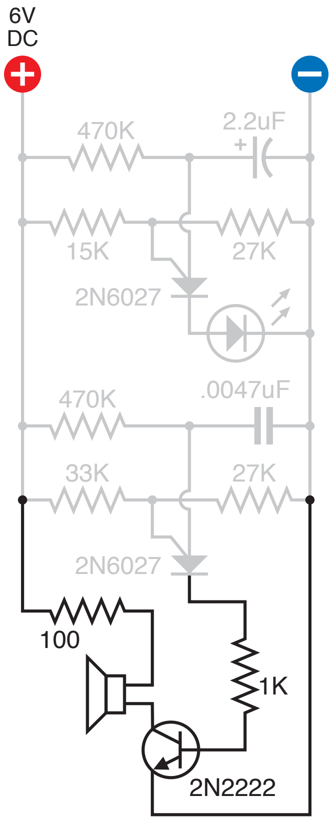

Figure 2-107. *By adding a 2N2222 general-purpose transistor, we amplify the signal from Q2:*

R8: 1K
Q3: 2N2222

Other components are the same as in the previous step in constructing this circuit.

Figure 2-108

Add the second 2N2222 as shown in Figure 2-109. In Figure 2-110, once again the previously wired section is in gray.

If the accumulation of electrical components is beginning to seem confusing, remember that each cluster of parts has a separate defined function. We can draw a block diagram to illustrate this, as in Figure 2-112.

Using the second 2N2222, you should find that the output is more clearly audible, at least within the limits of your tiny 1-inch loudspeaker. Cup your hands around it to direct the sound, and you'll find that the volume seems to increase. You can also try using a 3-inch loudspeaker, which will create a generally better audio output while still remaining within the limits of the little 2N2222 transistor. See Figure 2-106, shown previously, and Figure 2-111.

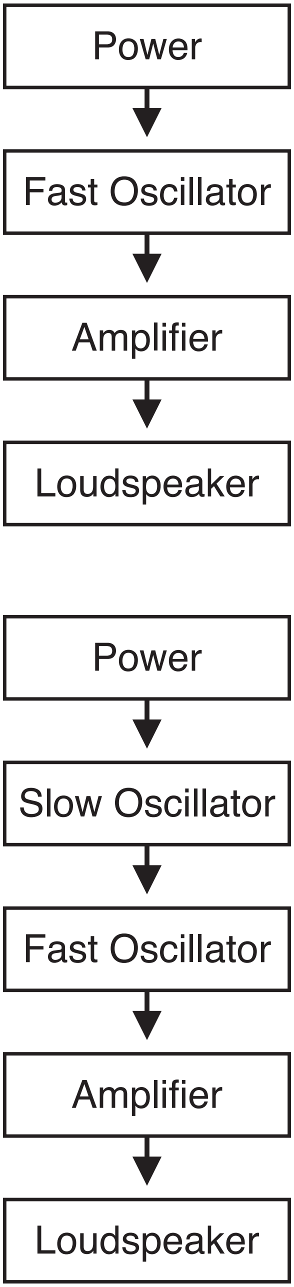

Figure 2-112. *Top: The basic functions of the noisemaking oscillator circuit shown as a block diagram. Bottom: The same functions with a slow oscillator added to control the fast oscillator.*

Step 4: Pulsed Output

If you wanted to use this audio signal as some kind of an alarm, a steady droning noise is not very satisfactory. A pulsing output would be a much better attention-getter.

Well, the first section of the circuit that you assembled created a pulsing signal about twice per second. You used it to flash an LED. Maybe we can get rid of the LED and feed the output from the first section to the second section. The lower block diagram in Figure 2-112 explains this concept.

Can it really be that simple? Well, yes and no. The trick is to make the output from the first section compatible with the input to the second section. If you simply connect a wire from the cathode of the first PUT to the anode of the second PUT, that's not going to work, because the second PUT is already oscillating nicely between low and high voltage, about 1,000 times each second. Add more voltage, and you will disrupt the balance that enables oscillation.

However, remember that the voltage on the gate of a PUT affects its threshold for conducting electricity. Maybe if we connect the output from Q1 to the gate of Q2, we'll be able to adjust that threshold automatically. The voltage still has to be in a range that the PUT finds acceptable, though. We can try various resistors to see which one works well.

This sounds like trial and error—and that's exactly what it is. Doing the math to predict the behavior of a circuit like this is far too complicated—for me, anyway. I just looked at the manufacturer's data sheet, saw the range of resistor values that the PUT would tolerate, and chose one that seemed as if it should work.

If you remove the LED and substitute R10 as shown in the breadboard diagram in Figure 2-113, you'll find that the fluctuating output from Q1 makes Q2 emit a two-tone signal. This is more interesting, but still not what I want. I'm thinking that if I make the pulses out of Q1 less abrupt, the result could be better, and the way to smooth a pulsing output is to hook up another capacitor that will charge at the beginning of each pulse and then release its charge at the end of each pulse. This is the function of C3 in Figure 2-114, and it completes the circuit so that it makes a whooping sound almost like a "real" alarm.

If you don't get any audio output, check your wiring very carefully. It's easy to make a wrong connection on the breadboard, especially between the three legs of each transistor. Use your meter, set to DC volts, to check that each section of the circuit has a positive voltage relative to the negative side of the power supply.

Figure 2-115 shows how your circuit should actually look on the breadboard.

Tweaking it

There's still a lot of room for creativity here:

- Adjust the frequency of the sound: Use a smaller or larger capacitor instead of C2 (half or twice the current value). Use a smaller or larger value for R5.
- Adjust the pulsing feature: Use a smaller or larger capacitor instead of C1 (half or twice the current value). Use a smaller or larger value for R2.
- General performance adjustments: try a larger value for R1. Try smaller or larger values for C3.
- Try running the circuit at 7.5 volts, 10 volts, and 12 volts.

The circuits in this book are suggested as only a starting point. You should always try to tweak them to make them your own. As long as you follow the general rule of protecting transistors and LEDs with resistors, and respecting their requirements for positive and negative voltage, you're unlikely to burn them out. Of course, accidents will happen—I myself tend to be careless, and fried a couple of LEDs while working on this circuit, just because I connected them the wrong way around.

Step 5: Enhancements

A noisemaking circuit is just the output of an alarm. You would need several enhancements to make it useful:

1. Some kind of an intrusion sensor. Maybe magnetic switches for windows and doors?
2. A way to start the sound if any one of the sensors is triggered. The way this is usually done is to run a very small but constant current through all of the switches in series. If any one switch opens, or if the wire itself is broken, this interrupts the current, which starts the alarm. You could make this happen with a double-throw relay, keeping the relay energized all the time until the circuit is broken, at which point, the relay relaxes, opening one pair of contacts and closing the other pair, which can send power to the noisemaker.

   The trouble is that a relay draws significant power while it's energized, and it also tends to get hot. I want my alarm system to draw very little current while it's in "ready" mode, so that it can be powered by a battery. Alarm systems should never depend entirely on AC house current.

   If we don't use a relay, can we use a transistor to switch on the rest of the circuit when the power is interrupted? Absolutely; in fact, one transistor will do it.
3. But how do we arm the alarm in the first place? Really, we need a three-step procedure. First, check a little light that comes on when all the doors and windows are closed. Second, press a button that starts a 30-second countdown, giving you time to leave, if that's what you want to do. And third, after 30 seconds, the alarm arms itself.

4. If the alarm is triggered, what then? If someone forces open a window, should the alarm stop sounding as soon as the window is closed again? No, the alarm should lock itself on, until you turn it off.
5. How do you turn it off? Some kind of secret-code keypad would be good.
6. But to avoid driving everyone crazy if the alarm is triggered when you're not there, it should eventually stop itself, perhaps after about 10 minutes. At that point it should remain quiet but should light an LED to tell you what happened. You can then press a reset button to switch off the LED.

Implementing the Wish List

I've compiled a wish list that seems likely to make the project at least five times as complicated as it is already. Well, that's what tends to happen when you go beyond little demo circuits and try to design something that will be useful in everyday life. Suddenly you find yourself having to accommodate all kinds of circumstances and situations.

Actually, I can and will show you how to take care of all the enhancements on the wish list, but I'm thinking that they will require us to get a little more serious about electronics projects in general first. If you're going to build something ambitious, you'll want to make it more permanent, and probably more compact, than a breadboard with components pushed into it.

You will need to know how to connect everything permanently with solder, on a piece of perforated board that you can install in a neat little project box with switches and lights on the outside.

I'm going to deal with soldering and packaging in the next chapter. After that, we'll get back to the alarm project.

3

Getting Somewhat More Serious

IN THIS CHAPTER

Shopping List: Experiments 12 Through 15
Experiment 12: Joining Two Wires Together
Experiment 13: Broil an LED
Experiment 14: A Pulsing Glow
Experiment 15: Intrusion Alarm Revisited

I don't know how far you'll want to delve into electronics, but I do know that I've shown you about as much as I can with just a handful of components, some wires, a breadboard, and a few tools. To continue, you'll need:

- Some more tools and supplies
- Basic soldering skills
- Additional knowledge about:
  - Integrated circuits
  - Digital electronics
  - Microcontrollers
  - Motors

The tools are not particularly exotic or expensive, and the soldering skills are easily acquired. Learning to join wires with solder is far easier than mastering high-level crafts such as jewelry making or welding.

As for additional areas of knowledge about electronics, they are no more challenging than those that I have covered already.

By the end of this section, you should be able to transplant components from a breadboard onto perforated board, where you will solder everything together, and then mount the board in a little box with switches and warning lights on the front, for everyday use.

Shopping List: Experiments 12 Through 15

Tools

Each of the following tools is rated Essential, Recommended, or Optional. The Essential tools will take you through this chapter of the book. If you supplement them with the Recommended tools, they should be sufficient to get you to the end of the book. The Optional tools will make your work easier, but whether they're worth the money is for you to decide. Remember that URLs for manufacturers and sources of supply are all listed in the appendix.

I am assuming that you already have some commonly used workshop basics, such as an electric drill.

Essential: Pencil-type 15-watt soldering iron

Examples are RadioShack part 64-2051, McMaster-Carr catalog item 7016A34, or Xytronic model 252. See Figure 3-1. Soldering irons rated at 15 watts are less common than those that deliver 25 watts or more. Still, the 15-watt size is desirable for the small-scale work you'll be doing, and greatly reduces the risk of damaging components by inflicting excess heat.

When comparing prices, remember that a plated tip, which costs a little more, will last longer, will be easier to keep clean, and will conduct heat more reliably than a plain copper tip. If the manufacturer's specification doesn't mention a plated tip, the soldering iron probably doesn't have one.

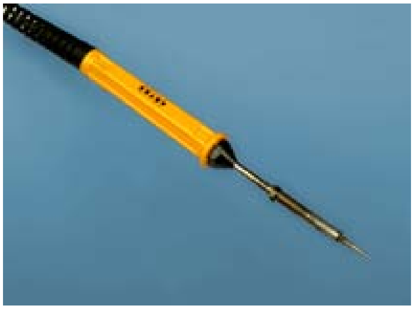

Figure 3-1. *The low wattage of this pencil-style soldering iron enables you to use it safely on sensitive components, and the sharp tip helps to apply heat selectively.*

Essential: General-duty soldering iron, 30 to 40 watts

Although most of the projects in this book entail small, heat-sensitive components and thin wire, at some point you're likely to want to make a solder joint with larger components and/or thicker wire. A 15-watt soldering iron will be unable to deliver enough heat. You should consider having a larger soldering iron in reserve, especially because they are relatively inexpensive.

Personally, I like the Weller Therma-Boost, shown in Figure 3-2, because it has an extra button that delivers more heat on demand. This is useful when you want the iron to get hot quickly, or if you are trying to solder very thick wire, which absorbs a lot of heat.

If you can't find or don't like the Weller, almost any 30-watt or 40-watt soldering iron will do. Check eBay or your local hardware store.

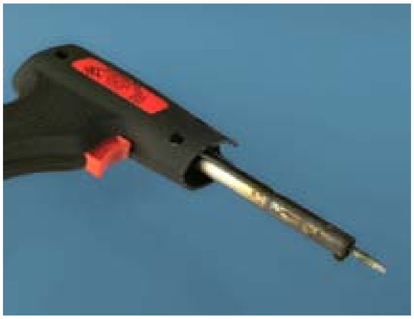

Figure 3-2. *This higher-wattage soldering iron delivers the additional heat necessary for thicker wire or larger components. The discoloration quickly occurs as a result of everyday use and has no effect on the capability of the iron, as long as the tip of it is clean.*

Essential: Helping hand

The so-called "helping hand" (or "third hand") has two alligator clips that hold components or pieces of wire precisely in position while you join them with solder. Some versions of the "helping hand" also feature a magnifying lens, a wire spiral in which you can rest your soldering iron, and a little sponge that you use to clean the tip of your iron when it becomes dirty. These additional features are desirable. Helping hands are available from all electronics hobby sources. Examples are the catalog item HH55 from Elenco or model 64-2991 from RadioShack. See Figure 3-3.

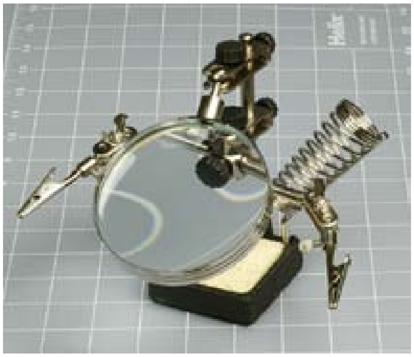

Figure 3-3. *The helping hand is fitted with two alligator clips to hold your work. The metal spiral is a safe place to holster a hot soldering iron, and you use the sponge to wipe its tip.*

Essential: Magnifying lens

No matter how good your eyes are, a small, handheld, powerful magnifying lens is essential when you are checking solder joints on perforated board. The three-lens set in Figure 3-4 is designed to be held close to your eye, and is more powerful than the large lens on a "helping hand." The folding lens in Figure 3-5 stands on your workbench for hands-free operation. Both are available from RadioShack and similar items are stocked by art supply stores and hobby shops. Plastic lenses are quite acceptable if you treat them carefully.

Figure 3-4. *As long as you treat it carefully, a cheap set of plastic magnifying lenses is perfectly acceptable. Handheld magnification is essential for inspecting the solder joints that you make on perforated board.*

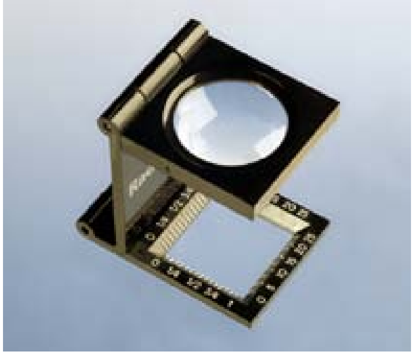

Figure 3-5. *This kind of folding magnifier can stand on your desktop and is useful for checking part numbers on tiny components.*

Essential: Clip-on meter test leads

The probes that came with your multimeter require you to hold them in contact while you make a reading. This requires both hands, preventing you from doing anything else at the same time.

When you use a pair of "minigrabber" probes with little spring-loaded clips at the end, you can attach the Common (negative) lead from your meter to the negative side of your circuit and leave it there, while you touch or attach the positive probe elsewhere.

The Pomona model 6244-48-0 (shown in Figure 3-6) from Meter Superstore and some other suppliers is what you need. If you have trouble finding it or you object to the cost, you may consider making your own by buying a couple of "banana plugs" (such as RadioShack part 274-721) that will fit the sockets on your meter, and then use 16-gauge or thicker stranded wire to connect the plugs with IC test clips, such as Kobiconn 13IC331 or RadioShack "mini hook clips," part number 270-372C. See Figures 3-7 and 3-8.

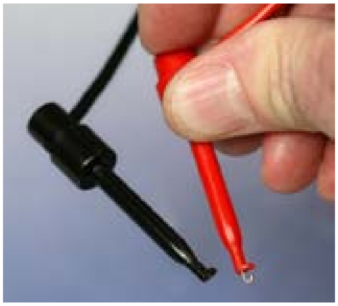

Figure 3-6. *These "minigrabber" add-ons for meter leads make it much easier to measure voltage or current. Push the spring-loaded button, and a little copper hook slides out. Attach it to a wire, release the button, and you have your hands free for other tasks. It's a mystery that meters are not supplied with these grabbers as standard equipment.*

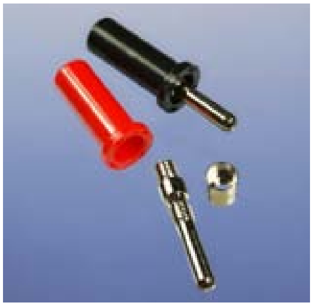

Figure 3-7. *To make your own minigrabber meter leads, first attach a banana plug to a wire by sliding the wire through the cap, into the plug, and out through a hole in the side.*

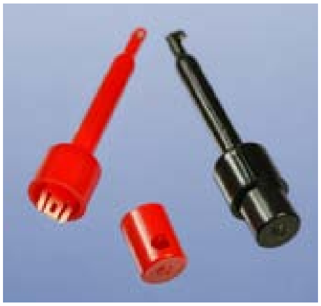

Figure 3-8. *Then screw a collar over the protruding piece of wire, and screw on the cap. The other end of the wire is soldered to a probe.*

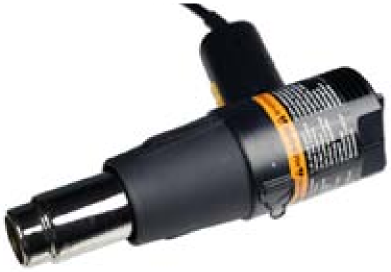

Figure 3-9. *Like an overpowered hair dryer, the heat gun is used with heat-shrink tubing to create a snug, insulated sheath around bare wire.*

Essential: Heat gun

After you join two wires with solder, you often need to insulate them. Electrical tape, sometimes called insulating tape, is messy and tends to come unstuck. You'll be using heat-shrink tube, which forms a safe, permanent sheath around a bare-metal joint. To make the tube shrink, use a heat gun, which is like a very powerful hair dryer. They're available from any hardware supply source, and I suggest you buy the cheapest one you can find. See Figure 3-9.

Essential: Solder pump

This little gadget sucks up hot, melted solder when you are trying to remove a solder joint that you made in the wrong place. Available from All Electronics (catalog item SSR-1) or RadioShack 64-2086. See Figure 3-10.

Essential: Desoldering wick

Also known as desoldering braid. See Figure 3-11. You use this to soak up solder, in conjunction with the Solder Pump. Available from All Electronics (catalog item SWK) or RadioShack (part 64-2090).

Essential: Miniature screwdriver set

Dinky little electronic parts often have dinky little screws in them, and if you try to use the wrong size of screwdriver, you'll tend to mash the heads of the screws. I like the Stanley precision set, part number 66-052, shown in Figure 3-12. But any set will do as long as it has both small Phillips and straight-blade screwdrivers.

Recommended: Soldering stand

Like a holster for a gun, you rest your soldering iron in this stand when the iron is hot but not on use. Examples are catalog item 50B-205 from All Electronics, RadioShack model 64-2078, or check eBay. See Figure 3-13. This item may be built into the helping hand, but you need an extra one for your second soldering iron.

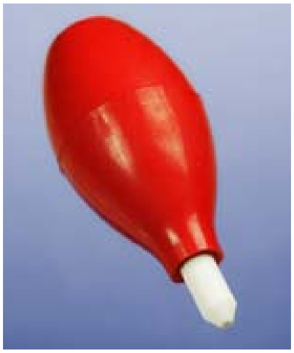

Figure 3-10. *To remove a solder joint, you can heat the solder until it's liquid, then suck it up into this squeezable rubber bulb.*

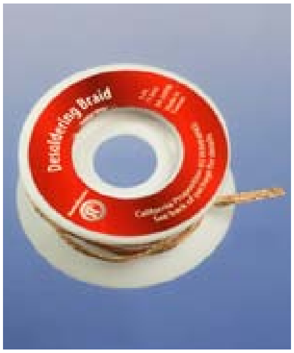

Figure 3-11. *An additional option for removing liquid solder is to soak it up in this copper braid.*

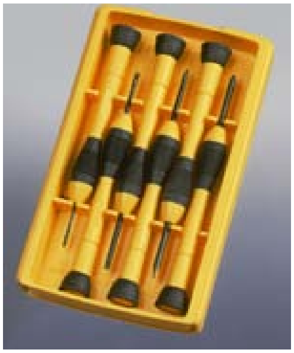

Figure 3-12. *A set of small screwdrivers is essential.*

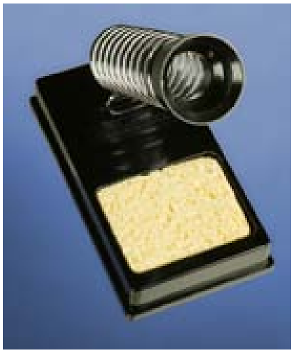

Figure 3-13. *A safe and simple additional stand for a hot soldering iron.*

Recommended: Miniature hand saw

I assume that you will want to mount a finished electronics project in a decent-looking enclosure. Consequently, you are likely to need tools to cut, shape, and trim thin plastic. For example, you may want to cut a square hole so that you can mount a square power switch in it.

Power tools are not suitable for this kind of delicate work. A miniature handsaw (a.k.a. a "hobby saw") is ideal for trimming things to fit. X-Acto makes a range of tiny saw blades. I suggest the #15 blade, plus the handle that it fits in, shown in Figure 3-14. Available online from Tower Hobbies, Hobbylinc, ArtCity, and many other arts/crafts sources. Also look for the larger X-Acto saw blade, #234 or #239, which you can use for cutting perforated board.

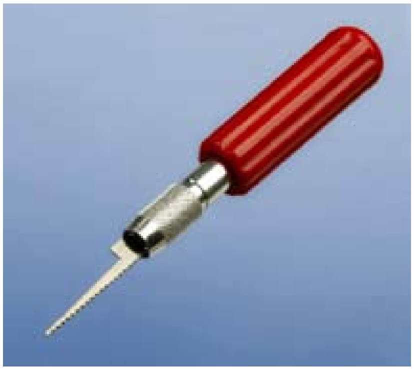

Figure 3-14. *X-Acto makes a range of small saw blades that are ideal for cutting square holes to mount components in plastic panels.*

Recommended: Miniature vise

A miniature vise can do things that the helping hand cannot. I use mine when I'm sawing small pieces of plastic and as a dead weight to anchor a piece of perforated board while I'm working on it. See Figure 3-15.

Look for a cast-iron vise that is listed as being 1 inch or slightly larger, available from Megahobby, eBay, and other arts/crafts sources. Also consider the PanaVise, which has a tilting head to allow you to turn your work to any angle.

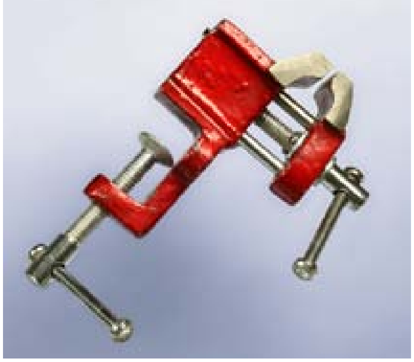

Figure 3-15. *This one-inch vise is available from the McMaster-Carr catalog.*

Recommended: Deburring tool

A deburring tool instantly smoothes and bevels any rough edge (when you have sawn or drilled a piece of plastic, for instance) and also can enlarge holes slightly. This may be necessary because some components are manufactured to metric sizes, which don't fit in the holes that you drill with American bits. Your small local hardware store may not stock deburring tools, but they are very inexpensively available from Sears, McMaster-Carr, KVM Tools, or Amazon. See Figure 3-16.

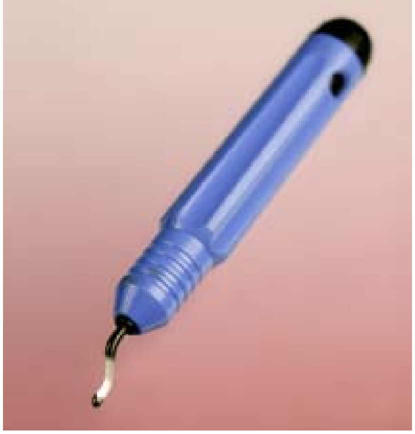

Figure 3-16. *This cunning little blade, safety-tipped with a round bump on the end, removes rough edges from saw cuts with a single stroke, and can enlarge holes that are almost big enough—but not quite.*

Optional: Hand-cranked countersink

You need a countersink to bevel the edges of screw holes to accept flat-headed screws. If you use a countersink bit in an electric drill, it won't give you precise control when you're working with thin, soft plastic.

Handheld countersinks that you grasp and turn like a screwdriver are easy to find, but McMaster-Carr (catalog item 28775A61) is the only source I've found for a hand-cranked tool that is much quicker to use. It comes with a set of bits, as shown in Figure 3-17.

Optional: Pick and hook set

Made by Stanley, part number 82-115, available from Amazon and hardware stores. You can find imported imitations for a few dollars less. See Figure 3-18.

Optional: Calipers

These may seem like a luxury, but are useful for measuring the external diameter of a round object (such as the screw thread on a switch or a potentiometer) or the internal diameter of a hole (into which you may want a switch or potentiometer to fit).

I like Mitutoyo calipers, and the low-end model 505-611 (shown in Figure 3-19) does everything I need. You can find cheaper brands, but economizing on precision measuring tools may not be a wise policy in the long term. The manufacturer's site will show you all their available models, after which you can Google "Mitutoyo" to find retail sources.

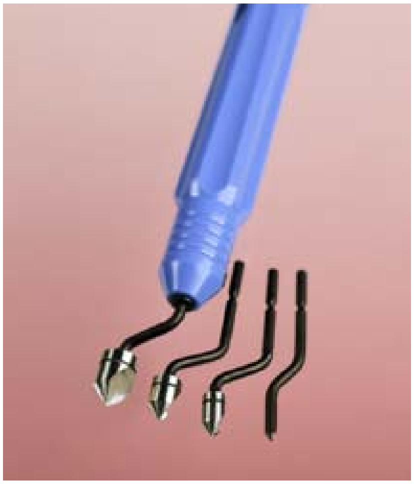

Figure 3-17. *You spin this countersink tool like a hand crank to add just the right amount of bevel to a hole, so that it will accommodate a flat-head screw.*

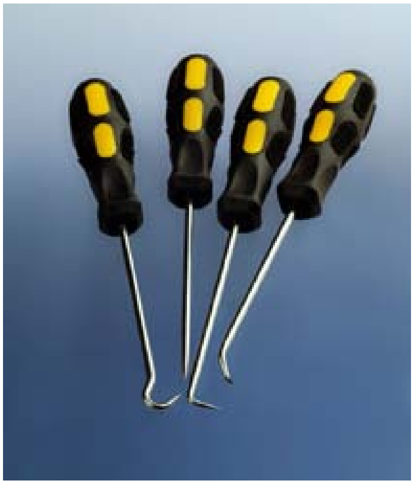

Figure 3-18. *This pick-and-hook set is useful in many unexpected ways.*

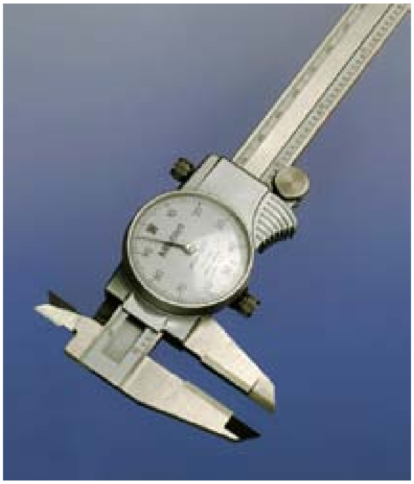

Figure 3-19. *Calipers can be digital (which automatically convert from millimeters to 1/64 inch to 1/1,000 inch), or analog like these (so you never need to worry about a dead battery).*

Supplies

Solder

This is the stuff that you will melt to join components together on a permanent (we hope) basis. You need some very thin solder, size 0.022 inches, for very small components, and thicker solder, 0.05 inches, for heavier items. Avoid buying solder that is intended for plumbers, or for craft purposes such as creating jewelry. A range of solder thicknesses is shown in Figure 3-20. You want to make sure to get lead-free solder.

Electronics solder has a nonacidic rosin core that is appropriate for electronic components. Rolls of solder are available from all hobby-electronics sources including All Electronics, RadioShack, and Jameco, or search for "electronic solder" on Amazon.

Figure 3-20. *Spools of solder in various thicknesses.*

Wire

You'll need some stranded wire to make flexible external connections with the circuit that you'll be building. Look for 22-gauge stranded hookup wire, in red, black, and green, 10 feet (minimum) of each.

If you want to install the intrusion alarm after completing that project in Experiment 15, you'll need white-insulated two-conductor wire of the type sold for doorbells or furnace controls. This is available by the foot from Lowe's, Home Depot, Ace Hardware, and similar stores. You'll decide how much to buy after you measure the distances between the magnetic sensor switches that you decide to install.

Heat-shrink tube

For use in conjunction with your heat gun, described previously. You'll need a range of sizes in any colors of your choice. See Figure 3-21. Check RadioShack part 278-1627, other electronics suppliers, or your local hardware store. Prices will vary widely. You can buy the cheapest.

Copper alligator clips

These absorb heat when you are soldering delicate components. The Mueller BU-30C is a full-size solid copper alligator clip for maximum heat absorption. RadioShack sells smaller clips (part number 270-373, shown in Figure 3-22) that are suitable for tiny components.

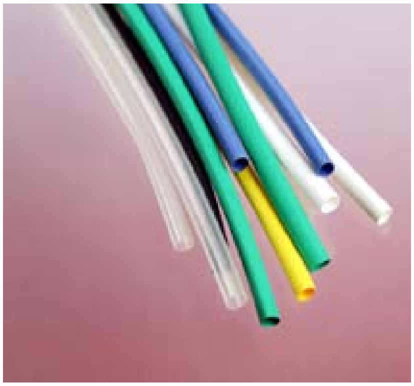

Figure 3-21. *Slide heat-shrink tubing over a bare joint and apply heat from a heat gun to make a tight insulating seal around the joint.*

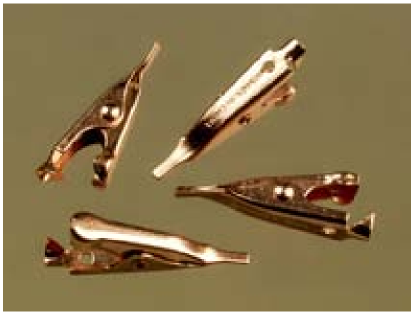

Figure 3-22. *These small clips absorb heat to protect components when you're soldering them.*

Perforated board

When you're ready to move your circuit from a breadboard to a more permanent location, you'll want to solder it to a piece of perforated board, often known as "prototyping board" but also called "perfboard."

You need the type that has copper strips etched onto the back, in exactly the same "breadboard layout" as the conductors hidden inside a breadboard, so that you can retain the same layout of your components when you solder them into place. Examples are RadioShack part 276-150 (shown in Figure 3-23) for small projects and part 276-170 (in Figure 3-24) for larger projects, such as Experiment 15.

For very small projects in which you will connect components using their wires alone, you need perfboard that isn't etched with copper strips connecting the holes. I like the Twin Industries 7100 range (available from Mouser.com) or Vectorboard from Newark Electronics, shown in Figure 3-25. You use a saw to cut out as small a piece as you need. Cheaper options are RadioShack part 276-147 (shown in Figure 3-26), or PC-1 from All Electronics. These have little copper circles around each hole that are not necessary for our purposes, but not a problem, either.

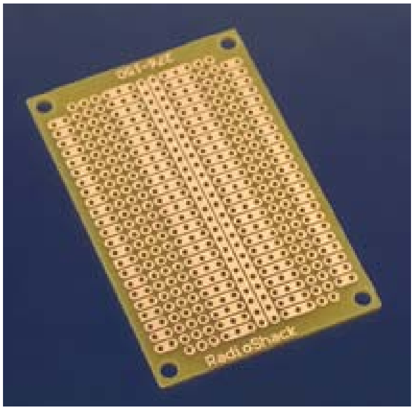

Figure 3-23. *This perforated board has a pattern of copper traces similar to the pattern inside a breadboard, so that you can lay out the components with minimal risk of wiring errors, when you're ready to create a permanently soldered version of your project.*

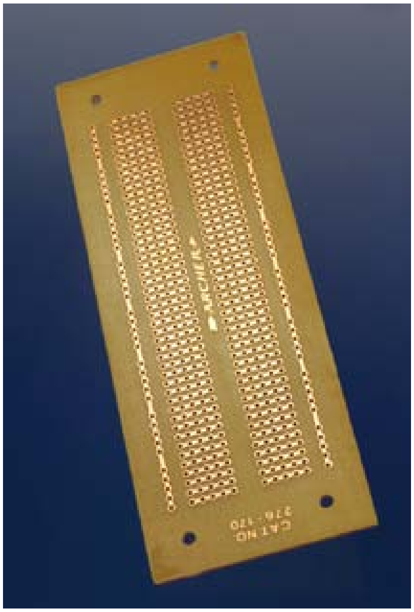

Figure 3-24. *A larger example of perforated board with breadboard geometry.*

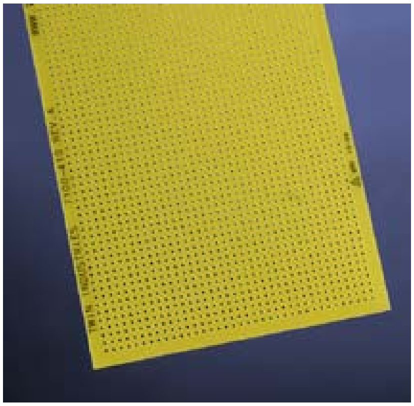

Figure 3-25. *Plain perforated board (with no copper traces) can be used for mounting components when you want to do point-to-point wiring.*

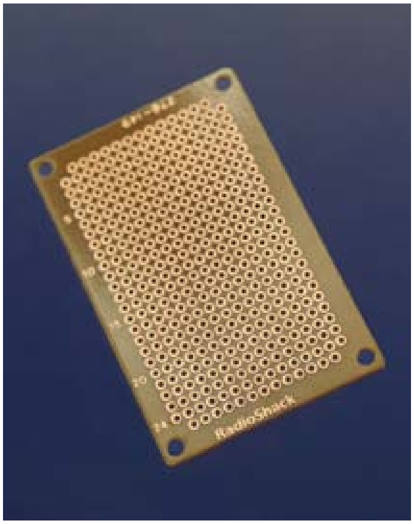

Figure 3-26. *A small piece of perforated board with individual copper solder pads to assist you in mounting components.*

Plywood

When you use a soldering iron, hot drops of solder tend to fall onto your table or workbench. The solder solidifies almost instantly, can be difficult to remove, and will leave a scar. Consider using a 2-foot square of half-inch plywood to provide disposable protection. You can buy it precut at Home Depot or Lowe's.

Machine screws

To mount components behind a panel, you need small machine screws (or "bolts"). They look nice if they have flat heads that fit flush against the panel. I suggest stainless-steel machine screws, #4 size, in 1/2-, 5/8-, 3/4-, and 1-inch lengths, 100 of each, plus 400 washers and 400 #4 locknuts of the type that have nylon inserts, so that they won't work loose. Check McMaster-Carr for a large and reasonably priced selection.

Project boxes

A project box is just a small box (usually plastic) with a removable lid. You mount your switches, potentiometers, and LEDs in holes that you drill through the box, and you attach your circuit on a perforated board that goes inside the box. Search All Electronics for "project box" or RadioShack for "project enclosure."

You need a box measuring approximately 6 inches long, 3 inches wide, and 2 inches high, such as RadioShack part 270-1805. Anything similar will do. I suggest you buy a couple other sizes as well, as they will be useful in the future.

Components

Power plugs, sockets, and binding posts

After you finish a project and put it in a box, you'll need a convenient way to supply it with power. Buy yourself a pair of insulated binding posts, such as RadioShack part 274-661, shown in Figure 3-27. Also obtain a panel-mounted power jack, size N, such as RadioShack part 274-1583, and DC power plug, size N, such as RadioShack 274-1573. The plug-and-socket pair is pictured in Figure 3-28.

Finally, you will need interconnects that are sized to fit a perforated board that is drilled at intervals of 1/10 inch. Sometimes known as "single inline sockets and headers," but also known as "boardmount sockets and pin-strip headers," they come in strips of 36 or more, and you can snip off as many as you need. Examples are Mill-Max part numbers 800-10-064-10-001000 and 801-93-050-10-001000, or 3M part numbers 929974-01-36-RK and 929834-01-36-RK. You can buy them from the usual electronics suppliers. Figure 3-29 shows headers before and after being snapped into small sections. Make sure that the interconnects have a terminal spacing of 0.1 inch.

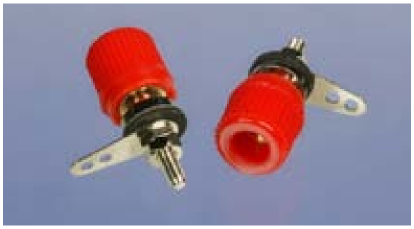

Figure 3-27. *These terminals, also known as binding posts, enable a solderless connection with wires that have stripped ends. Also available in black.*

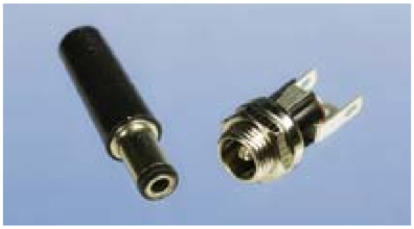

Figure 3-28. *The socket on the right can be mounted in a project box to receive power from the plug on the left.*

Battery

After you complete Experiment 15 at the end of this section of the book, if you want to use the project on a practical basis, you'll need a 12-volt battery. Search online for "12v battery" and you'll find many sealed, rechargeable lead-acid batteries that are designed for alarm systems, some measuring as small as 1×2×3-inch and costing under $10. You need a charger with it, which will probably cost you about $10.

Switches and relays

You will need the same DPDT relay and the same SPDT toggle switch that were mentioned in Chapter 2 shopping list.

For Experiment 15, you'll need magnetic switches that you can apply to doors or windows, such as the Directed model 8601, available from dozens of sources online.

Also you will need a DPDT pushbutton switch, ON-(ON) type, with solder terminals. Examples are model MPG206R04 by Tyco or model MB2061SS1W01-RO by NKK (with optional cap). Or search eBay for "DPDT pushbutton."

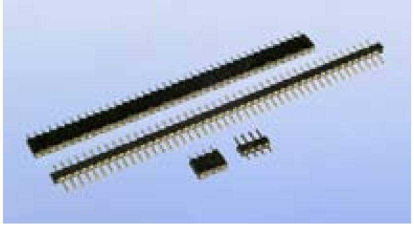

Figure 3-29. *Single inline sockets (top) and headers (middle) allow you to make very compact plug-and-socket connections to a PC board. They can be sawn, cut, or snapped into smaller sections (bottom). The terminals are 0.1 inch apart.*

Diodes

Buy at least half-a-dozen red 5 mm LEDs rated for approximately 2 volts, such as the Optek part number OVLFR3C7, Lumex part number SSL-LX-5093IT, or Avago part HLMP-D155. Buy half-a-dozen similar green LEDs at the same time.

In addition, you'll need a signal diode, type 1N4001 (any brand will do). Figure 3-30 shows an example, highly magnified. They're cheap, and likely to be useful in the future, so buy 10 of them.

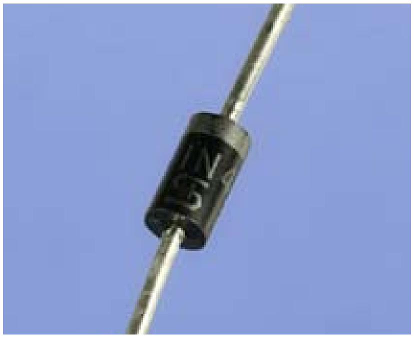

Figure 3-30. *This 1N4001 diode is about 1/4 inch long and can handle up to 50 volts.*

Soldering Irons Get Hot!

Please take these basic precautions:

Use a proper stand (such as the one incorporated in your helping hands) to hold your soldering iron. Don't leave it lying on a workbench.

If you have infants or pets, remember that they may play with, grab, or snag the wire to your soldering iron. They could injure themselves (or you).

Be careful never to rest the hot tip of the iron on the power cord that supplies electricity to the iron. It can melt the plastic in seconds and cause a dramatic short circuit.

If you drop a soldering iron, don't be a hero and try to catch it. Most likely you will grab the hot part, which hurts. (I speak from experience.) When you burn your hand, you will instinctively let go of the iron, so you may as well let it drop freely without the intermediate step of burning yourself while it's on its way to the floor. Naturally, you should pick it up quickly after it does hit the floor, but by then you will have gained the necessary time in which to make a sensible decision to grab it by the cool end.

Always bear in mind that others in your home are more at risk of hurting themselves on a soldering iron than you are, because they won't know that it's hot. Most soldering irons have no warning lights to tell you that they're plugged in. As a general rule, always assume that a soldering iron is hot, even if it's unplugged. It may retain sufficient heat to burn you for longer than you expect.

Loudspeaker

To complete the project in Experiment 15, you'll need a loudspeaker small enough to fit inside your project box but louder than the 1-inch speaker that you used previously. It should be 2 inches or 2.5 inches (50 to 60 mm) in diameter. If you can find a 100Ω speaker, it will give you more output, but an 8Ω speaker will be acceptable.

Experiment 12: Joining Two Wires Together

Your adventure into soldering begins with the prosaic task of joining one wire to another, but will lead quickly to creating a full electronic circuit on perforated board. So let's get started!

You will need:

- 30-watt or 40-watt soldering iron
- 15-watt pencil-type soldering iron
- Thin solder (0.022 inches or similar)
- Medium solder (0.05 inches or similar)
- Wire strippers and cutters
- "Helping hand" gadget to hold your work
- Shrink-wrap tubing, assorted
- Heat gun
- Something to protect your work area from drops of solder

Your First Solder Joint

We'll start with your general-duty soldering iron—the one rated for 30 or 40 watts. Plug it in, leave it safely in its holder, and find something else to do for five minutes. If you try to use a soldering iron without giving it time to get fully hot, you will *not* make good joints.

Strip the insulation from the ends of two pieces of 22-gauge solid wire and clamp them in your helping hand so that they cross each other and touch each other, as shown in Figure 3-31.

To make sure that the iron is ready, try to melt the end of a thin piece of solder on the tip of the iron. The solder should melt instantly. If it melts slowly, the iron isn't hot enough yet.

Now follow these steps (shown in Figures 3-32 through 3-36):

1. Make sure the tip of the soldering iron is clean (wipe it on the moistened sponge in the base of your helping hand if necessary), then touch it against the intersection of the wires steadily for three seconds to heat them. If you have hard tap water, use distilled water to wet the sponge to avoid a buildup of mineral deposits on the tip of your soldering iron.
2. While maintaining the iron in this position, feed a little solder onto the intersection of the wires, also touching the tip of the soldering iron. Thus, the two wires, the solder, and the tip of the iron should all come together at one point. The solder should spread over the wires within another two seconds.
3. Remove the iron and the solder. Blow on the joint to cool it. Within 10 seconds, it should be cool enough to touch.
4. Unclamp the wires and try to tug them apart. Tug hard! If they defeat your best attempts to separate them, the wires are electrically joined and should stay joined. If you didn't make a good joint, you will be able to separate the wires relatively easily, probably because you didn't apply enough heat or enough solder to connect them.

The reason I asked you to begin by using the higher-powered soldering iron is that it delivers more heat, which makes it easier to use.

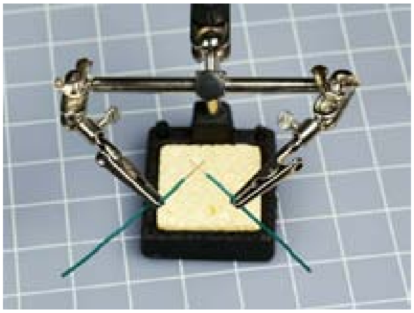

Figure 3-31. *A helping hand work aid is shown here holding two wires with their stripped ends touching. The magnifying glass has been hinged out of the way.*

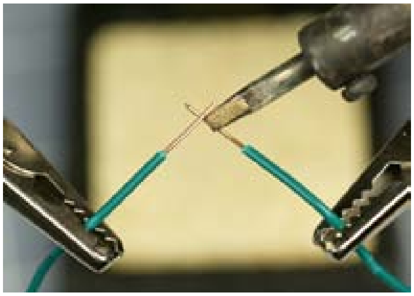

Figure 3-32

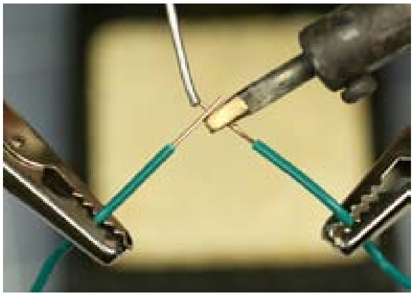

Figure 3-33

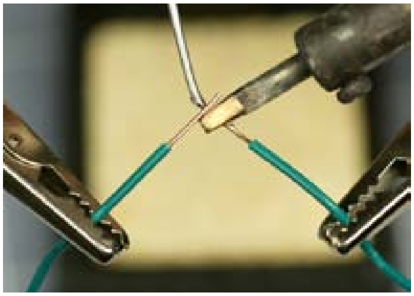

Figure 3-34

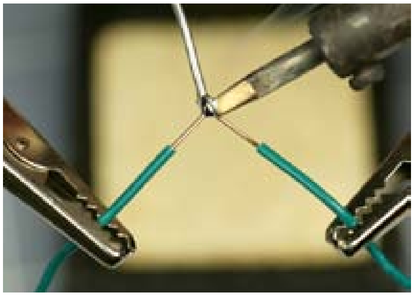

Figure 3-35. *This and the preceding three figures illustrate four steps to making a solder joint: apply heat to the wires, bring in the solder while maintaining the heat, wait for the solder to start to melt, and wait a moment longer for it to form a completely molten bead. The whole process should take between 4 and 6 seconds.*

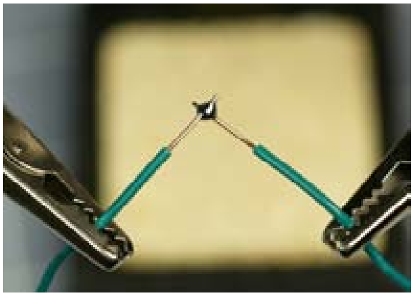

Figure 3-36. *The completed joint should be shiny, uniform, and rounded in shape.*

BACKGROUND

Soldering myths

Myth #1: Soldering is very difficult.

Millions of people have learned how to do it, and statistically, you are unlikely to be less coordinated than all of them. I have a lifelong problem with a tremor in my hands that makes it difficult for me to hold small things steadily. I also get impatient with repetitive detail work. If I can solder components, almost anyone should be able to.

Myth #2: Soldering involves poisonous chemicals.

Modern solder contains no lead. You should avoid inhaling the fumes for prolonged periods, but that also applies to everyday products such as bleach and paint. If soldering was a significant health hazard, we should have seen a high death rate among electronics hobbyists decades ago.

Myth #3: Soldering is hazardous.

A soldering iron is less hazardous than the kind of iron that you might use to iron a shirt, because it delivers less heat. In fact, in my experience, soldering is safer than most activities in a typical home or basement workshop. That doesn't mean you can be careless!

Soldering alternatives

As recently as the 1950s, connections inside electronic appliances such as radio sets were still being hand-soldered by workers on production lines. But the growth of telephone exchanges created a need for a faster way to make large numbers of rapid, reliable point-to-point wiring connections, and "wire wrap" became a viable alternative.

In a wire-wrapped electronics project, components are mounted on a circuit board that has long, gold-plated, sharp-cornered square pins sticking out of the rear. Special silver-plated wire is used, with an inch of insulation stripped from its ends. A manual or power-driven wire-wrap tool twirls the end of a wire around one of the pins, applying sufficient tension to "cold-weld" the soft silver plating of the wire to the pin. The wrapping process exerts sufficient pressure to make a very reliable joint, especially as 7 to 9 turns of wire are applied, each turn touching all four corners of the pin.

During the 1970s and 1980s, this system was adopted by hobbyists who built their own home computers. A wire-wrapped circuit board from a hand-built computer is shown in Figure 3-37. The technique was used by NASA to wire the computer in the Apollo spacecraft that went to the moon, but today, wire-wrapping has few commercial applications.

The widespread industrial use of "through-hole" components, such as the chips on early desktop computers, encouraged development of wave soldering, in which a wave or waterfall of molten solder is applied to the underside of a preheated circuit board where chips have been inserted. A masking technique prevents the solder from sticking where it isn't wanted.

Today, surface-mount components (which are significantly smaller than their through-hole counterparts) are glued to a circuit board with a solder paste, and the entire assembly is then heated, melting the paste to create a permanent connection.

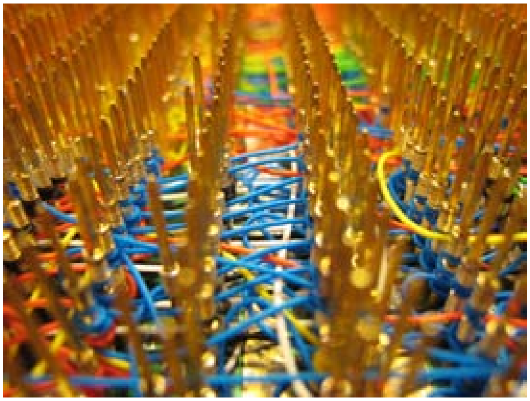

Figure 3-37. *This picture shows some of the wire-wrapping in Steve Chamberlin's custom-built, retro 8-bit CPU and computer. "Back in the day," connecting such a network of wires with solder joints would have been unduly time-consuming and prone to faults. Photo credit: Steve Chamberlin.*

TOOLS

Eight most common soldering errors

1. Not enough heat.

   The joint looks OK, but because you didn't apply quite enough heat, the solder didn't melt sufficiently to realign its internal molecular structure. It remained granular instead of becoming a solid, uniform blob, and you end up with a "dry joint," also known as a "cold joint," which will come apart when you pull the wires away from each other. Reheat the joint thoroughly and apply new solder.

   A leading cause of underheated solder is the temptation to use the soldering iron to carry solder to the joint. This results in the cold wires reducing the temperature of the solder. What you should do is touch the soldering iron to heat the wires first, and then apply the solder. This way, the wires are hot and help to melt the solder, which wants to stick to them.

   Because this is such a universal problem, I'll repeat myself: *Never melt solder on the tip of the iron and then use it to carry the solder to the joint.*

   You don't want to put hot solder on cold wires. You want to put cold solder on hot wires.

2. Too much heat.

   This may not hurt the joint, but can damage everything around it. Vinyl insulation will melt, exposing the wire and raising the risk of short circuits. You can easily damage semiconductors, and may even melt the internal plastic components of switches and connectors.

   Damaged components must be desoldered and replaced, which will take time and tends to be a big hassle (see "Tools: Desoldering" on page 109 for advice).

3. Not enough solder.

   A thin connection between two conductors may not be strong enough. When joining two wires, always check the underside of the joint to see whether the solder penetrated completely.

4. Moving the joint before the solder solidifies.

   You may create a fracture that you won't necessarily see. It may not stop your circuit from working, but at some point in the future, as a result of vibration or thermal stresses, the fracture can separate just enough to break electrical contact. Tracking it down will then be a chore. If you clamp components before you join them, or use perforated board to hold the components steady, you can avoid this problem.

5. Dirt or grease.

   Electrical solder contains rosin that cleans the metal that you're working with, but contaminants can still prevent solder from sticking. If any component looks dirty, clean it with fine sandpaper before joining it.

6. Carbon on the tip of your soldering iron.

   The iron gradually accumulates flecks of black carbon during use, and they can act as a barrier to heat transfer. Wipe the tip of the iron on the little sponge mounted in the base of your soldering iron stand or your helping hand.

7. Inappropriate materials.

   Electronic solder is designed for electronic components. It will not work with aluminum, stainless steel, or various other metals. You may be able to make it stick to chrome-plated items, but only with difficulty.

8. Failure to test the joint.

   Don't just assume that it's OK. Always test it, by applying manual force if you can (see Figures 3-38 and 3-39 for the ideal protocol) or, if you can't get a grip on the joint, slip a screwdriver blade under it and flex it just a little, or use small pliers to try to pull it apart. Don't be concerned about ruining your work. If your joint doesn't survive rough treatment, it wasn't a good joint.

Of the eight errors, dry/cold joints are by far the worst, because they are easy to make and can look OK.

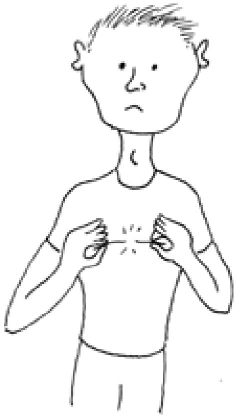

Figure 3-38. *Test result of a bad solder joint.*

Figure 3-39. *Test result of a good solder joint.*

Your Second Solder Joint

Time now to try your pencil-style soldering iron. Once again, you must leave it plugged in for a good five minutes to make sure it's hot enough. In the meantime, don't forget to unplug your other soldering iron, and put it somewhere safe while it cools.

This time I'd like you to align the wires parallel with each other. Joining them this way is a little more difficult than joining them when they cross each other, but it's a necessary skill. Otherwise, you won't be able to slide heat-shrink tubing over the finished joint to insulate it.

Figures 3-40 through 3-44 show a successful joint of this type. The two wires do not have to make perfect contact with each other; the solder will fill any small gaps. But the wires must be hot enough for the solder to flow, and this can take an extra few seconds when you use the low-wattage pencil-style iron.

Be sure to feed the solder in as shown in the pictures. Remember: don't try to carry the solder to the joint on the tip of the iron. Heat the wires first, and then touch the solder to the wires and the tip of the iron, while keeping it in contact with the wires. Wait until the solder liquifies, and you will see it running eagerly into the joint. If this doesn't happen, be more patient and apply the heat for a little longer.

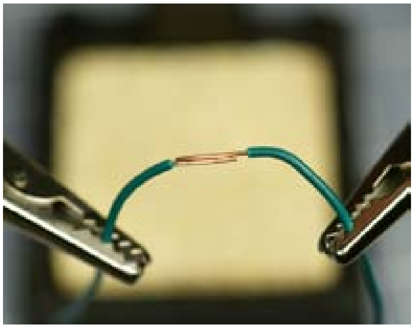

Figure 3-40

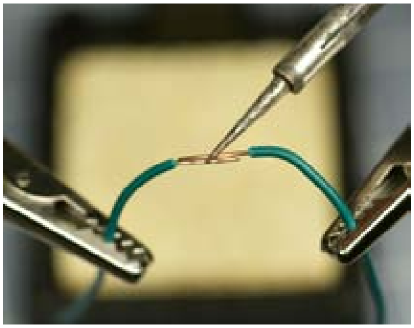

Figure 3-41

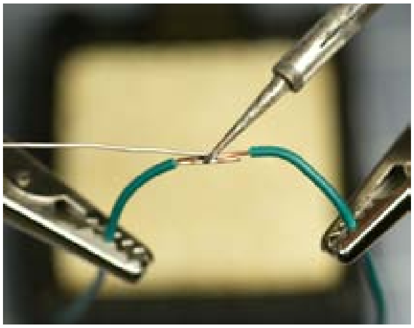

Figure 3-42

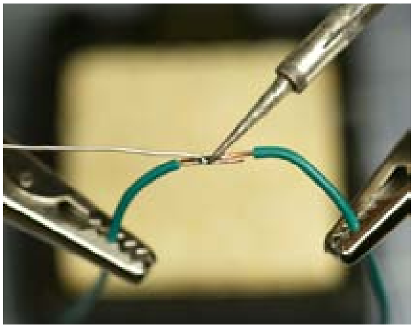

Figure 3-43. *This and the preceding three figures show how joining two wires that are parallel is more difficult, and the low-wattage, pencil-type soldering iron will require longer to heat them sufficiently for a good joint. Thinner solder can be used.*

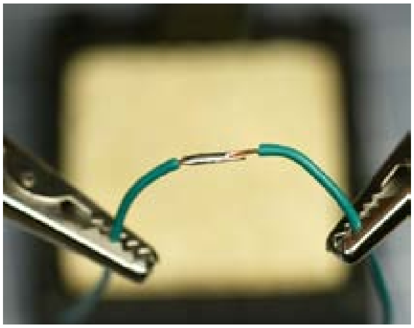

Figure 3-44. *The finished joint has enough solder for strength, but not so much solder that it will prevent heat-shrink tubing from sliding over it.*

THEORY

Soldering theory

The better you understand the process of soldering, the easier it should be for you to make good solder joints.

The tip of the soldering iron is hot, and you want to transfer that heat into the joint that you are trying to make. In this situation, you can think of the heat as being like a fluid. The larger the connection is between the soldering iron and the joint, the greater the quantity of heat, per second, that can flow through it.

For this reason, you should adjust the angle of the soldering iron so that it makes the widest possible contact. If it touches the wires only at a tiny point, you'll limit the amount of heat flow. Figures 3-45 and 3-46 illustrate this concept. Once the solder starts to melt, it broadens the area of contact, which helps to transfer more heat, so the process accelerates naturally. Initiating it is the tricky part.

The other aspect of heat flow that you should consider is that it can suck heat away from the places where you want it, and deliver it to places where you don't want it. If you're trying to solder a very heavy piece of copper wire, the joint may never get hot enough to melt the solder, because the heavy wire conducts heat away from the joint. You may find that even a 40-watt iron isn't powerful enough to overcome this problem, and if you are doing heavy work, you may need a more powerful iron.

As a general rule, if you can't complete a solder joint in 10 seconds, you aren't applying enough heat.

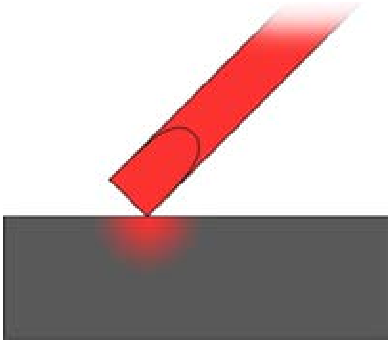

Figure 3-45. *With only a small surface area of contact between the iron and the working surface, an insufficient amount of heat is transferred.*

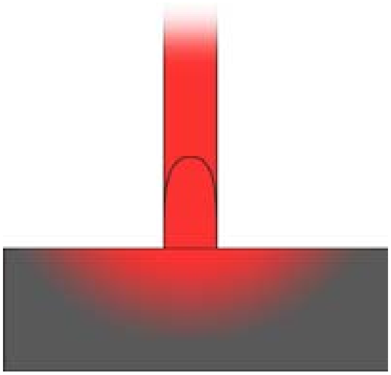

Figure 3-46. *A larger area of contact between the soldering iron and its target will greatly increase the heat transfer.*

TOOLS

Desoldering

Desoldering is much, much harder than soldering. Two simple tools are available:

- *Suction pump*. First, you apply the soldering iron to make the solder liquid. Then you use this simple gadget to try to suck up as much of the liquid as possible. Usually it won't remove enough metal to allow you to pull the joint apart, and you will have to try the next tool. Refer back to Figure 3-10.
- *Desoldering wick or braid*. Desoldering wick, also known as braid, is designed to soak up the solder from a joint, but again, it won't clean the joint entirely, and you will be in the awkward position of trying to use both hands to pull components apart while simultaneously applying heat to stop the solder from solidifying. Refer back to Figure 3-11.

I don't have much advice about desoldering. It's a frustrating experience (at least, I think so) and can damage components irrevocably.

Heat Guns Get Hot, Too!

Notice the chromed steel tube at the business end of your heat gun. Steel costs more than plastic, so the manufacturer must have put it there for a good reason—and the reason is that the air flowing through it becomes so hot that it would melt a plastic tube.

The metal tube stays hot enough to burn you for several minutes after you've used it. And, as in the case of soldering irons, other people (and pets) are vulnerable, because they won't necessarily know that the heat gun is hot. Most of all, make sure that no one in your home ever makes the mistake of using a heat gun as a hair dryer (Figure 3-47).

This tool is just a little more hazardous than it appears.

Adding Insulation

After you've succeeded in making a good inline solder connection between two wires, it's time for the easy part. Choose some heat-shrink tubing that is just big enough to slide over the joint with a little bit of room to spare.

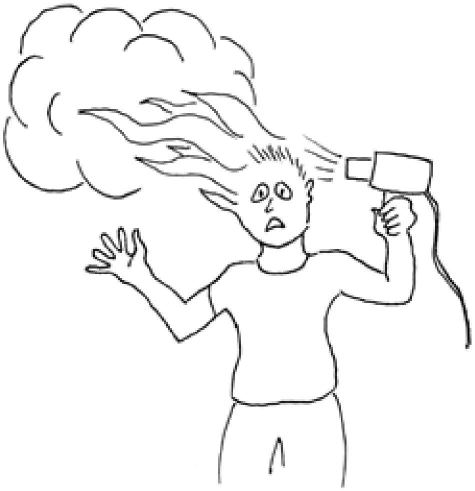

Figure 3-47. *Other members of your family should understand that although a heat gun looks like a hair dryer, appearances may be deceptive.*

Slide the tubing along until the joint is centered under it, hold it in front of your heat gun, and switch on the gun (keeping your fingers away from the blast of superheated air). Turn the wire so that you heat both sides. The tubing should shrink tight around the joint within half a minute. If you overheat the tubing, it may shrink so much that it splits, at which point you must remove it and start over. As soon as the tubing is tight around the wire, your job is done, and there's no point in making it any hotter. Figures 3-48 through 3-50 show the desired result. I used white tubing because it shows up well in photographs. Different colors of heat-shrink tubing all perform the same way.

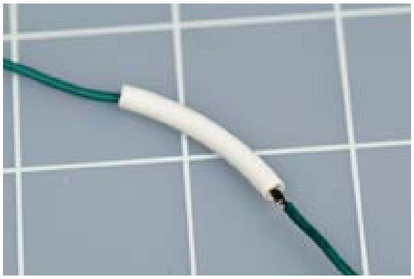

Figure 3-48. *Slip the tubing over your wire joint.*

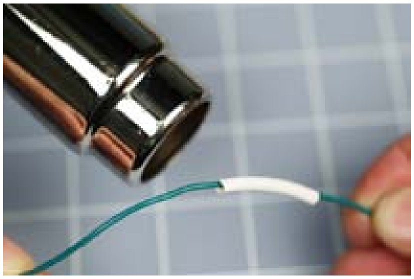

Figure 3-49. *Apply heat to the tubing.*

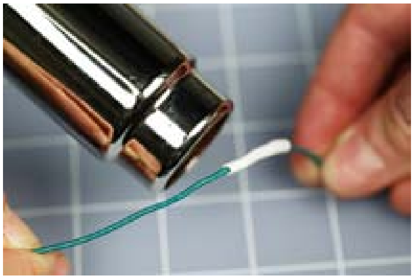

Figure 3-50. *Leave the heat on the tubing until it shrinks to firmly cover the joint.*

I suggest you next practice your soldering skills on a couple of practical projects. In the first one, you can add color-coded, solid-core wires to your AC adapter, and in the second one, you can shorten the power cord for a laptop power supply. You can use your larger soldering iron for both of these tasks, because neither of them involves any heat-sensitive components.

Modifying an AC Adapter

In the previous chapter, I mentioned the irritation of being unable to push the wires from your AC adapter into the holes of your breadboard. So, let's fix this right now:

1. Cut two pieces of solid-conductor 22-gauge wire—one of them red, the other black or blue. Each should be about 2 inches long. Strip a quarter-inch of insulation from both ends of each piece of wire.
2. Trim the wire from your AC adapter. You need to expose some fresh, clean copper to maximize your chance of getting the solder to stick.

   I suggest that you make one conductor longer than the other to minimize the chance of the bare ends touching and creating a short circuit. Use your meter, set to DC volts, if you have any doubt about which conductor is positive.

Solder the wires and add heat-shrink tubing as you did in the practice session. The result should look like Figure 3-51.

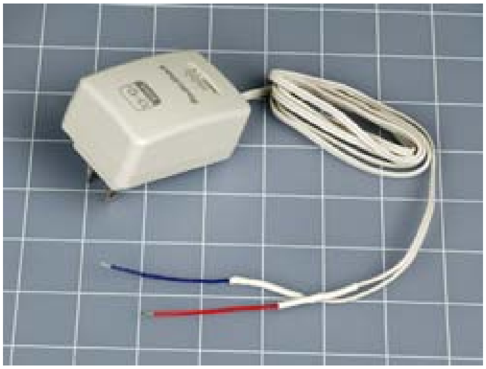

Figure 3-51. *Solid-core color-coded wires, soldered onto the wires from an AC adapter, provide a convenient way to feed power to a breadboard. Note that the wires are of differing lengths to reduce the risk of them touching each other.*

Choose the Right Tubing

If you use heat-shrink tubing on 110v AC cord, as is being done in this experiment, make sure you use tubing that's been rated for 110v use.

Shortening a Power Cord

When I travel, I like to minimize everything. It always annoys me that the power cord for the power supply of my laptop is 4 feet long. The thinner wire that connects the power supply to the computer is also 4 feet long, and I just don't need that much wire.

After searching exhaustively I couldn't find any laptop power cables shorter than 3 feet, so I decided to shorten one myself. If you feel no need to do this, you should try the following procedure on an old extension cord, just as an exercise. You do need to go through these steps to acquire some practice in soldering heavier, stranded wire and using heat-shrink tubing:

1. Use your wire cutters to chop the wire, and then a utility knife to split the two conductors, with one shorter than the other. When splicing a power cord or similar cable containing two or more conductors, it's good to avoid having the joints opposite each other. They fit more snugly if they are offset, and there's less risk of a short circuit if a joint fails.

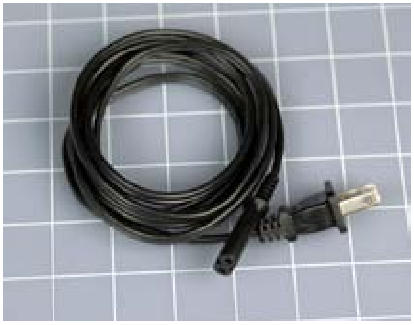

Figure 3-52

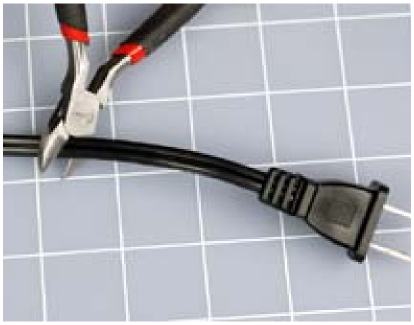

Figure 3-53

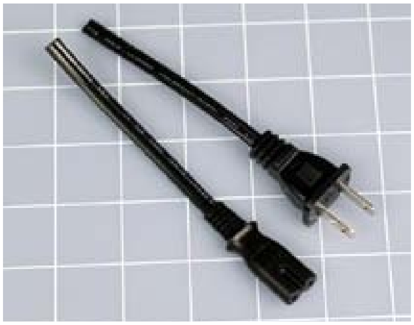

Figure 3-54

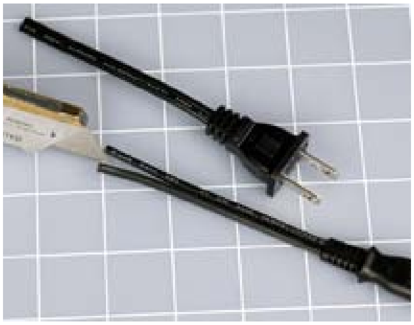

Figure 3-55

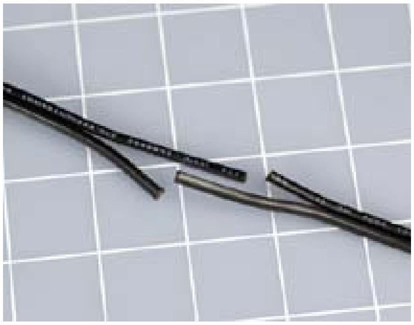

Figure 3-56

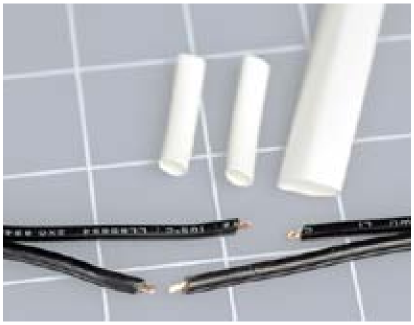

Figure 3-57

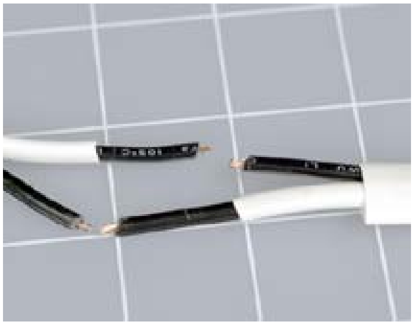

Figure 3-58. *Figures 3-52 through 3-58 illustrate the sequence of steps to prepare for making a shortened power cord for a laptop computer power supply.*

2. Strip off a minimal amount of insulation. One-eighth of an inch (3 mm) is sufficient. The automatic wire strippers that I mentioned in the shopping list in Chapter 1 are especially convenient, but regular wire strippers will do the job.

3. Cut two pieces of heat-shrink tubing, each 1 inch long, big enough to slide over the separate conductors in your cable. Cut a separate 2-inch piece of larger tubing that will slide over the entire joint when it's done. The steps described so far are illustrated in Figures 3-52 through 3-58.

4. Now for the most difficult part: activating your human memory. You have to remember to slide the tubing onto the wire *before* you make your solder joint, because the plugs on the ends of the wires will prevent you from adding any heat-shrink tubing later. If you're as impatient as I am, it's very difficult to remember to do this every time.

5. Use your helping hand to align the first joint. Push the two pieces of wire together so that the strands intermingle, and then squeeze them tight between finger and thumb, so that there are no little bits sticking out. A stray strand of wire can puncture heat-shrink tubing when the tubing is hot and soft and is shrinking around the joint.
6. The wire that you're joining is much heavier than the 22-gauge wire that you worked with previously, so it will suck up more heat, and you must touch the soldering iron to it for a longer time. Make sure that the solder flows all the way into the joint, and check the underside after the joint is cool. Most likely you'll find some bare copper strands there. The joint should become a nice solid, rounded, shiny blob. Keep the heat-shrink tubing as far away from the joint as possible while you're using the soldering iron, so that heat from the iron doesn't shrink the tubing prematurely, preventing you from sliding it over the joint later.

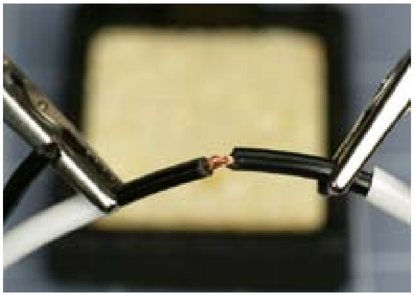

Figure 3-59

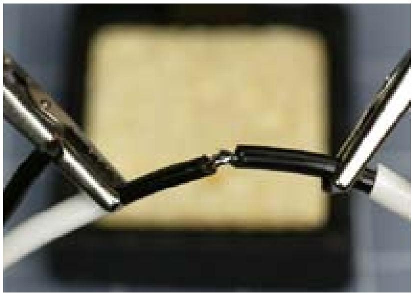

Figure 3-60

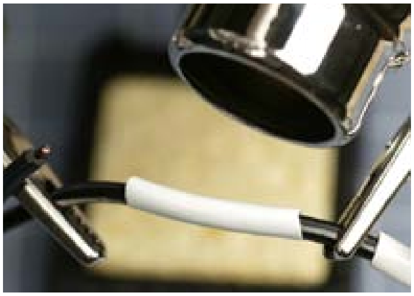

Figure 3-61

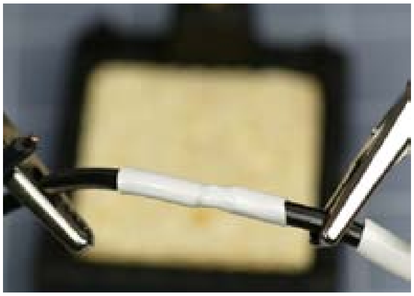

Figure 3-62

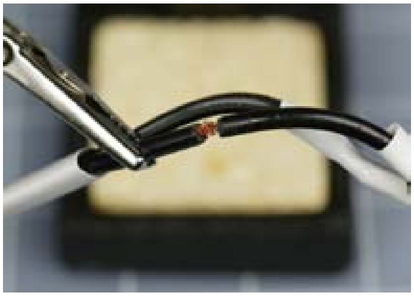

Figure 3-63

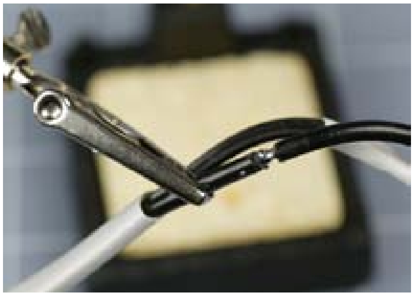

Figure 3-64

7. When the joint has cooled, slide the heat-shrink tubing over it, and apply the heat gun. Now repeat the process with the other conductor. Finally, slide the larger piece of tubing over the joint. You did remember to put the large tubing onto the wire at the beginning, didn't you?

Figures 3-59 through 3-65 show the steps all the way through to the end.

If you have completed the soldering exercises so far, you now have sufficient basic skills to solder your first electronic circuit. But first, I want you to verify the vulnerability of components to heat.

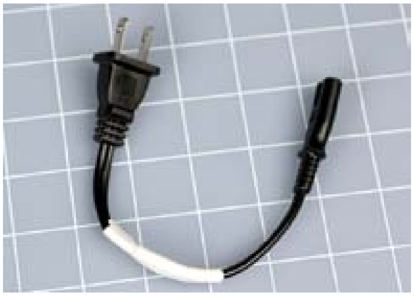

Figure 3-65. *Completion of the shortened power cord for a laptop power supply.*

Experiment 13: Broil an LED

In Chapter 1, you saw how an LED can be damaged if too much current flows through it. The electricity caused heat, which melted the LED. Unsurprisingly, you can just as easily melt it by applying too much heat to one of its leads with a soldering iron. The question is: how much heat is too much? Let's find out.

You will need:

- 30-watt or 40-watt soldering iron
- 15-watt pencil-type soldering iron
- A couple of LEDs (that are expendable)
- 680Ω resistor
- Wire cutters and sharp-nosed pliers
- "Helping hand" gadget to hold your work

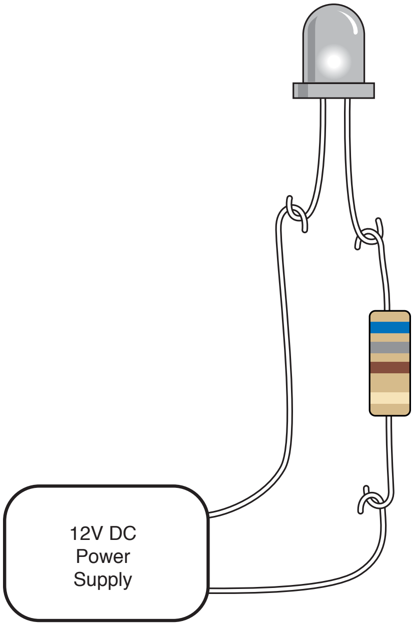

Figure 3-66. *By literally hooking together the leads from a resistor and a white-light LED, we minimize pathways for heat to escape during the subsequent test.*

I don't want you to use alligator clips to join the LED to a power supply, because the alligator clip will divert and absorb some of the heat from your soldering iron. Instead, please use some sharp-nosed pliers to bend each of the leads from an LED into little hooks, and do the same thing with the wires on a 680Ω load resistor. Finally bend the new wires on your AC adapter so that they, too, are tiny hooks. Now you can put the hooks together like links in a chain, as shown in Figure 3-66.

Grip the plastic body of the LED in your helping hand. Plastic is not a good thermal conductor, so the helping hand shouldn't siphon too much heat away from our target. The resistor can dangle from one of the leads on the LED, and the wire from the AC adapter can hang from that, a little farther down. Gravity should be sufficient to make this work. Set your AC adapter to deliver 12 volts as before, plug it in, and your LED should be shining brightly. I used a white LED in this experiment, because it's easier to photograph.

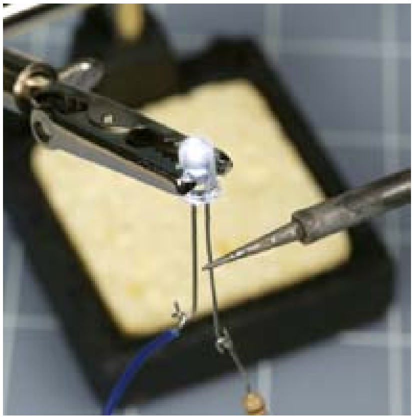

Figure 3-67. *Applying heat with a 15-watt soldering iron. A typical LED should withstand this treatment for two or three minutes, but if you substitute a 30-watt soldering iron, the LED is likely to burn out in under 15 seconds.*

Make sure your two soldering irons are really hot. They should have been plugged in for at least five minutes. Now take the pencil-style iron and hold its tip firmly against one of the leads on your glowing LED, while you check the time with a watch. Figure 3-67 shows the setup.

I'm betting that you can sustain this contact for a full three minutes without burning out the LED. This is why you use a 15-watt soldering iron for delicate electronics work—it doesn't endanger the components.

Allow your LED wire to cool, and then apply your more powerful soldering iron to the same piece of wire as before. Again, make sure it is completely hot, and I think you'll find that the LED will go dark after as little as 10 seconds (note, some LEDs can survive higher temperatures than others). This is why you *don't* use a 30-watt soldering iron for delicate electronics work.

The large iron doesn't necessarily reach a higher temperature than the small one. It just has a larger heat capacity. In other words, a greater quantity of heat can flow out of it, at a faster rate.

Throw away your burned-out LED. Substitute a new one, connected as before, but add a full-size copper alligator clip to one of the leads up near the body of the LED, as shown in Figure 3-68. Press the tip of your 30-watt or 40-watt soldering iron against the lead just *below* the alligator clip. This time, you should be able to hold the powerful soldering iron in place for a full two minutes without burning out the LED.

Imagine the heat flowing out through the tip of your soldering iron, into the wire that leads to the LED—except that the heat meets the alligator clip along the way, as shown in Figure 3-69. The clip is like an empty vessel waiting to be filled. It offers much less resistance to heat than the remainder of the wire leading to the LED, so the heat prefers to flow into the copper clip, leaving the LED unharmed. At the end of your experiment, if you touch the clip, you'll find that it's hot, while the LED remains relatively cooler.

The alligator clip is known as a heat sink, and it should be made of copper, because copper is one of the best conductors of heat.

Because the 15-watt soldering iron failed to harm the LED, you may conclude that the 15-watt iron is completely safe, eliminating all need for a heat sink. Well, this may be true. The problem is, you don't really know whether some semiconductors may be more heat-sensitive than LEDs. Because the consequences of burning out a component are so exasperating, I suggest you should play it safe and use a heat sink in these circumstances:

- If you apply 15-watt iron extremely close to a semiconductor for 20 seconds or more.
- If you apply a 30-watt iron near resistors or capacitors for 10 seconds or more. (Never use it near semiconductors.)
- If you apply a 30-watt iron near anything meltable for 20 seconds or more. Meltable items include insulation on wires, plastic connectors, and plastic components inside switches.

Rules for Heat Sinking

1. Full-size copper alligator clips do work better.
2. Clamp the alligator clip as close as possible to the component and as far as possible from the joint. (You don't want to suck too much heat away from the joint.)
3. Make sure there is a metal-to-metal connection between the alligator clip and the wire to promote good heat transfer.

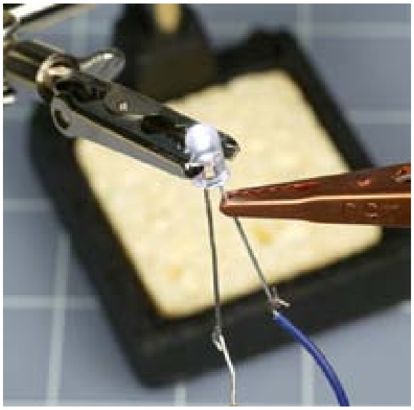

Figure 3-68. *When a copper alligator clip is used as a heat sink, you should be able to apply a 30-watt soldering iron (below the clip) without damaging the LED.*

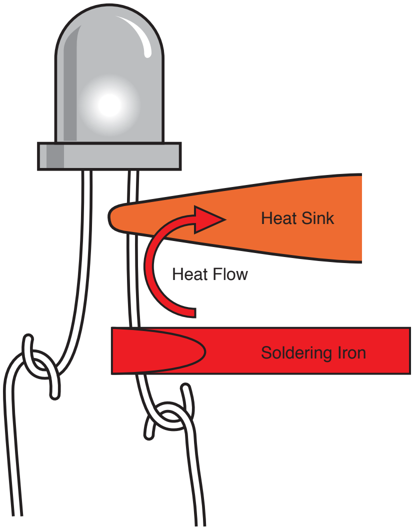

Figure 3-69. *The heat sink intercepts the heat, sucks it up, and protects the LED from damage.*

FUNDAMENTALS

All about perforated board

For the remainder of this book, you'll be using perforated board whenever you want to create permanent, soldered circuits. There are three ways to do this:

1. Point-to-point wiring. You use perforated board that has no connections behind the holes. Either the board has no copper traces on it at all, as in Figure 3-70, or you will find a little circular copper circle around each hole, as in Figure 3-71. These circles are not connected with each other and are used only to stabilize the components that you assemble.

   Point-to-point wiring allows you to place the components in a convenient, compact layout that can be very similar to a schematic. Under the board you bend the wires to link the components, and solder them together, adding extra lengths of wire if necessary. The advantage of this system is that it can be extremely compact. The disadvantage is that the layout can be confusing, leading to errors.

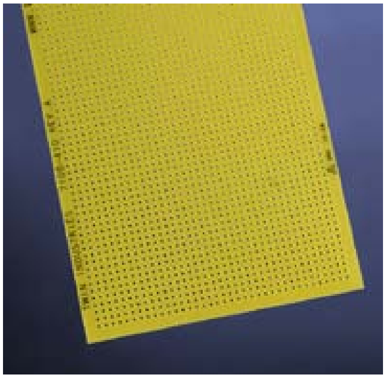

Figure 3-70

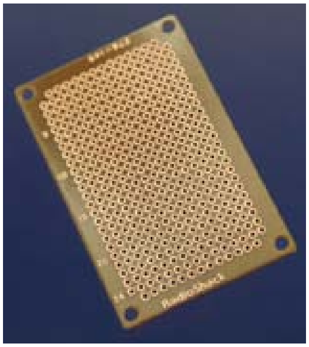

Figure 3-71. *Either this type of perforated board or the type in Figure 3-70 can be used for point-to-point wiring in Experiment 14.*

2. Breadboard-style wiring. Use perforated board that is printed with copper traces in exactly the same pattern as the conductors inside a breadboard. Once your circuit works on the breadboard, you move the components over to the perfboard one by one, maintaining their exact same positions relative to each other. You solder the "legs" of the components to the copper traces, which complete the circuit. Then you trim off the surplus wire. The advantage of this procedure is that it's quick, requires very little planning, and minimizes the possibility for errors. The disadvantage is that it tends to waste space. A cheap example is shown in Figure 3-72.
3. You can etch your own circuit board with customized copper traces that link your components in a point-to-point layout. This is the most professional way to complete a project, but it requires more time, trouble, and equipment than is practical in this book.

   Point-to-point wiring is like working with alligator clips, on a much smaller scale. The first soldered project will use this procedure.

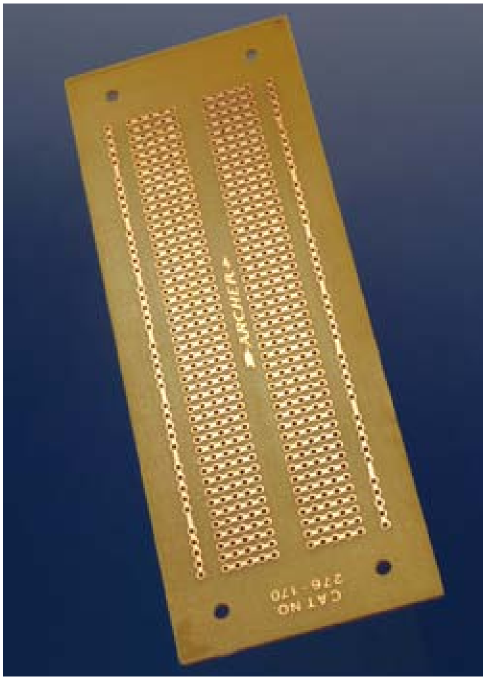

Figure 3-72. *Perforated board etched with copper in variants of a breadboard layout. This example is appropriate for Experiment 15.*

Experiment 14: A Pulsing Glow

You will need:

- Breadboard
- 15-watt pencil-type soldering iron
- Thin solder (0.022 inches or similar)
- Wire strippers and cutters
- Plain perforated board (no copper etching necessary)
- Small vise or clamp to hold your perforated board
- Resistors, various
- Capacitors, electrolytic, 100 µF and 220 µF, one of each
- Red LED, 5 mm, rated for 2 volts approximately
- 2N6027 programmable unijunction transistor

Your first circuit using a PUT was a slow-speed oscillator that made an LED flash about twice each second. The flashes looked very "electronic," by which I mean that the LED blinked on and off without a gradual transition between each state. I'm wondering if we can modify this circuit to make the LED pulse in a more gentle, interesting way, like the warning light on an Apple MacBook when it's in "sleep" mode. I'm thinking that something of this sort might be wearable as an ornament, if it's small enough and elegant enough.

I'm also thinking that this first soldering project will serve three purposes. It will test and refine your skill at joining wires together, will teach you point-to-point wiring with perfboard, and will give you some additional insight into the way that capacitors can be used to adjust timing.

Look back at the original schematic in Experiment 11, on page 82. Refresh your memory about the way it worked. The capacitor charges through a resistor until it has enough voltage to overcome the internal resistance in the PUT. Then the capacitor discharges through the PUT and flashes the LED.

If you drew a graph of the light coming out of the LED, it would be a thin, square-shaped pulse, as shown in Figure 3-73. How can we fill it out to make it more like the curve in Figure 3-74, so that the LED fades gently on and off, like a heartbeat?

One thing is obvious: the LED is going to be emitting a greater total amount of light in each cycle. Therefore, it's going to need more power. This means that C1, in Figure 3-75, must be a larger capacitor.

When we have a larger capacitor, it takes longer to charge. To keep the flashes reasonably frequent, we'll need a lower-value resistor for R1 to charge the capacitor quickly enough. In addition, reducing the values of R2 and R3 will program the PUT to allow a longer pulse.

Most important, I want to discharge the capacitor through a resistor to make the onset of the pulse gradual instead of sudden. Remember, when you have a resistor in series with a capacitor, the capacitor not only charges more slowly, but discharges more slowly.

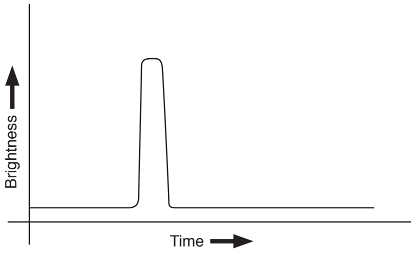

Figure 3-73

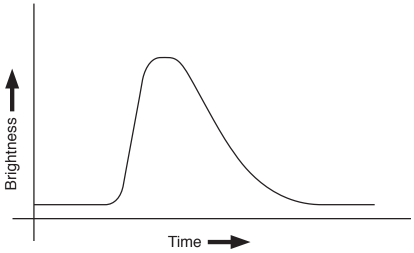

Figure 3-74. *The original PUT oscillator circuit in Experiment 11 made the LED emit sharp, short flashes. The upper graph shows what we might find if we measured light output over time. The second graph shows a gentler onset to each flash, followed by a slow fade-out. Capacitors can be used to create this effect.*

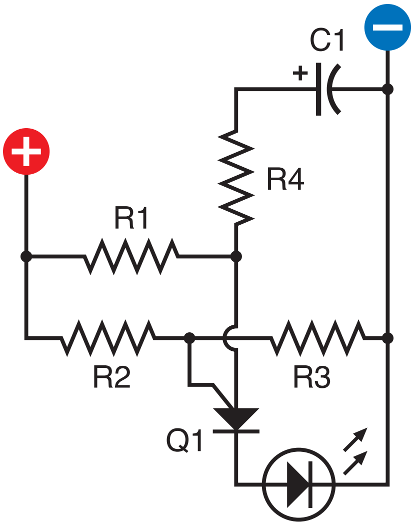

Figure 3-75. *The first step toward creating a gentler flashing effect is to use a larger capacitor for C1 and discharge it through a resistor, R4. Lower-value resistors are necessary to charge the capacitor rapidly enough.*

R1: 33K
R2: 1K
R3: 1K
R4: 1K
C1: 100 μF electrolytic
Q1: 2N6027

Figure 3-75 shows these features. Compare it with Figure 2-103 on page 85. R1 is now 33K instead of 470K. R2 and R3 are reduced to 1K. R4 also is 1K, to so that the capacitor takes longer to discharge through it. And C1 is now 100 μF instead of 2.2 μF.

Assemble this circuit on a breadboard, and compare the results when you include R4 or bypass it with a plain piece of jumper wire. It softens the pulse a bit, but we can work on it some more. On the output side of the PUT, we can add another capacitor. This will charge itself when the pulse comes out of the PUT, and then discharge itself gradually through another resistor, so that the light from the LED dies away more slowly.

Figure 3-76 shows the setup. C2 is large—220 μF—so it sucks up the pulse that comes out of the PUT, and then gradually releases it through 330Ω resistor R5 and the LED. You'll see that the LED behaves differently now, fading out inside of blinking off. But the resistances that I've added have dimmed the LED, and to brighten it, you should increase the power supply from 6 volts to 9 volts.

Remember that a capacitor imposes a smoothing effect only if one side of it is grounded to the negative side of the power supply. The presence of the negative charge on that side of the capacitor attracts the positive pulse to the other side.

I like the look of this heartbeat effect. I can imagine a piece of wearable electronic jewelry that pulses in this sensual way, very different from the hard-edged, sharp-on-and-off of a simple oscillator circuit. The only question is whether we can squeeze the components into a package that is small enough to wear.

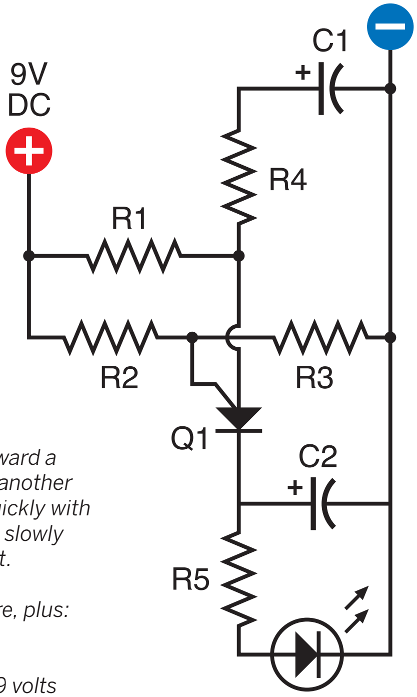

Figure 3-76. *The second step toward a gentler flashing effect is to add another capacitor, C2, which charges quickly with each pulse and then discharges slowly through R5 and the LED below it.*

Same components as before, plus:
R5: 330Ω
C2: 220 μF electrolytic
Power supply increased to 9 volts

Figure 3-77. *On a dark night in a rural area, the heartbeat flasher may be attractive in unexpected ways.*

Resizing the Circuit

The first step is to look at the physical components and imagine how to fit them into a small space. Figure 3-78 shows a 3D view of a compact arrangement. Check this carefully, tracing all the paths through the circuit, and you'll see that it's the same as the schematic. The trouble is that if we solder the components together like this, they won't have much strength. All the little wires can bend easily, and there's no easy way to mount the circuit in something or on something.

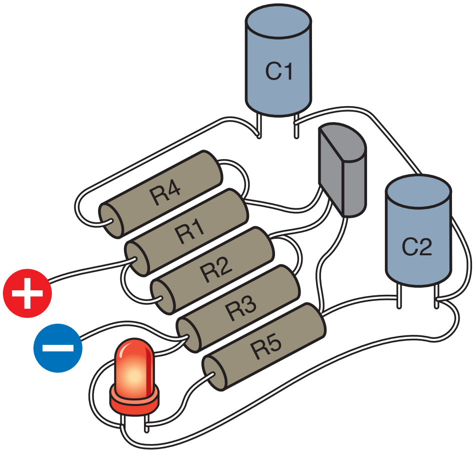

Figure 3-78. *This layout of components replicates their connections in the schematic diagram while squeezing them into a minimal amount of space.*

The answer is to put it on a substrate, which is one of those terms that people in the electronics field like to use, perhaps because it sounds more technical than "perfboard." But perforated board is what we need, and Figure 3-79 shows the components transferred onto a piece of board measuring just 1 inch by 0.8 inch.

The center version of this diagram uses dotted lines to show how the components will be connected with each other underneath the board. Mostly the leads that stick out from underneath the components will be long enough to make these connections.

Finally, the bottom version of the perfboard diagram shows the perfboard flipped left-to-right (notice the L and the R have been transposed to remind you, and I've used a darker color to indicate the underside of the board). Orange circles indicate where solder joints will be needed.

The LED should be unpluggable, because we may want to run it at some distance from the circuit. Likewise the power source should be unpluggable. Fortunately we can buy miniature connectors that fit right into the perforated board. You may have to go to large online retail suppliers such as Mouser.com for these. Some manufacturers call them "single inline sockets and headers," while others call them "boardmount sockets and pinstrip headers." Refer back to Figure 3-29 and check the shopping list for more details.

This is a very compact design that will require careful work with your pencil-style soldering iron. Because a piece of perforated board as small as this will tend to skitter around, I suggest that you apply your miniature vise to one end to anchor it with some weight while still allowing you to turn it easily.

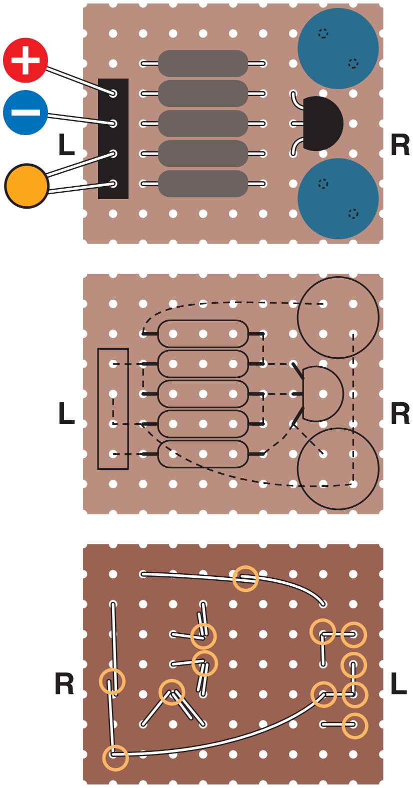

Figure 3-79. *Perforated board can be used to support the layout of components. Their leads are soldered together under the board to create the circuit. The middle diagram shows the wires under the board as dashed lines. The bottom diagram shows the board from underneath, flipped left to right. Orange circles indicate where solder joints will be necessary.*

When I'm working on this kind of project, I like to place it (with the vise attached) on a soft piece of polyurethane foam—the kind of slab that is normally used to make a chair cushion. The foam protects the components from damage when the board is upside-down, and again helps to prevent the work from sliding around unpredictably.

Step by Step

Here's the specific procedure for building this circuit:

1. Cut the small piece of perfboard out of a sheet that has no copper traces on it. You can cut the section using your miniature hobby saw, or you may be able to snap the board along its lines of holes, if you're careful. Alternatively, use a small ready-cut piece of perfboard with copper circles on it that are not connected to one another. You'll ignore the copper circles in this project. (In the next experiment, you'll deal with the additional challenge of making connections between components and copper traces on perforated board.)
2. Gather all the components and carefully insert them through holes in the board, counting the holes to make sure everything is in the right place. Flip the board over and bend the wires from the components to anchor them to the board and create connections as shown. If any of the wires isn't long enough, you'll have to supplement it with an extra piece of 22-gauge wire from your supply. You can remove all the insulation, as we'll be mounting the perfboard on a piece of insulating plastic.
3. Trim the wires approximately with your wire cutters.
4. Make the joints with your pencil soldering iron. Note that in this circuit, you are just joining wires to each other. The components are so close together that they'll prevent each other from wiggling around too much. If you are using board with copper pads (as I did), and some solder connects with them, that's OK—as long as it doesn't creep across to the neighboring component and create a short circuit.
5. Check each joint using a close-up magnifying glass, and wiggle it with pointed-nosed pliers. If there isn't enough solder for a really secure joint, reheat it and add more. If solder has created a connection that shouldn't be there, use a utility knife to make two parallel cuts in the solder, and scrape away the little section between them.

Generally, I insert three or four components, trim the wires approximately, solder them, trim their wires finally, then pause to check the joints and the placement. If I solder too many components in succession, there's a greater risk of missing a bad joint, and if I make an error in placing a component, undoing it will be much more problematic if I have already added a whole lot more components around it.

Figures 3-80 and 3-81 show the version of this project that I constructed, before I trimmed the board to the minimum size.

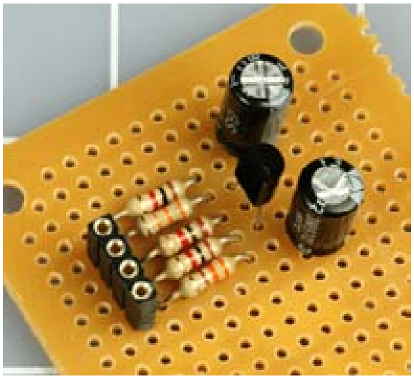

Figure 3-80. *Components mounted on a piece of perforated board.*

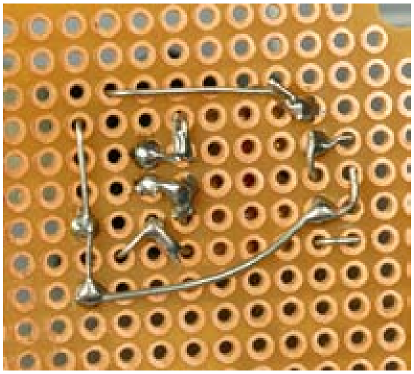

Figure 3-81. *The assembly seen from below. The copper circles around the holes are not necessary for this project. Some of them have picked up some solder, but this is irrelevant as long as no unintentional short circuits are created.*

Flying Wire Segments

The jaws of your wire cutters exert a powerful force that peaks and then is suddenly released when they cut through wire. This force can be translated into sudden motion of the snipped wire segment. Some wires are relatively soft, and don't pose a risk, but harder wires can fly in unpredictable directions at high speed, and may hit you in the eye. The leads of transistors are especially hazardous in this respect.

I think it's a good idea to wear safety glasses when trimming wires.

Finishing the Job

I always use bright illumination. This is not a luxury; it is a necessity. Buy a cheap desk lamp if you don't already have one. I use a daylight-spectrum fluorescent desk lamp, because it helps me identify the colored bands on resistors more reliably. Note that this type of fluorescent lamp emits quite a lot of ultraviolet light, which is not good for the lens in your eye. Avoid looking closely and directly at the tube in the lamp, and if you wear glasses, they will provide additional protection.

No matter how good your close-up vision is, you need to examine each joint with that close-up magnifier. You'll be surprised how imperfect some of them are. Hold the magnifier as close as possible to your eye, then pick up the thing that you want to examine and bring it closer until it comes into focus.

Finally, you should end up with a working circuit. You can insert the wires from your power supply into two of the tiny power sockets, and plug a red LED into the remaining two sockets. Remember that the two center sockets are negative, and the two outer sockets are positive, because it was easier to wire the circuit this way. You should color-code them to avoid mistakes.

So now you have a tiny circuit that pulses like a heartbeat. Or does it? If you have difficulty making it work, retrace every connection and compare it with the schematic. If you don't find an error, apply power to the circuit, attach the black lead from your meter to the negative side, and then go around the circuit with the red lead, checking the presence of voltage. Every part of this circuit should show at least some voltage while it's working. If you find a dead connection, you may have made a bad solder joint, or missed one entirely.

When you're done, now what? Well, now you can stop being an electronics hobbyist and become a crafts hobbyist. You can try to figure out a way to make this thing wearable.

First you have to consider the power supply. Because of the components that I used, we really need 9 volts to make this work well. How are you going to make this 9-volt circuit wearable, with a bulky 9-volt battery?

I can think of three answers:

1. You can put the battery in a pocket, and mount the flasher on the outside of the pocket, with a thin wire penetrating the fabric. Note that the tiny power connector on the perforated board will accept two 22-gauge wires if they are solid core, or if they are stranded (like the wires from a 9-volt battery connector) but have been thinly coated with solder.
2. You could mount the battery inside the crown of a baseball cap, with the flasher on the front.
3. You can put together three 3-volt button batteries in a stack, held in some kind of plastic clip. If you try this option, it may not be a good idea to try to solder wire to a battery. You will heat the liquid stuff inside the battery, which may not be good for it, and may not be good for you if the liquid starts boiling and the battery bursts open. Also, solder doesn't stick easily to the metallic finish on most battery terminals.

Most LEDs create a sharply defined beam of light, which you may want to diffuse to make it look nicer. One way to do this is to use a piece of transparent acrylic plastic, at least 1/4 inch thick, as shown in Figure 3-82. Sandpaper the front of the acrylic, ideally using an orbital sander that won't make an obvious pattern. Sanding will make the acrylic translucent rather than transparent.

Drill a hole slightly larger than the LED in the back of the acrylic. Don't drill all the way through the plastic. Remove all fragments and dust from the hole by blasting some compressed air into it, or by washing it if you don't have an air compressor. After the cavity is completely dry, get some transparent silicone caulking or mix some clear five-minute epoxy and put a drop in the bottom of the hole. Then insert the LED, pushing it in so that it forces the epoxy to ooze around it, making a tight seal. See Figure 3-82.

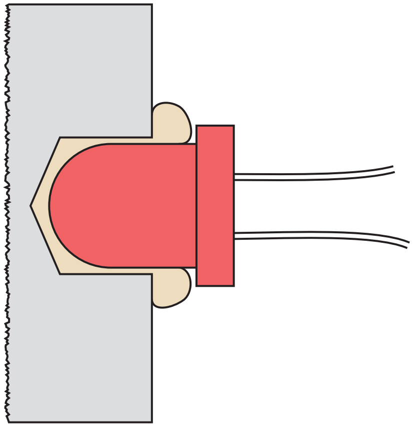

Figure 3-82. *This cross-sectional view shows a sheet of transparent acrylic in which a hole has been drilled part of the way from the back toward the front. Because a drill bit creates a hole with a conical shape at the bottom, and because the LED has rounded contours, transparent epoxy or silicone caulking can be injected into the hole before mounting the LED.*

Try illuminating the LED, and sand the acrylic some more if necessary. Finally, you can decide whether to mount the circuit on the back of the acrylic, or whether you want to run a wire to it elsewhere.

Because the LED will flash at about the speed of a human heart while the person is resting, it may look as if it's measuring your pulse, especially if you mount it on the center of your chest or in a strap around your wrist. If you enjoy hoaxing people, you can suggest that you're in such amazingly good shape, your pulse rate remains constant even when you're taking strenuous exercises.

To make a good-looking enclosure for the circuit, I can think of options ranging from embedding the whole thing in clear epoxy to finding a Victorian-style locket. I'll leave you to consider alternatives, because this is a book about electronics rather than handicrafts.

However, I will address one final issue: how long will this gadget continue flashing?

If you check the following section "Essentials: Battery life," you'll find that a regular alkaline 9-volt battery should keep the LED flashing for about 50 hours.

ESSENTIALS

Battery life

Any time you finish a circuit that you intend to run from a battery, you'll want to calculate the likely battery life. This is easily done, because manufacturers rate their batteries according to the "ampere hours" they can deliver. Keep the following in mind:

- The abbreviation for amp-hours is Ah, sometimes printed as AH. Milliampere-hours are abbreviated mAh.
- The rating of a battery in amp-hours is equal to the current, in amps, multiplied by the number of hours that the battery can deliver it.

Thus, in theory 1 amp-hour can mean 1 amp for 1 hour, or 0.1 amp for 10 hours, or 0.01 amp for 100 hours—and so on. In reality, it's not as simple as this, because the chemicals inside a battery become depleted more quickly when you draw a heavy current, especially if the battery gets hot. You have to stay within limits that are appropriate to the size of the battery.

For instance, if a small battery is rated for 0.5 amp-hours, you can't expect to draw 30 amperes from it for 1 minute. But you should be able to get 0.005 amps (i.e., 5 milliamps) for 100 hours without any trouble. Remember, though, that the voltage delivered by a battery will be greater than its rated voltage when the battery is fresh, and will diminish below its rated voltage while the battery is delivering power.

According to some test data that I trust (I think they are a little more realistic than the estimates supplied by battery manufacturers), here are some numbers for typical batteries:

- Typical 9 volt alkaline battery: 0.3 amp-hours, while delivering 100 mA.
- Typical AA size, 1.5-volt alkaline battery: 2.2 amp-hours, while delivering 100 mA.
- Rechargeable nickel-metal hydride battery: about twice the endurance of a comparably sized alkaline battery.
- Lithium battery: maybe three times the endurance of an alkaline battery.

BACKGROUND

Maddened by measurement

Throughout most of this book, I've mostly used measurements in inches, although sometimes I've digressed into the metric system, as when referring to "5-mm LEDs." This isn't inconsistency on my part; it reflects the conflicted state of the electronics industry, where you'll find inches and millimeters both in daily use, often in the very same data sheet.

The United States is the only major nation still using the old system of units that originated in England. (The other two holdouts are Liberia and Myanmar, according to the CIA's *World Factbook*.) Still, the United States has led many advances in electronics, especially the development of silicon chips, which have contacts spaced 1/10 inch apart. These standards became firmly established, and show no sign of disappearing.

To complicate matters further, even in the United States, you can encounter two incompatible systems for expressing fractions of an inch. Drill bits, for instance, are measured in multiples of 1/64 inch, while metal thicknesses may be measured in decimals such as 0.06 inch (which is approximately 1/16 inch).

The metric system is not necessarily more rational than the U.S. system. Originally, when the metric system was formally introduced in 1875, the meter was defined as being 1/10,000,000 of the distance between the North Pole and the equator, along a line passing through Paris—a quixotic, Francocentric conceit. Since then, the meter has been redefined three times, in a series of efforts to achieve greater accuracy in scientific applications.

As for the usefulness of a 10-based system, moving a decimal point is certainly simpler than doing calculations in 64ths of an inch, but the only reason we count in tens is because we happen to have evolved with that number of digits on our hands. A 12-based system would really be more convenient, as numbers would be evenly divisible by 2 and 3.

As we're stuck with the whimsical aspects of length measurement, I've created the charts in Figures 3-83 and 3-84 to assist you in going from one system to another. From these you will see that when you need to drill a hole for a 5 mm LED, a 3/16-inch drill bit is about right. (In fact, it results in a better, tighter fit than if you drill an actual 5 mm hole.)

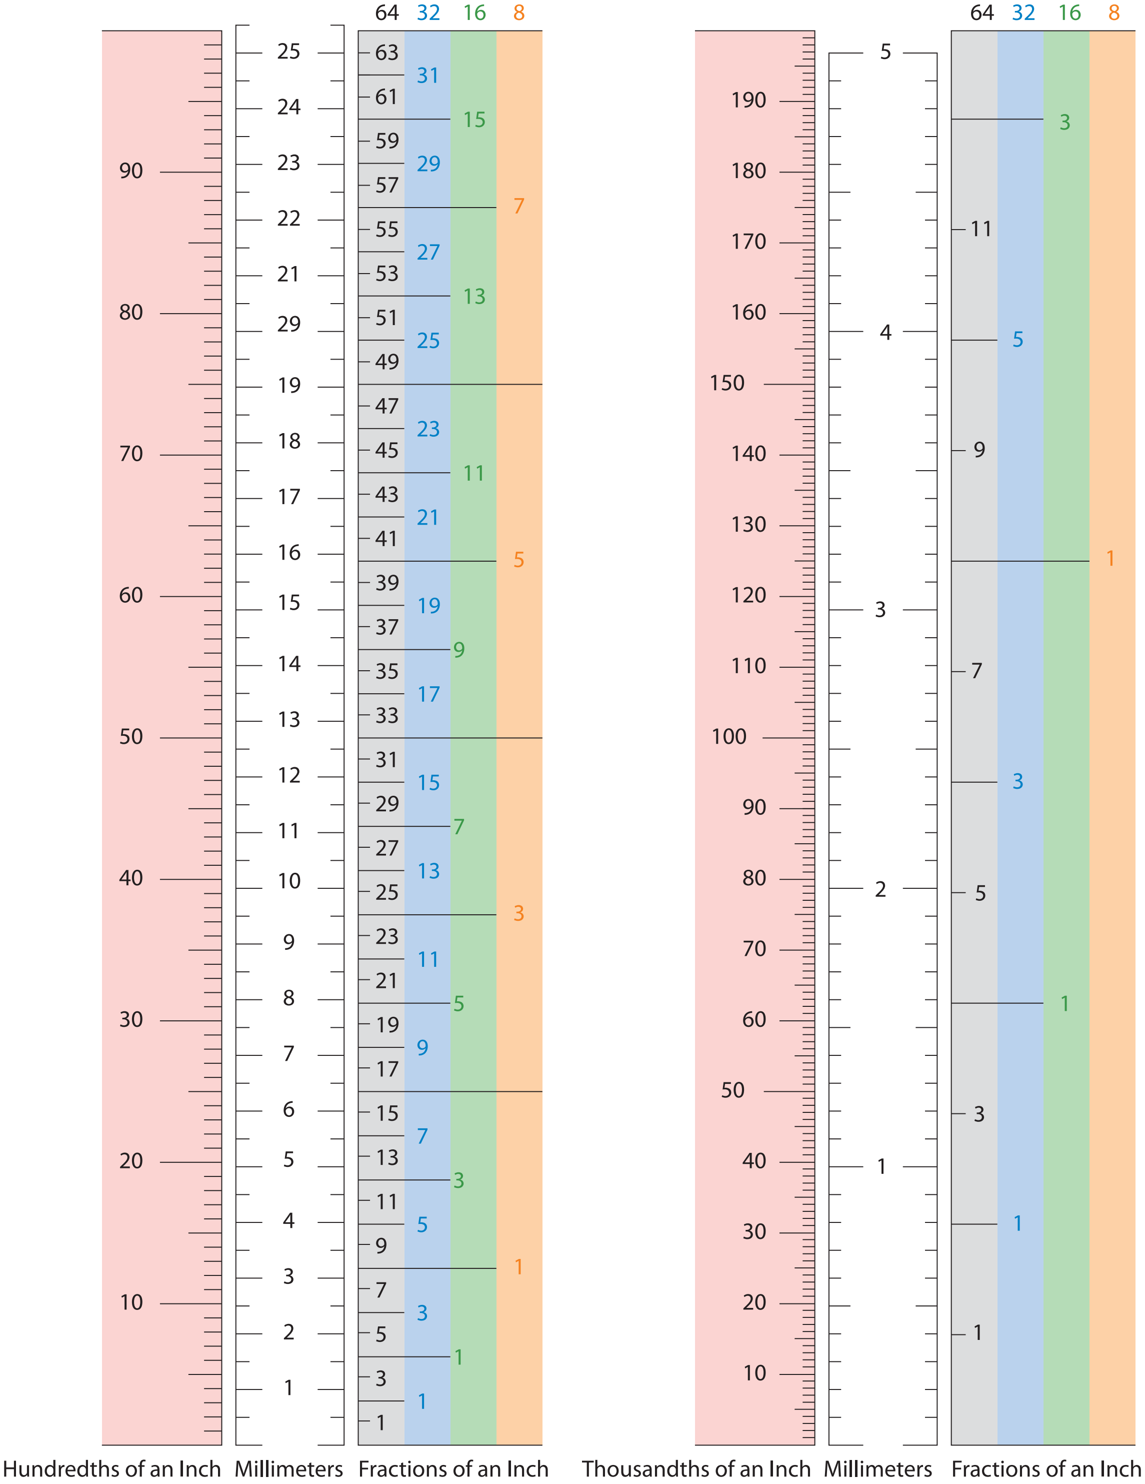

Figure 3-83. *Because units of measurement are not standardized in electronics, conversion is often necessary. The chart on the right is a 5x magnification of the bottom section of the chart on the left.*

Experiment 15: Intrusion Alarm Revisited

Time now to add some of the enhancements to the intrusion alarm that I discussed at the end of Experiment 11. I'm going to show you how the alarm can be triggered if you install various detectors on windows and doors in your home. I'll also show how the alarm can be wired so that it locks itself on and continues to make noise even after a door or window is reclosed.

This experiment will demonstrate the procedure for transferring a project from a breadboard to a piece of perforated board that has copper connections laid out identically to the ones inside the breadboard, as shown earlier in Figure 3-72. And you'll mount the finished circuit in a project box with switches and connectors on the front.

When all is said and done, you'll be ready for wholesale circuit building. The explanations in the rest of this book will get gradually briefer, and the pace will increase.

You will need:

- 15-watt pencil-type soldering iron
- Thin solder (0.022 inches or similar)
- Wire strippers and cutters
- Perforated board etched with copper in a breadboard layout
- Small vise or clamp to hold your perforated board
- The same components that you used in Experiment 11, plus:
    - 2N2222 NPN transistor. Quantity: 1.
    - DPDT relay. Quantity: 1.
    - SPDT toggle switch. Quantity: 1.
    - 1N4001 diode. Quantity: 1.
    - Red and green 5mm LEDs. Quantity: 1 each.
    - Project box, 6 × 3 × 2 inches.
    - Power jack, type N, and matching power socket, type N.
    - Binding posts.
    - Stranded 22-gauge wire, three different colors.
    - Magnetic sensor switches, sufficient for your home.
    - Alarm network wiring, sufficient for your home.

Magnetic Sensor Switches

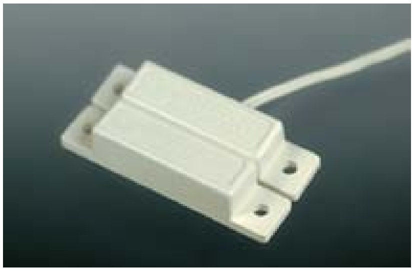

Figure 3-85. *In this simple alarm sensor switch, the lower module contains a magnet, which opens and closes a reed switch sealed into the upper module.*

A typical alarm sensor switch consists of two modules: the magnetic module and the switch module, as shown in Figures 3-85 and 3-86. The magnetic module contains a permanent magnet, and nothing else. The switch module contains a "reed switch," which makes or breaks a connection (like a contact inside a relay) under the influence of the magnet. When you bring the magnetic module close to the switch module, you may faintly hear the reed switch click as it flips from one state to the other.

Like all switches, reed switches can be normally open or normally closed. For this project, you want the kind of switch that is normally open, and closes when the magnetic module is close to it.

Attach the magnetic module to the moving part of a door or window, and attach the switch module to the window frame or door frame. When the window or door is closed, the magnetic module is almost touching the switch module. The magnet keeps the switch closed until the door or window is opened, at which point the switch opens.

The only question is: how do we use this component to trigger our alarm? As long as a small current flows through all our magnetic sensor switches, the alarm should be off, but if the flow of current stops, the alarm should switch on.

We could use a relay that is "always on" while the alarm is armed. When the circuit is interrupted, the relay relaxes and its other pair of contacts closes, which could power up the alarm noisemaker.

But I don't like this idea. Relays take significant power, and they can get hot. Most of them are not designed to be kept "always-on." I'd prefer to handle the task using a transistor.

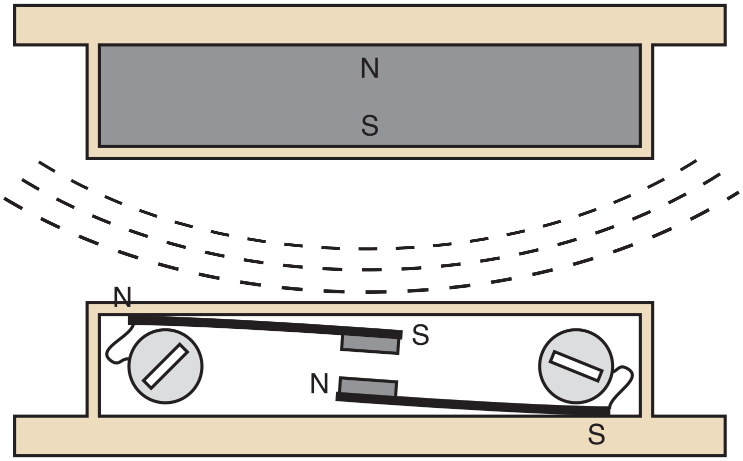

Figure 3-86. *This cutaway diagram shows a reed switch (bottom) and the magnet that activates it (top), inside an alarm sensor. The switch contains two flexible magnetized strips, the upper one with its south pole adjacent to an electrical contact, the lower one with its north pole adjacent to an electrical contact. When the south pole of the magnet approaches the switch, the magnetic force (shown as dashed lines) repels the south contact and attracts the north contact, causing them to snap together. Two screws on the outside of the casing are connected with the strips inside.*

A Break-to-Make Transistor Circuit

First, recall how an NPN transistor works. When the base is not sufficiently positive, the transistor blocks current between its collector and emitter, but when the base is relatively positive, the transistor passes current.

Take a look at the schematic in Figure 3-87, which is built around our old friend the 2N2222 NPN transistor. When the switch is closed, it connects the base of the transistor to the negative side of the power supply through a 1K resistor. At the same time, the base is connected with the positive side of the power supply through a 10K resistor. Because of the difference in resistances and the relatively high turn-on voltage for the LED, the base is forced below its turn-on threshold, and as a result, the transistor will not pass much current. The LED will glow dimly at best.

Now what happens when the switch is opened? The base of the transistor loses its negative power supply and has only its positive power supply. It becomes much more positive, above the turn-on threshold for the transistor, which tells the transistor to lower its resistance and pass more current. The LED now glows brightly. Thus, when the switch is turned off and breaks the connection, the LED is turned on.

This seems to be what we want. Imagine a whole series of switches instead of just one switch, as shown in Figure 3-88. The circuit will still work the same way, even if the switches are scattered all over your home, because the resistance in the wires connecting the switches will be trivial compared with the resistance of the 1K resistor.

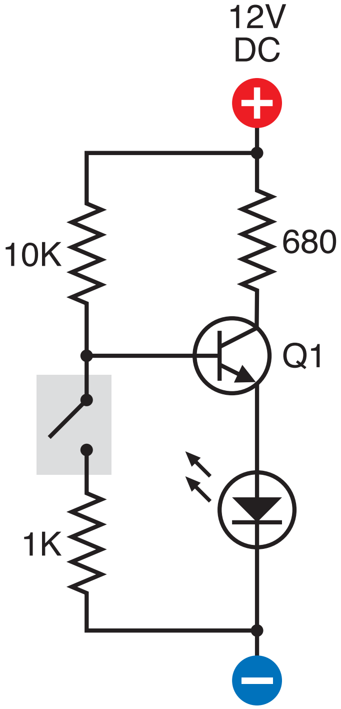

Figure 3-87. *In this demonstration circuit, when the switch is opened, it interrupts negative voltage to the base of the transistor, causing the transistor to lower its resistance, allowing current to reach the LED. Thus, when the switch is turned off, it turns on the LED.*

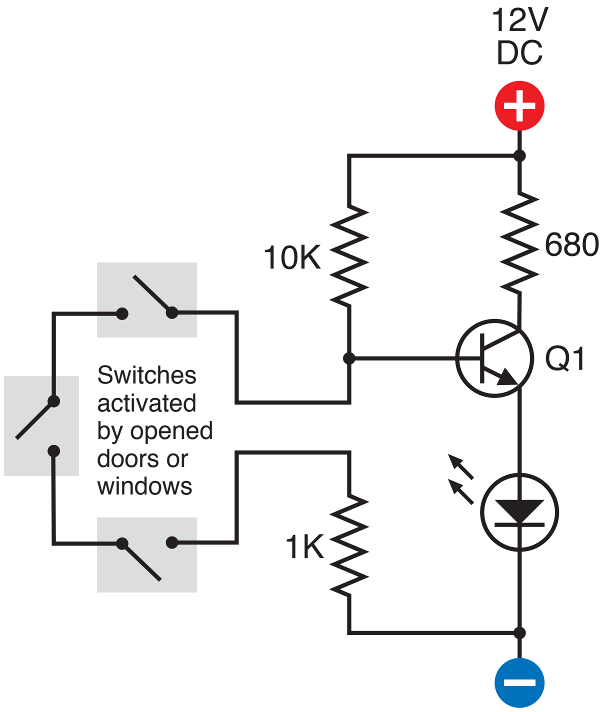

Figure 3-88. *A network of switches, wired in series, can be substituted for the single switch in Figure 3-87. Now any one switch will break continuity and trigger the transistor.*

I have shown the switches open, because that's the way the schematic for a switch is drawn, but imagine them all closed. The base of the transistor will now be supplied through the long piece of wire connecting all the closed switches, and the LED will stay dark. Now if just one switch is opened, or if anyone tampers with the wire linking them, the base of the transistor loses its connection to negative power, at which point the transistor conducts power and the LED lights up.

While all the switches remain closed, the circuit is drawing very little current—probably about 1.1 mA. So you could run it from a typical 12-volt alarm battery.

Now suppose we swap out the LED and put a relay in there instead, as shown in Figure 3-89. I don't mind using a relay in this location, because the relay will not be "always on." It will normally be off, and will draw power only when the alarm is triggered.

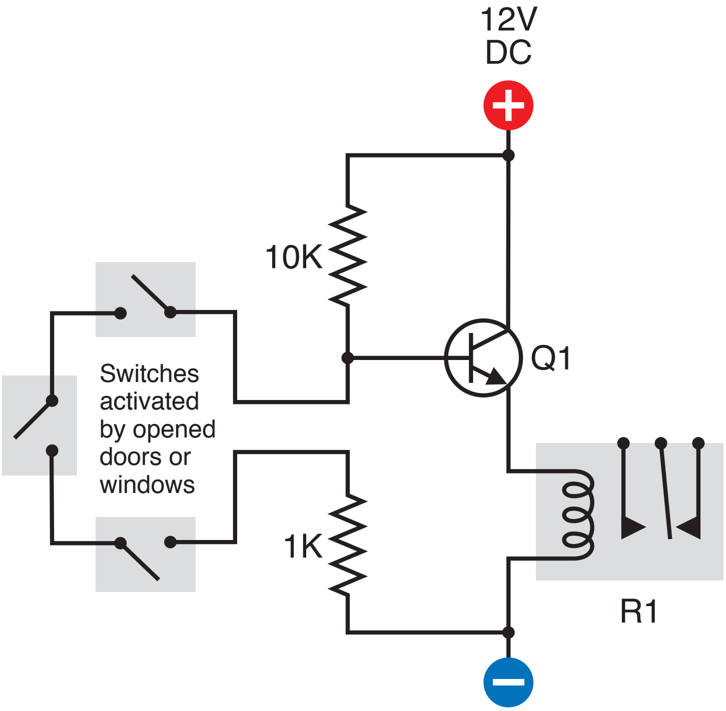

Figure 3-89. *If the LED and 680Ω resistor shown in are removed, and a relay takes their place, the relay will be activated when any switch in the sensor network is opened.*

Try one of the 12-volt relays that you used previously. You should find that when you open the switch, the relay is energized. When you close the switch, the relay goes back to sleep. Note that I eliminated the 680Ω resistor from the circuit, because the relay doesn't need any protection from the 12-volt power supply.

Self-Locking Relay

There's only one remaining problem: we want the alarm to continue making noise even after someone who has opened a door or window closes it again quickly. In other words, when the relay is activated, it must lock itself on.

One way to do this would be by using a latching relay. The only problem is that we would then need another piece of circuitry to unlatch it. I prefer to show you how you can make any relay keep itself switched on after it has received just one jolt of power. This idea will be useful to you later in the book as well.

The secret is to supply power to the relay coil through the two contacts inside the relay that are normally open. (Note that this is exactly opposite to the relay oscillator, which supplied power to its coil through the contacts that were normally closed. That setup caused the relay to switch itself off almost as soon as it switched itself on. This setup causes the relay to keep itself switched on, as soon as it has been activated.)

In Figure 3-90, the four schematics illustrate this. You can imagine them as being like frames in a movie, photographed microseconds apart. In the first picture, the switch is open, the relay is not energized, and nothing is happening. In the second, the switch has been closed to energize the coil. In the third, the coil has pulled the contact inside the relay, so that power now reaches the coil via two paths. In the fourth, the switch has been opened, but the relay is still powering its own coil through its contacts. It will remain locked in this state until the power is disconnected.

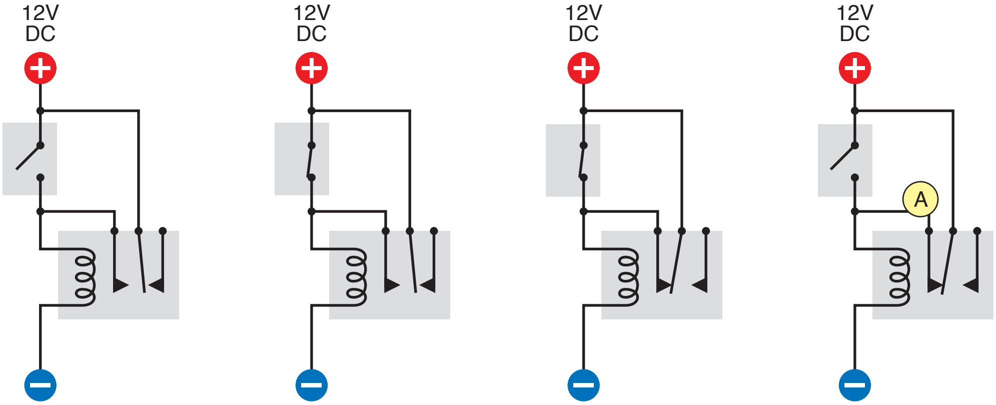

Figure 3-90. *This sequence of schematics shows the events that occur when a relay is energized. Initially, the switch is open. Then the switch is closed, activating the relay. The relay then powers itself through its own internal contacts. The relay remains energized even after the switch is opened again. Power switched by the relay can be taken from the circuit at point A.*

All we need to do, to make use of this idea, is to substitute the transistor for the on/off switch, and tap into the circuit at point A, running a wire from there to the noisemaking module.

Figure 3-91 shows how that would work. When the transistor is activated by any of the network of sensor switches, as previously explained, the transistor conducts power to the relay. The relay locks itself on, and the transistor becomes irrelevant.

Figure 3-92. *This block diagram previously shown in Figure 2-112 on page 90 has been updated to include the magnetic-switch network and locking-relay control system.*

Because I've been adding pieces to the original alarm noisemaker circuit, I've updated the block diagram from Figure 2-112 to show that we can still break this down into modules with simple functions. The revised diagram is shown in Figure 3-92.

Blocking Bad Voltage

One little problem remains: in the new version of the circuit, if the transistor goes off while the relay is still on, current from the relay can flow back up the wire to the emitter of the transistor, where it will try to flow backward through the transistor to the base, which is "more negative," as it is linked through all the magnetic switches and the 1K resistor to the negative side of the power supply.

Applying power backward through a transistor is not a nice thing to do. Therefore the final schematic in this series shows one more component, which you have not seen before: a diode, labeled D1. See Figure 3-93. The diode looks like the heart of an LED, and indeed, that's pretty much what it is, although some diodes are much more robust. It allows electricity to flow in only one direction, from positive to negative, as shown by its arrow symbol. If current tries to flow in the opposite direction, the diode blocks it. The only price you pay for this service is that the diode imposes a small voltage drop on electricity flowing in the "OK" direction.

So now, positive flow can pass from the transistor, through the diode, to the relay coil, to get things started. The relay then supplies itself with power, but the diode prevents the positive voltage from getting back into the transistor the wrong way.

Perhaps a more elegant solution to the problem is to connect the NO leg of the relay via a 10k resistor to the base connection. When the relay is not energized, the NO leg is inert and simply behaves as a parasitic capacitance on the node. When the relay becomes energized, the NO leg shunts +12V through the common terminal via a 10k resistor into the base of the transistor. In this circuit configuration, the transistor is never exposed to a potentially harmful voltage and you are not depending on leakage currents of non-ideal elements to protect devices.

However, I needed an opportunity to introduce you to the concept of diodes. You can check the following section "Essentials: All about diodes" to learn more.

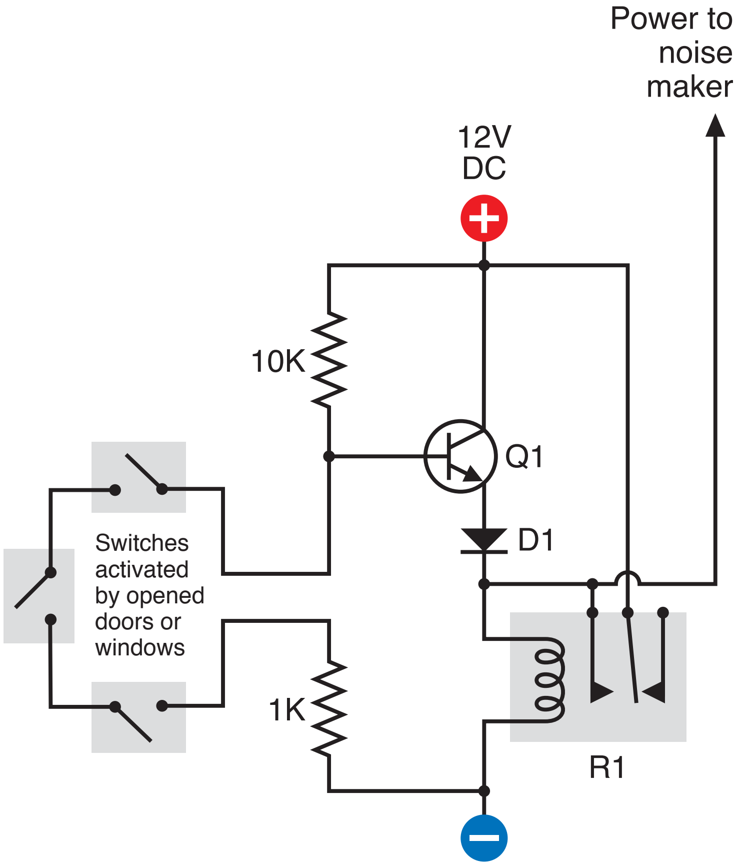

Figure 3-93. *Diode D1 has been added to protect the emitter of Q1 from positive voltage when the relay is energized.*

ESSENTIALS

All about diodes

A diode is a very early type of semiconductor. It allows electricity to flow in one direction, but blocks it in the opposite direction. (A light-emitting diode is a much more recent invention.) Like an LED, a diode can be damaged by reversing the voltage and applying excessive power, but most diodes generally have a much greater tolerance for this than LEDs. The end of the diode that blocks positive voltage is always marked, usually with a circular band, while the other end remains unmarked. Diodes are especially useful in logic circuits, and can also convert alternating current (AC) into direct current (DC).

A Zener diode is a special type that we won't be using in this book. It blocks current completely in one direction, and also blocks it in the other direction until a threshold voltage is reached—much like a PUT.

Signal diodes are available for various different voltages and wattages. The 1N4001 diode that I recommend for the alarm activation circuit is capable of handling a much greater load at a much higher voltage, but I used it because it has a low internal resistance. I wanted the diode to impose a minimal voltage drop, so that the relay would receive as much voltage as possible.

It's good practice to use diodes at less than their rated capacity. Like any semiconductor, they can overheat and burn out if they are subjected to mistreatment.

The schematic symbol for a diode has only one significant variant: sometimes the triangle is outlined instead of filled solid black (see Figure 3-94).

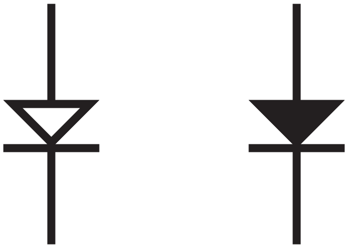

Figure 3-94. *Either of these schematic symbols may be used to represent a diode, but the one on the right is more common than the one on the left.*

Completing the Breadboard Alarm Circuit

It's time now to breadboard the control circuit for your alarm noisemaker. Figure 3-95 shows how this can be done. I am assuming that you still have the noisemaker, which functions as before. I'm assuming that you still have its relevant components mounted on the top half of the breadboard. To save space, I'm just going to show the additional components mounted on the bottom half of the same breadboard.

It's important to remember that you are not supplying power directly to the left and right "rails" on the breadboard anymore; you are supplying power to the relay-transistor section, and when the relay closes its contacts, the *relay* supplies power to the rails. These then feed the power up to the top half of the breadboard. So disconnect your power supply from the breadboard rails and reconnect it as shown in Figure 3-95.

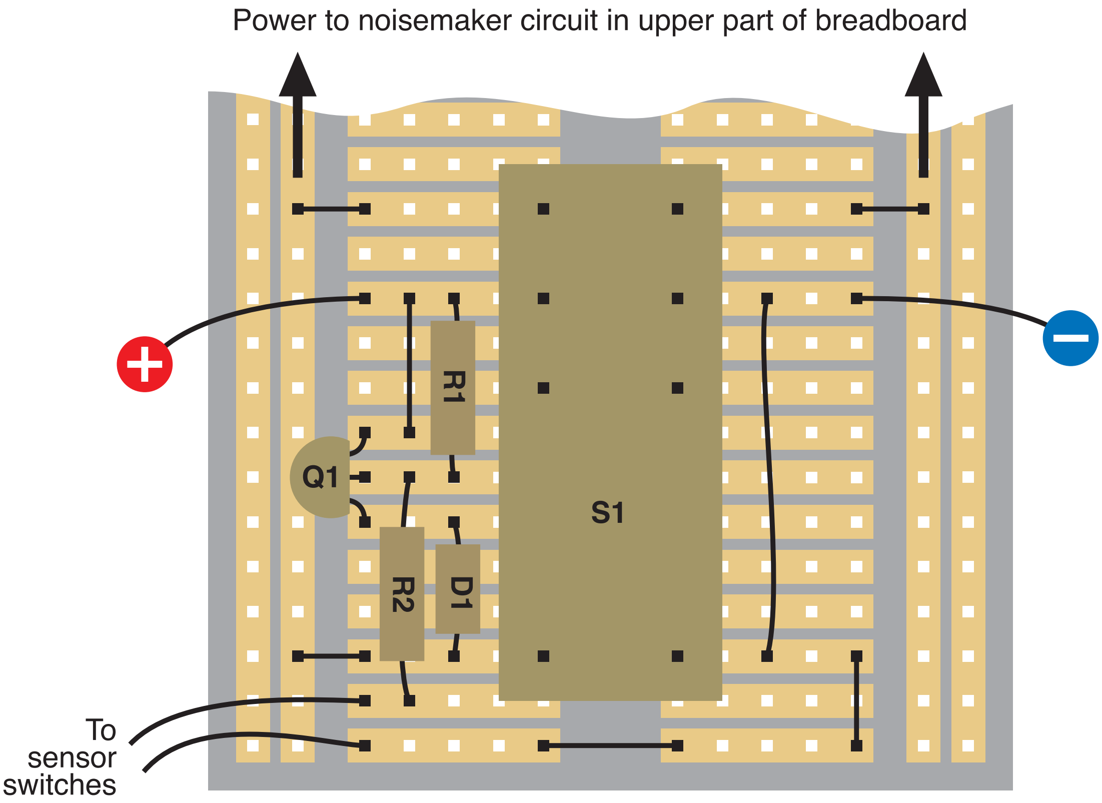

Figure 3-95. *The schematic that was developed in the previous pages can be emulated with components on a breadboard, as shown here. S1 is a DPDT relay. Wires to the sensor switch network and to the power supply must be added where shown.*

Because it's a double-pole relay, I am using it to switch negative as well as positive. This means that when the relay contacts are open, the noisemaking section of the circuit is completely isolated from the rest of the world.

The breadboarded relay circuit is exactly the same as the schematic in Figure 3-93. The components have just been rearranged and squeezed together so that they will fit alongside the relay. Two wires at the lower-left corner go to the network of magnetic sensor switches that will trip the alarm; for testing purposes, you can just hold the stripped ends of these two wires together to simulate all the switches being closed, and separate the wires to simulate a switch opening.

Two more wires bring power to the breadboard on either side of the relay. This is where you should connect your power supply during testing. The output from the relay, through its top pair of contacts, is connected with the rails of the breadboard by a little jumper wire at top left, and another at top right. Don't forget to include them! One more little wire at the lower-left corner (easily overlooked) connects the lefthand side rail to the lefthand coil terminal of the relay, so that when the relay is powering the noisemaker circuit, it powers itself as well.

When you mount the diode, remember that the end of it that is marked with a band around it is the end that blocks positive current. In this circuit, that's the lower end of the diode.

Try it to make sure that it works. Short the sensor wires together and then apply power. The alarm should remain silent. You can use your meter to check that no voltage exists between the side rails. Now separate the sensor wires, and the relay should click, supplying power to the side rails, which activates the noisemaker. Even if you bring the sensor wires back together, the relay should remain locked on. The only way to unlock it is to disconnect the power supply.

When the circuit is active, the transistor followed by the diode drops the voltage slightly, but the 12-volt relay should still work.

In my test circuit, trying three different relays, they drew between 27 and 40 milliamps at 9.6 volts. Some current still leaked through the transistor when it was in its "off" mode, but only a couple of milliamps at 0.5 volts. This low voltage was far below the threshold required to trip the relay.

Ready for Perfboarding

If the circuit works, the next step is to immortalize it on perforated board. Use the type of board that has a breadboard contact pattern etched on it in copper, as shown in Figure 3-72 on page 116. Check the following section, "Essentials: Perfboard procedure," for guidance on the best way to make this particular kind of solder joint—and the subsequent section for the most common problems.

ESSENTIALS

Perfboard soldering procedure

Carefully note the position of a component on your breadboard, and then move it to the same relative position on the perfboard, poking its wires through the little holes.

Turn the perfboard upside down, make sure that it's stable, and examine the hole where the wire is poking through, as shown in Figure 3-96. A copper trace surrounds this hole and links it with others. Your task is to melt solder so that it sticks to the copper and also to the wire, forming a solid, reliable connection between the two of them.

Take your pencil-style soldering iron in one hand and some solder in your other hand. Hold the tip of the iron against the wire and the copper, and feed some thin solder to their intersection. After two to four seconds, the solder should start flowing.

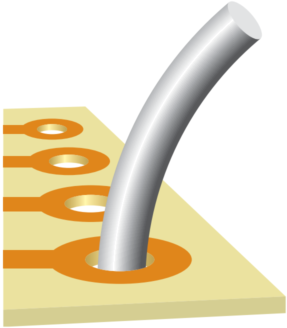

Figure 3-96

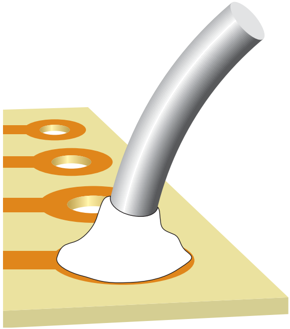

Figure 3-97

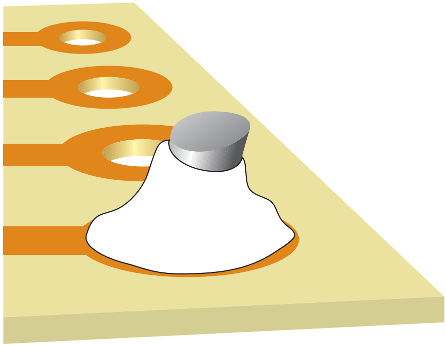

Figure 3-98. *To establish a connection between a section of wire and a copper trace on perforated board, the wire is pushed through the hole, and solder (shown in pure white for illustrative purposes) completes the connection. The wire can then be snipped short.*

Allow enough solder to form a rounded bump sealing the wire and the copper, as shown in Figure 3-97. Wait for the solder to harden thoroughly, and then grab the wire with pointed-nosed pliers and wiggle it to make sure you have a strong connection. If all is well, snip the protruding wire with your cutters. See Figure 3-98.

Because solder joints are difficult to photograph, I'm using drawings to show the wire before and after making a reasonably good joint, which is shown in pure white, outlined with a black line.

Actual soldered perfboard is shown in the photographs in Figures 3-99 and 3-100.

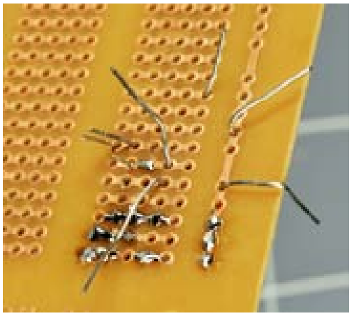

Figure 3-99. *This photograph was taken during the process of transferring components from breadboard to perforated board. Two or three components at a time are inserted from the other side of the board, and their leads are bent over to prevent them from falling out.*

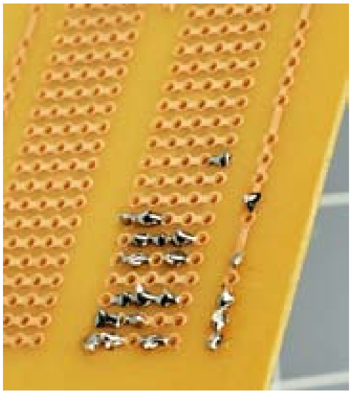

Figure 3-100. *After soldering, the leads are snipped short and the joints are inspected under a magnifying glass. Another two or three components can now be inserted, and the process can be repeated.*

TOOLS

Four most common perfboarding errors

1. Too much solder

Before you know it, solder creeps across the board, touches the next copper trace, and sticks to it, as depicted in Figure 3-101. When this happens, you have to wait for it to cool, and then cut it with a utility knife. You can also try to remove it with a rubber bulb and solder wick, but some of it will tend to remain.

Even a microscopic trace of solder is enough to create a short circuit. Check the wiring under a magnifying glass while turning the perfboard so that the light strikes it from different angles (or use your solder wick to suck it away).

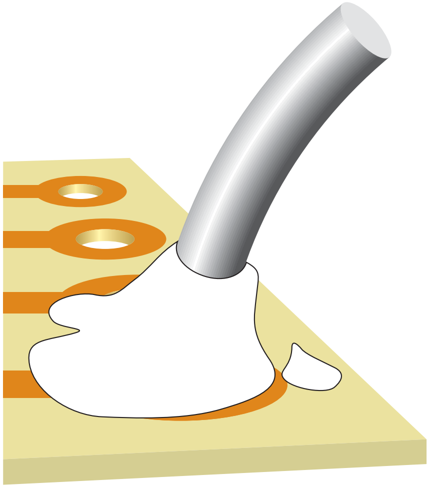

Figure 3-101. *If too much solder is used, it makes a mess and can create an unwanted connection with another conductor.*

2. Not enough solder

If the joint is thin, the wire can break free from the solder as it cools. Even a microscopic crack is sufficient to stop the circuit from working. In extreme cases, the solder sticks to the wire, and sticks to the copper trace around the wire, yet doesn't make a solid bridge connecting the two, leaving the wire encircled by solder yet untouched by it, as shown in Figure 3-102. You may find this undetectable unless you observe it with magnification.

You can add more solder to any joint that may have insufficient solder, but be sure to reheat the joint thoroughly.

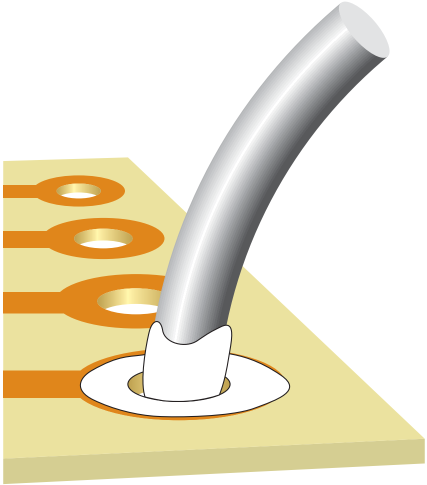

Figure 3-102. *Too little solder (or insufficient heat) can allow a soldered wire to remain separate from the soldered copper on the perforated board. Even a hair-thin gap is sufficient to prevent an electrical connection.*

3. Components incorrectly placed

It's very easy to put a component one hole away from the position where it should be. It's also easy to forget to make a connection.

I suggest that you print a copy of the schematic, and each time you make a connection on the perforated board, you eliminate that wire on your hardcopy, using a highlighter.

4. Debris

When you're trimming wires, the little fragments that you cut don't disappear. They start to clutter your work area, and one of them can easily get trapped under your perforated board, creating an electrical connection where you don't want it.

This is another reason for working with something soft, such as polyurethane foam, under your project. It tends to absorb or hold little pieces of debris, reducing the risk of you picking them up in your wiring.

Clean the underside of your board with an old (dry) toothbrush before you apply power to it, and keep your work area as neat as possible. The more meticulous you are, the fewer problems you'll have later.

Once again, be sure to check every joint with a magnifying glass.

Transferring components from the breadboard to the perforated board should be fairly simple, as long as you don't try to move too many at once. Follow the suggestions described in previous section "Essentials: Perfboard procedure," and pause frequently to check your connections. Impatience is almost always the cause of errors in this kind of work.

Figure 3-103 shows the noisemaker section of the circuit on perfboard, with the components positioned to minimize wasted space. Figure 3-104 shows the perfboard with the relay and its associated components added. The two black wires will go to the loudspeaker, the black-and-red pair of wires will bring power to the board, and the green wires will go to the magnetic sensor switches. Each wire penetrates the board, and its stripped end is soldered to the copper beneath.

Test it now, in the same way that you tested the same circuit on the breadboard. If it doesn't work, check the following section, "Essentials: Real-world fault tracing." If it does work, you're ready to trim the board and mount it in a project box.

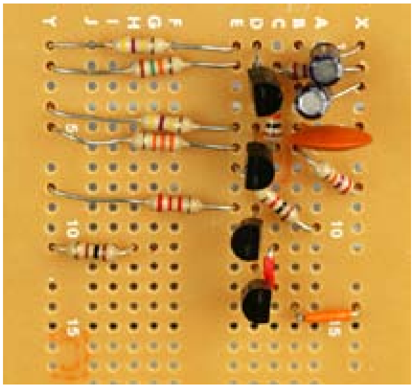

Figure 3-103. *The noisemaker circuit has been transplanted from breadboard to perforated board, with no additions or changes.*

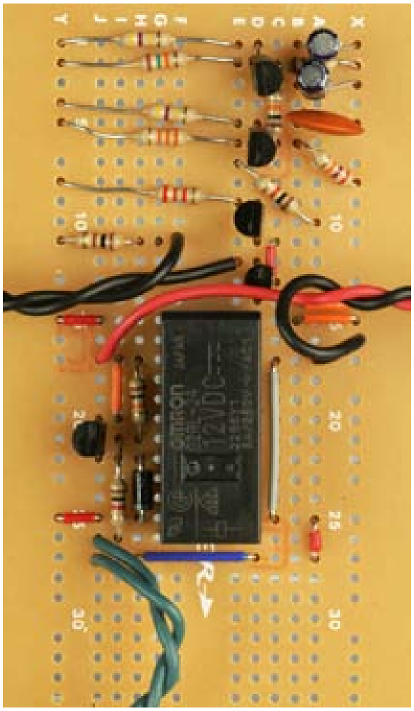

Figure 3-104. *The relay-transistor control circuit has been added. Wires to external devices have been stripped and poked into the perforated board, where they are soldered in place. The green wires connect with the sensor network, the black wires go to the loudspeaker, and the red-and-black wires supply power.*

ESSENTIALS

Real-world fault tracing

Here's a real-life description of the procedure for tracing a fault.

After I assembled the perfboard version of the combined noisemaker and relay circuit, I checked my work, applied power—and although the relay clicked, no sound came out of the loudspeaker. Of course, everything had worked fine on the breadboard.

First I looked at component placement, because this is the easiest thing to verify. I found no errors. Then I flexed the board gently while applying power—and the loudspeaker made a brief "beep." Any time this happens, you can be virtually certain that a solder joint has a tiny crack in it.

The next step was to anchor the black lead of my meter to the negative side of the power supply, and then switch on the power and go through the circuit point by point, from top to bottom, checking the voltage at each point with the red lead of the meter. In a simple circuit like this, every part should show at least some voltage.

But when I got to the second 2N2222 transistor, which powers the loudspeaker, its output was completely dead. Either I had melted the transistor while soldering it (unlikely), or there was a bad joint. I checked the perfboard beneath the transistor with the magnifying glass, and found that solder had flowed around one of the leads of the transistor without actually sticking to it. The gap must have been less than one-thousandth of an inch, but still, that was enough. Probably, the problem had been caused by dirt or grease.

This is the kind of patient inquiry you need to follow when a circuit doesn't work. Check whether your components are placed correctly, check your power supply, check the power on the board, check the voltage at each stage, and if you are persistent, you'll find the fault.

Switches and Inputs for the Alarm

Now you need to make the system easy to use. The block diagram in Figure 3-105 shows one additional box near the top of the sequence: User Controls. These will consist of switches, LEDs, and connections to the outside world. To plan this part of the job, first I have to summarize the way in which our alarm system works at this point in its evolution.

A full-featured home alarm system normally has two modes: in-home and away-from-home:

- Using the in-home mode, you switch on the alarm while you are at home so that it will alert you if an intruder opens a door or window.
- Using the away-from-home mode, typically you enter a code number, after which you have 30 seconds to leave and close the door behind you. When you return, you trigger the alarm by opening the door, but now you have 30 seconds to go to the control panel and enter your code number again to stop the alarm from sounding.

So far, the alarm system that you've been building has only an in-home mode. Still, many people find this function useful and reassuring. Later in the book I'll suggest a way in which you can modify it to incorporate an away-from-home mode, but for now, making it practical for in-home use is enough of a challenge.

Consider how it should be used on an everyday basis. It should have an on/off switch, naturally. When it's on, any of the magnetic sensor switches should trigger the alarm. But what if you switch it on without realizing that you've left a window open? At that time it won't be appropriate for the alarm to sound. What you really need is a circuit-test feature, to tell you if all the doors and windows are closed. Then you can switch on the alarm.

I think a pushbutton would be useful to test the alarm circuit. When you press it, a green LED should light up to indicate that the circuit is good. After you see the green light, you let go of the pushbutton and turn on the power switch, which illuminates a red LED, to remind you that the alarm is now armed and ready.

One additional feature would be useful: an alarm noisemaker test feature, so that you can be sure that the system is capable of sounding its alert when required to do so.

The circuit shown in Figure 3-106 incorporates all of these features. S1 is a SPDT switch; S2 is a DPDT momentary pushbutton of ON-(ON) type. The schematic shows it in its "relaxed" mode, when the button is not being pressed.

D1 is a red LED, D2 is a green LED, J1 is a power input jack (to be connected with an external 12-volt supply), and R1 is a 680Ω resistor to protect the LEDs. Note that J1 follows the usual practice of supplying positive voltage in its center contact, and negative in the circular shell around the center.

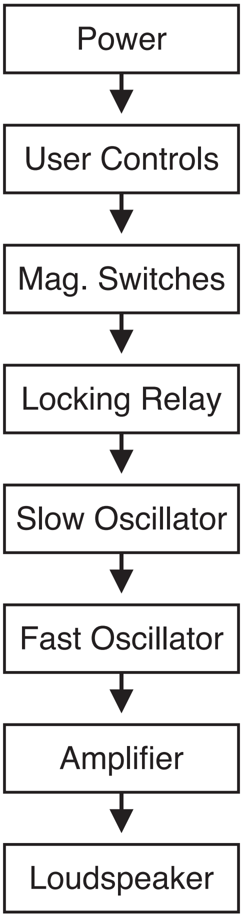

Figure 3-105. *The final block diagram for this phase of the project shows where user controls fit in the series of functions.*

When S1 is in its Off position, it still supplies positive power through its upper contact to S2, the pushbutton. When the pushbutton is pressed, so that it goes into its "Test" position, the pole of S2 connects with the power and sends it out through the sensor switches on doors and windows. The wires to these switches will be attached via a couple of binding posts, shown here as two circles. If the sensor switches are all closed, power returns through the second binding post, passes through the lower set of contacts in S2, and lights D2, the green LED. Because S1 is not supplying power to the alarm circuit board, the alarm does not sound at this time.

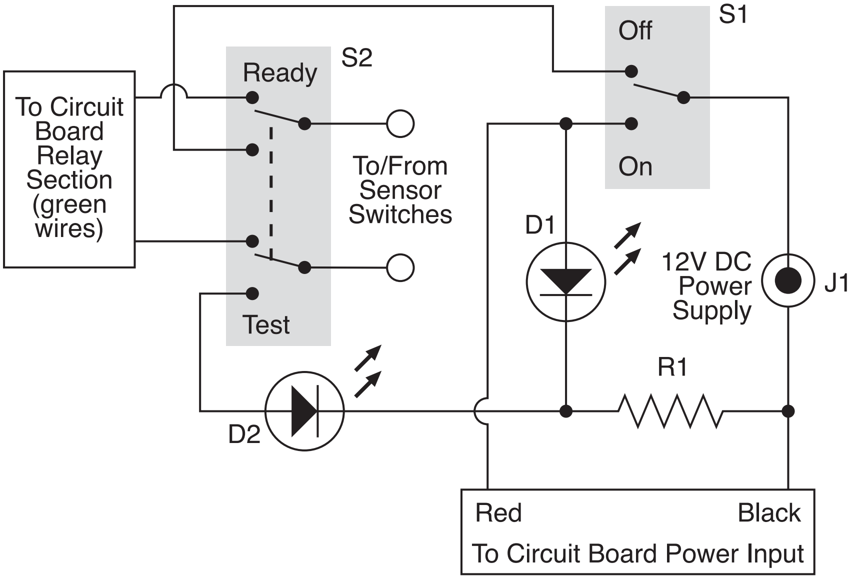

Figure 3-108. *This schematic suggests a convenient way to add an on/off switch, a continuity testing feature, and a noisemaker testing feature to the alarm.*

Now if S1 is turned to its On position, it sends power to the components on the perforated board. The transistor circuit sends power out along the green wires to S2, and as long as the button is not being pressed, the power goes out through the switch network and back through S2, to the transistor, keeping its base relatively negative. So the alarm remains silent. But as soon as a sensor switch is opened, the circuit is broken and the alarm sounds. The only way to stop it will be by switching S1 into its Off position.

Finally, if you press S2, the pushbutton, while S1 is in its On mode, you interrupt the network of switches and activate the noisemaker. In this way, S2 does dual duty: when S1 is off, pushbutton S2 tests the sensor switches for continuity. When S1 is on, S2 tests the noisemaker to make sure it creates a noise. I think this is the simplest possible way to implement these features.

Installing the Switches

If you bought a project box from RadioShack, it may have come with two optional top panels: one made of metal, the other made of plastic. I'll assume that you'll use the plastic one, as you'll have more trouble drilling holes in metal. The type of plastic used by RadioShack is ABS, which is very easy to shape with the tools that I have recommended.

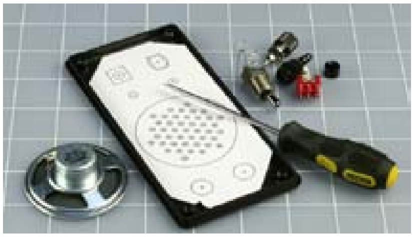

Figure 3-107. *A printed layout for the switches, LEDs, and other components has been taped to the underside of the lid of the project box. An awl is pressed through the paper to mark the center of each hole to be drilled in the lid.*

You have to choose a layout for the switches and other components that will share the top panel of the project box. I like a layout to be neat, so I take the trouble to draw it using illustration software, but a full-size pencil sketch is almost as good. Just make sure there's room for the components to fit together, and try to place them similarly to the schematic, to minimize the risk of confusion.

Tape your sketch to the inside of the top panel, as shown in Figure 3-107, and then use a sharp pointed tool, such as a pick, to press through and mark the plastic at the center of each hole. The indentations will help to center your bit when you drill the holes. Remember that you'll need to make multiple holes to vent the sound from the loudspeaker, which will be beneath the top panel of the box. The result is shown in Figure 3-108.

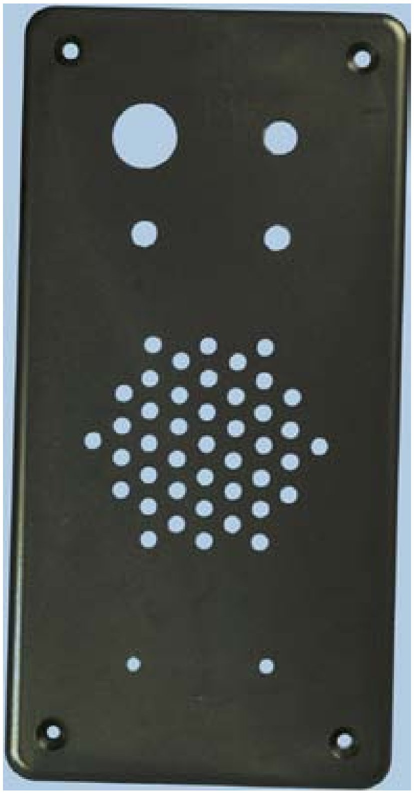

Figure 3-108. *The exterior of the panel after drilling. A small handheld cordless drill can create a neat result if the holes were marked carefully.*

I placed all the components on the top panel, with the exception of the power input jack, which I positioned at one end of the box. Naturally, each hole has to be sized to fit its component, and if you have calipers, they'll be very useful for taking measurements and selecting the right drill bit. Otherwise, make your best guess, too small being better than too large. A deburring tool is ideal for slightly enlarging a hole so that a component fits snugly. This may be necessary if you drill 3/16-inch holes for your 5-inch mm LEDs. Fractionally enlarge each hole, and the LEDs should push in very snugly.

If your loudspeaker lacks mounting holes, you'll have to glue it in place. I used five-minute epoxy to do this. Be careful not to use too much. You don't want any of the glue to touch the speaker cone.

Drilling large holes in the thin, soft plastic of a project box can be a problem. The drill bit tends to dig in and create a mess. You can approach this problem in one of three ways:

1. Use a Forstner drill bit if you have one. It creates a very clean hole.
2. Drill a series of holes of increasing size.
3. Drill a smaller hole than you need, and enlarge it with a deburring tool.

Regardless of which approach you use, you'll need to clamp or hold the top panel of the project box with its outside surface face-down on a piece of scrap wood. Then drill from the inside, so that your bit will pass through the plastic and into the wood.

Finally, mount the components in the panel, as shown in Figure 3-109, and turn your attention to the underneath part of the box.

The circuit board will sit on the bottom, held in place with four #4-size machine screws (bolts) with washers and nylon-insert locknuts. You need to use locknuts to eliminate the risk of a nut working loose and falling among components where it can cause a short circuit.

You'll have to cut the perfboard to fit, taking care not to damage any of the components on it. Also check the underside the board for loose fragments of copper traces after you finish cutting.

Drill bolt holes in the board, if necessary, taking care again not to damage any components. Then mark through the holes to the plastic bottom of the box, and drill the box. Countersink the holes (i.e., bevel the edges of a hole so that a flat-headed screw will fit into it flush with the surrounding surface), push the little bolts up from underneath, and install the circuit board. Be extremely careful not to attach the circuit board too tightly to the project box. This can impose bending stresses, which may break a joint or a copper trace on the board.

I like to include a soft piece of plastic under the board to absorb any stresses. Because you're using locknuts, which will not loosen, there's no need to make them especially tight.

Test the circuit again after mounting the circuit board, just in case.

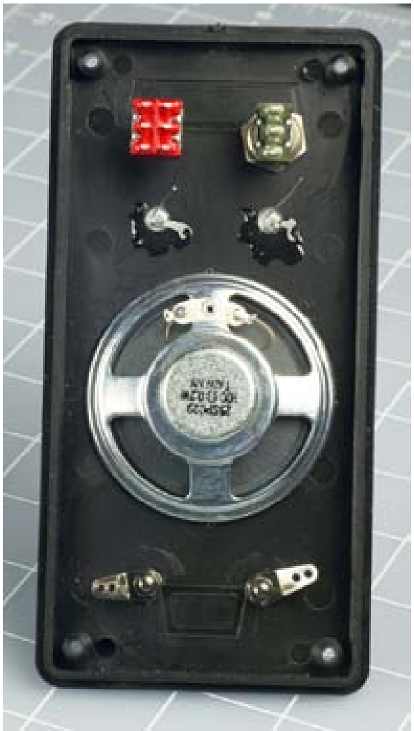

Figure 3-109. *Components have been added to the control panel of the project box (seen from the underside). The loudspeaker has been glued in place. Spare glue was dabbed onto the LEDs, just in case. The SPDT on/off switch is at the top right, the DPDT pushbutton is at top left, and the binding posts, which will connect with the network of magnetic sensor switches, are at the bottom.*

Soldering the Switches

Figure 3-110 shows how the physical switches should be wired together. Remember that S1 is a toggle switch and S2 is a DPDT pushbutton. Your first step is to decide which way up they should be. Use your meter to find out which terminals are connected when the switch is flipped, and when the button is pressed. You'll probably want the switch to be on when the toggle is flipped upward. Be especially careful with the orientation of the pushbutton, because if you wire it upside-down, it will constantly have the alarm in "test" mode, which is not what you want.

Remember, the center terminal of any double-throw switch is almost always the pole of the switch, connecting with the terminals immediately above it and below it.

Stranded wire is appropriate to connect the circuit board with the components in the top panel, because the strands flex easily and impose less stress on solder joints. Twisting each pair of wires together helps to minimize the mess.

Remember to install the LEDs with their short, negative wires connected with the resistor. This will entail some wire-to-wire soldering. You may want to protect some of these bare leads and joints with thin heat-shrink tubing, to minimize the risk of short circuits when you push all the parts into the box.

When you connect wires or components with the lugs on the switches, your pencil-style soldering iron probably won't deliver enough heat to make good joints. You can use your higher-powered soldering iron in these locations, but you absolutely must apply a good heat sink to protect the LEDs when you attach them, and don't allow the iron to remain in contact with anything for more than 10 seconds. It will quickly melt insulation, and may even damage the internal parts of the switches.

In projects that are more complex than this one, it would be good practice to link the top panel with the circuit board more neatly. Multicolored ribbon cable is ideal for this purpose, with plug-and-socket connectors that attach to the board. For this introductory project, I didn't bother. The wires just straggle around, as shown in Figure 3-111.

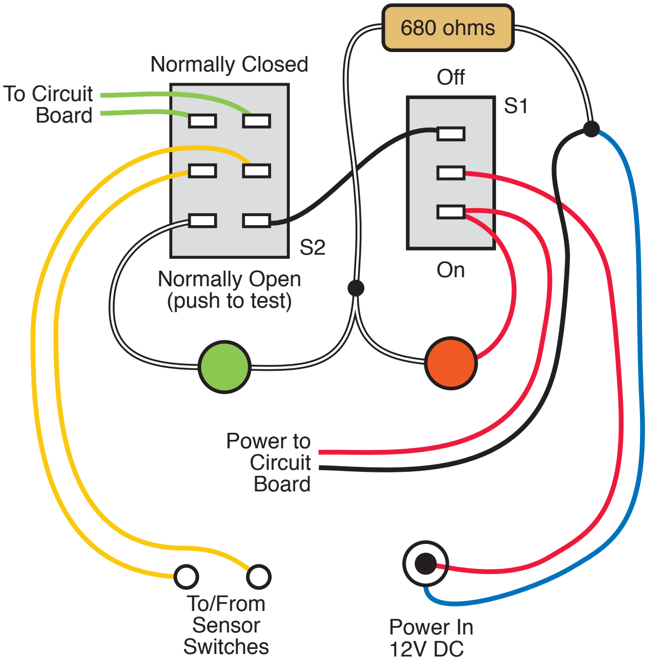

Figure 3-110. *The components can be wired together like this to replicate the circuit shown in The red and green circles are LEDs. Small, solid black circles indicate wire-to-wire solder joints.*

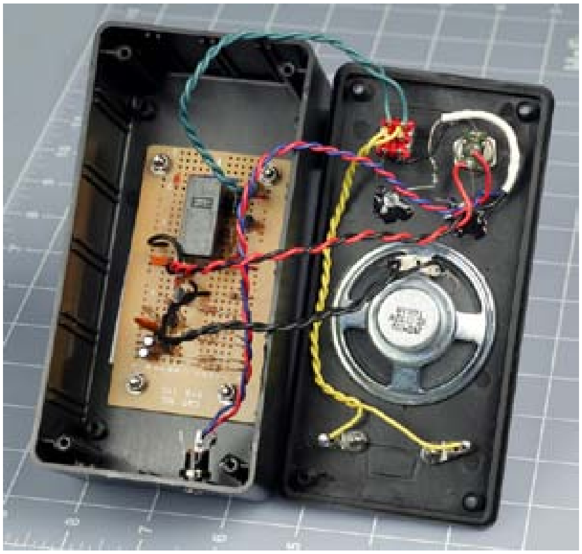

Figure 3-111. *The circuit board has been installed in the base of the project box, and the power input jack has been screwed into the end of the box. Twisted wire-pairs have been connected on a point-to-point basis, without much concern over neatness, as this is a relatively small project. The white insulation at the top-right corner of the front panel is heat-shrink tube that encloses a solder joint and the 680Ω load resistor. Soldering wires to the pushbutton switch requires care and precision, as the contacts are closely spaced.*

Final Test

When you've completed the circuit, test it! If you don't have your network of magnetic sensor switches set up yet, you can just use a piece of wire to connect the two binding posts. Make sure that S1 is in its Off position, then solder the appropriate plug to your 12-volt power source, and plug it into the power jack. When you press the button, the green LED should light up to show continuity between the two binding posts. Now disconnect the wire between the binding posts, press the button again, and the green LED should remain dark.

Reconnect the binding posts, flip S1 to its On position, and the red LED should light up. Press the button, and the alarm should start. Reset it by turning S1 off and then on again; then disconnect the wire between the binding posts. Again, the alarm should start, and it should continue even if you reconnect the wire.

If everything works the way it should, it's time to screw the top of the box in place, pushing the wires inside. Because you're using a large box, you should have no risk of metal parts touching each other accidentally, but still, proceed carefully.

Alarm Installation

Before you install your magnetic sensor switches, you should test each one by moving the magnetic module near the switch module and then away from it, while you use your meter to test continuity between the switch terminals. The switch should close when it's next to the magnet, and open when the magnet is removed.

Now draw a sketch of how you'll wire your switches together. Always remember that they have to be in series, not in parallel! Figure 3-112 shows the concept in theory. The two terminals are the binding posts on top of your control box (which is shown in green), and the dark red rectangles are the magnetic sensor switches on windows and doors. Because the wire for this kind of installation usually has two conductors, you can lay it as I've indicated but cut and solder it to create branches. The solder joints are shown as orange dots. Note how current flows through all the switches in series before it gets back to the control box.

Figure 3-113 shows the same network as you might actually install it in a situation where you have two windows and a door. The blue rectangles are the magnetic modules that activate the switch modules.

You'll need a large quantity of wire, obviously. The type of white, stranded wire that is sold for doorbells or furnace thermostats is good. Typically, it is 20-gauge or larger.

After you install all the switches, clip your meter leads to the wires that would normally attach to the alarm box. Set your meter to test continuity, and open each window or door, one at a time, to check whether you're breaking the continuity. If everything is OK, attach the alarm wires to the binding posts on your project box.

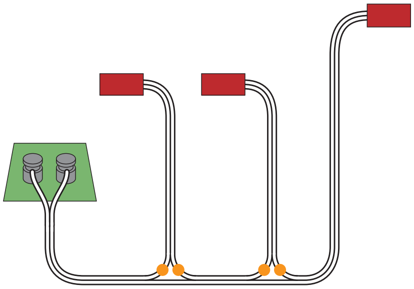

Figure 3-112. *Dual-conductor, white insulated wire can be used to connect the terminals on the alarm control box with magnetic sensors (shown in dark red). Because the sensors must be in series, the wire is cut and joined at positions marked with orange dots.*

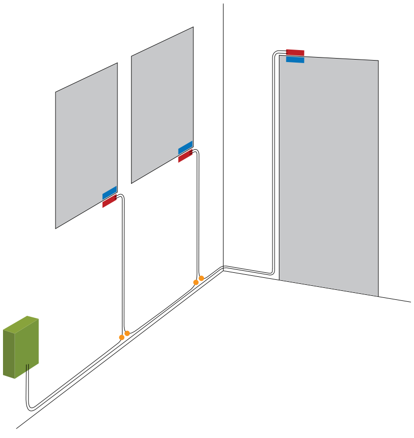

Figure 3-113. *In an installation involving two windows and a door, the magnetic components of the sensors (blue rectangles) could be placed as shown, while the switches (dark red) are located alongside them.*

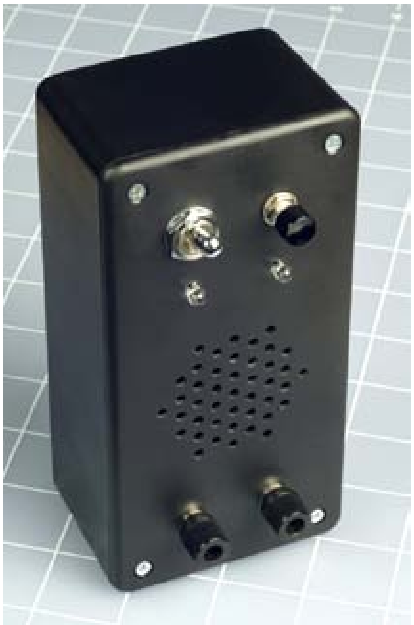

Figure 3-114. *The intrusion alarm completed and in its project box.*

Now deal with the power supply. Use your AC adapter, set to 12 volts, hooked up to your type N power plug, or attach the power plug to a 12-volt alarm battery.

If you use a battery, be especially careful that the wire leading to the center terminal of your power plug is positive! A 12-volt battery can deliver substantial current, which can fry your components if you connect it the wrong way around. It would be a shame to destroy your entire project at the very last step.

The only remaining task is to label the switch, button, power socket, and binding posts on the alarm box. You know that the switch turns the power on and off, and the button tests the circuit and the noisemaker, but no one else knows, and you might want to allow a guest to use your alarm while you're away. For that matter, months or years from now, you may forget some details. Will you remember that the power source for this unit should be 12 volts?

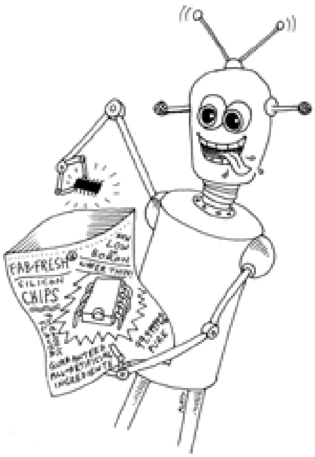
Labeling really is a good idea. But as you can see in Figure 3-114, I haven't quite gotten around to it for the box that I built.

Conclusion

The alarm project has taken you through the basic steps that you will usually follow any time you develop something:

1. Draw a schematic and make sure that you understand it.
2. Modify it to fit the pattern of conductors on a breadboard.
3. Install components on the breadboard and test the basic functions.
4. Modify or enhance the circuit, and retest.
5. Transfer to perforated board, test, and trace faults if necessary.
6. Add switches, buttons, power jack, and plugs or sockets to connect the circuit with the outside world.
7. Mount everything in a box (and add labeling).

While going through this sequence, I hope you've learned the basics of electricity, along with some simple electrical theory, and fundamentals about electronic components. This knowledge should enable you to move on to the much more powerful realm of integrated circuit—which I'll cover in Chapter 4.



4

Chips, Ahoy!

IN THIS CHAPTER

Shopping List: Experiments 16 Through 24
Experiment 16: Emitting a Pulse
Experiment 17: Set Your Tone
Experiment 18: Reaction Timer
Experiment 19: Learning Logic
Experiment 20: A Powerful Combination
Experiment 21: Race to Place
Experiment 22: Flipping and Bouncing
Experiment 23: Nice Dice
Experiment 24: Intrusion Alarm Completed

Before I get into the fascinating topic of integrated circuit (IC) chips, I have to make a confession: some of the things I asked you to do in Chapter 3 could have been done a bit more simply. Does this mean you have been wasting your time? No, I firmly believe that by building circuits with old-fashioned components—capacitors, resistors, and transistors—you acquire the best possible understanding of the principles of electronics. Still, you are going to find that integrated circuit chips, containing dozens, hundreds, or even thousands of transistor junctions, will enable some shortcuts.

Shopping List: Experiments 16 Through 24

Tools

The only new tool that I recommend using in conjunction with chips is a logic probe. This tells you whether a single pin on a chip has a high or low voltage, which can be helpful in figuring out what your circuit is doing. The probe has a memory function so that it will light its LED, and keep it lit, in response to a pulse that may have been too quick for the eye to see.

Search online and buy the cheapest logic probe you can find. I don't have any specific brand recommendations. The one shown in Figure 4-1 is fairly typical.

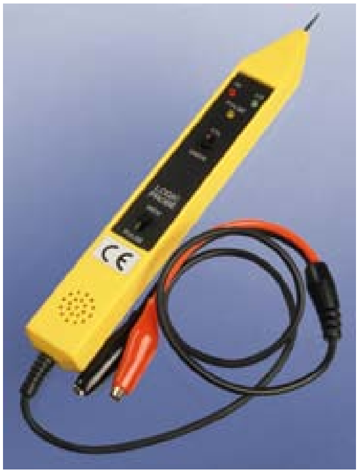


Figure 4-1. *A logic probe detects the high or low voltage on each pin of a chip, and reveals pulses that may occur too quickly for you to perceive them with the unaided eye.*

Supplies

Integrated circuit chips

If you buy everything on this shopping list, and you bought basic parts such as resistors and capacitors that were listed previously, you should have everything you need for all the projects in this chapter.

As chips are quite cheap (currently around 50 cents apiece), I suggest you buy extras. This way, if you damage one, you'll have some in reserve. You'll also have a stock for future projects.

Please read the next section, "Fundamentals: Choosing chips," before you begin chip-shopping. Chips should be easily obtainable from all the major electronics retail suppliers, and sometimes are found on eBay shops. Look in the appendix for a complete list of URLs.

FUNDAMENTALS

Choosing chips

Figure 4-2 shows what is often referred to as an integrated circuit (IC). The circuit is actually etched onto a tiny wafer or "chip" of silicon, embedded in a black plastic body, which is properly referred to as the "package." Tiny wires inside the package link the circuit with the two rows of pins on either side. Throughout this book, I will use the word "chip" to refer to the whole object, including its pins, as this is the most common usage.

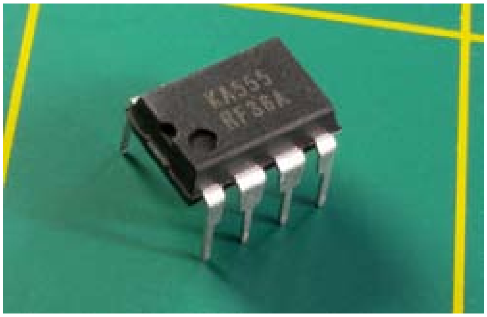

Figure 4-2. *An integrated circuit chip in Plastic Dual-Inline Pin package, abbreviated PDIP, or, more often, DIP.*

The pins are mounted at intervals of 1/10 inch in two rows spaced 3/10 inch apart. This format is known as a Plastic Dual Inline Package, abbreviated PDIP, or, more often, just DIP. The chip in the photograph has four pins in each row; others may have many more. The first thing you need to know, when shopping for chips, is that you'll only be using the DIP package. This book will not be featuring the more modern type, known as "surface-mount," because they're much smaller, more difficult to handle, and require special tools that are relatively expensive. Figure 4-3 shows a size comparison between a 14-pin DIP package and a 14-pin surface-mount package. Many surface-mount chips are even smaller than the one shown.

Just about every chip has a part number printed on it. In Figure 4-2, the part number is KA555. In Figure 4-3, the DIP chip's part number is M74HC00B1, and the surface-mount chip is a 74LVC07AD. You can ignore the second line of numbers and/or letters on each chip, as they are not part of the part number.

Notice in Figure 4-3 that even though the chips look quite different from each other, they both have "74" in their part numbers. This is because both of them are members of the "7400" family of logic chips, which originally had part numbers from 7400 and upward (7400, 7401, 7402, 7403, and so on). Often they are now referred to as "74xx" chips, where "xx" includes all the members of the family. I'll be using this family a lot, so you need to know how to buy them. I'll give you some advice on that without going into details yet about what the chips actually do.

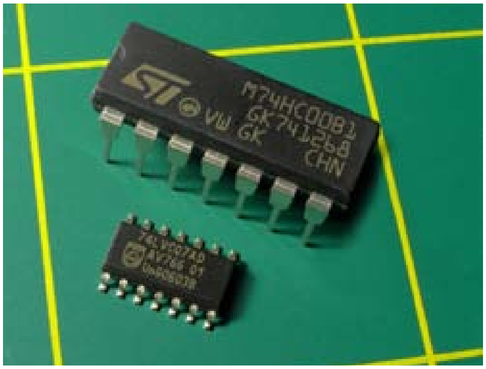

Figure 4-3. *The DIP chip, at the rear, has pins spaced 1/10 inch apart, suitable for insertion in a breadboard or perforated board. It can be soldered without special tools. The small-outline integrated circuit (SOIC) surface-mount chip (foreground) has solder tabs spaced at 1/20 inch. Other surface-mount chips have pins spaced at 1/40 inch or even less (these dimensions are often expressed in millimeters). Surface-mount chips are designed primarily for automated assembly and are difficult to work with manually. In this photo, the yellow lines are 1 inch apart to give you an idea of the scale.*

Take a look at Figure 4-4, which shows how to interpret a typical part number in a 74xx family member. The initial letters identify the manufacturer (which you can ignore, as it really makes no difference for our purposes). Skip the letters until you get to the "74." After that, you find two more letters, which are important. The 74xx family has evolved through many generations, and the letter(s) inserted after the "74" tell you which generation you're dealing with. Some generations have included:

- 74L
- 74LS
- 74C
- 74HC
- 74AHC

And there are more. Generally speaking, subsequent generations tend to be faster or more versatile than previous generations. In this book, for reasons I'll explain later, we are mostly using the HC generation.

FUNDAMENTALS

Choosing chips (continued)

After the letters identifying the generation, you'll find two (sometimes more) numerals. These identify the specific function of the chip. You can ignore any remaining letters and numerals. Looking back at Figure 4-3, the DIP chip part number, M74HC00B1 tells you that it is a chip in the 74xx family, HC generation, with its function identified by numerals 00. The surface-mount chip number, 74LVC07AD, tells you that it is in the 74xx family, LVC generation, with function identified by numerals 07. For convenience we could refer to the first chip as a "74HC00" and the second chip as a "74HC07" because, regardless of their different manufacturers and package sizes, the fundamental behavior of the circuit inside remains the same.

The purpose of this long explanation is to enable you to interpret catalog listings when you go chip shopping. You can search for "74HC00" and the online vendors are usually smart enough to show you appropriate chips from multiple manufacturers, even though there are letters preceding and following the term that you're searched for.

Suppose a circuit requires a 74HC04 chip. If you search for "74HC04" on the website of a parts supplier, you may find versions such as the CD74HC04M96 by Texas Instruments, the 74HC04N by NXP Semiconductors, or MM74HC04N by Fairchild Semiconductor. Because they all have "74HC04" in the middle, any of them will work.

Just be careful that you buy the larger DIP-style package, not the surface-mount package. If the part number has an "N" on the end, you can be sure that it's a DIP package. If there is no "N" on the end, it may or may not be a DIP package, and you will have to check a photo or additional description to make sure. If the part number begins with SS, SO, or TSS, it's absolutely definitely surface-mount, and you don't want it. Many catalogs show photographs of the chips to assist you in buying the right package style.

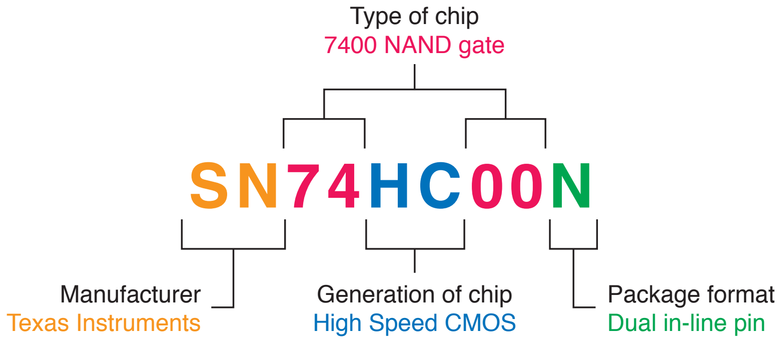

Figure 4-4. *Look for the chip family (74xx, in this case) with the correct generation (HC, in this case) embedded in the number. Make sure you buy the DIP version, not the surface-mount version. The manufacturer is unimportant.*

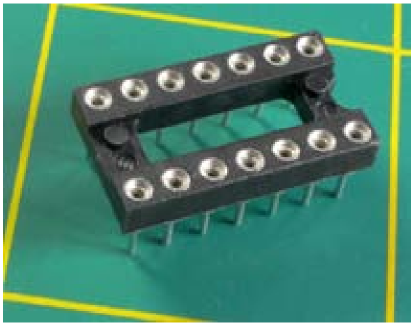

Figure 4-5. *When you're soldering a circuit onto perforated board, sockets eliminate the risk of overheating integrated circuit chips and reduce the risk of zapping them with static electricity, and enable easy replacement.*

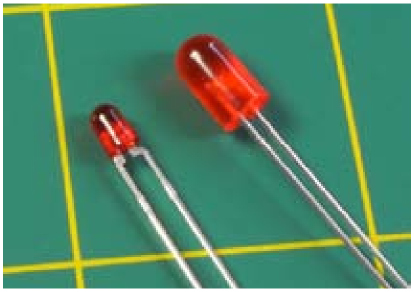

Figure 4-6. *An HC series logic chip is rated to deliver only 4mA at each pin. This is inadequate to drive a typical 5 mm LED (right), which is rated for 20mA forward current. Miniature, low-current LEDs (left) will use as little as 1mA in series with a suitable resistor, and are ideal for test circuits in which you want to see the output with a minimum of hassle.*

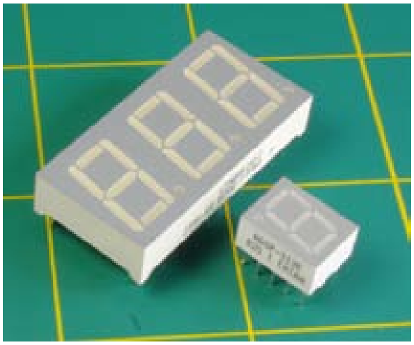

Figure 4-7. *Seven-segment displays are the simplest way to show a numeric output and can be driven directly by some CMOS chips. For finished projects, they are typically mounted behind transparent red acrylic plastic panels.*

Here's your chip list:

- 555 Timer. STMicroelectronics SA555N, Fairchild NE555D, RadioShack TLC555, or similar. Do not get the "CMOS" version of this chip, or any fancy versions such as those of high precision. Buy the cheapest you can find. Quantity: 10. The chip in Figure 4-2 is a 555 timer.
- Logic chips types 74HC00, 74HC02, 74HC04, 74HC08, 74HC32, and 74HC86. Actual part numbers could be M74HC00B1, M74HC02B1, M74HC04B1, and so on, by STMicroelectronics, or SN74HC00N, SN74HC02N, SN74HC04N, and so on, by Texas Instruments. Any other manufacturers are acceptable.
- Remember, each part number should have "HC" in the middle of it, and you want the DIP or PDIP package, not surface-mount. Quantity of each: At least 4.
- 4026 Decade Counter (a chip that counts in tens). Texas Instruments CD-4026BE or similar. Quantity: 4 (you'll need 3, but because this is a CMOS chip sensitive to static electricity, you should have at least one in reserve). Any chip with "4026" in its part number should be OK.
- 74LS92 counter chip, 74LS06 open-collector inverter chip, and 74LS27 triple-input NOR chip. Quantity: 2 of each. Note the "LS" in these part numbers! There will be one experiment in which I want you to use the LS generation instead of the HC generation.

IC sockets

I suggest that you avoid soldering chips directly onto perforated board. If you damage them, they're difficult to remove. Buy some DIP sockets, solder the sockets onto the board, and then plug the chips into the sockets. You can use the cheapest sockets you can find (you don't need gold-plated contacts for our purposes). You will need 8-pin, 14-pin, and 16-pin DIP sockets, such as parts 276-1995, 276-1999, and 276-1998 from RadioShack. See Figure 4-5. Quantity of each: 5 minimum.

Low-power LEDs

The logic chips that you'll be using are not designed to deliver significant power. You'll need to add transistors to amplify their output if you want to drive bright LEDs or relays. Because adding transistors is a hassle, I suggest an alternative: Special low-power LEDs that will draw as little as 1mA, such as the Everlight model T-100 Low Current Red, part number HLMPK150. Figure 4-6 shows a size comparison with a regular 5mm LED. Quantity: 10 (at a minimum).

LED numeric displays

In at least one of our projects, you'll want to illuminate some seven-segment LED numerals. You'll need either three individual numerals, or one package containing three numerals, such as the Kingbright High Efficiency Red Diffused, part number BC56-11EWA, which will be specifically referred to in schematics in this book. If you buy a different seven-segment display, it must be an LED with a "common cathode." (Don't buy liquid-crystal LCD numerals; they require different electronics to drive them.) If you have a choice of power consumption, buy whichever product consumes the least current. See Figure 4-7.

Latching relays

You're going to need a 5-volt latching relay that has two coils, instead of one. The first coil flips the relay one way; the second coil flips it back. The relay consumes no additional power while remaining passively in each state. I suggest the Panasonic DS2E-SL2-DC5V relay. If you buy a different relay, it must be dual-coil latching to run off 5 volts DC, switching at least 1 amp, in a "2 form C" package, to fit your breadboard.

Potentiometers

You'll need 5K, 10K, and 100K linear potentiometers (one of each). Also, a 10K trimmer potentiometer (which you may find described just as a "trimmer"). The manufacturer is unimportant.

Voltage regulators

Because many logic chips require precisely 5 volts DC, you need a voltage regulator to deliver this. The LM7805 does the job. Here again, the chip number will be preceded or followed with an abbreviation identifying the manufacturer and package style, as in the LM7805CT from Fairchild. Any manufacturer will do, but the package should look like the one in Figure 4-8, and if you have a choice, buy a regulator that can deliver at least 1 amp.

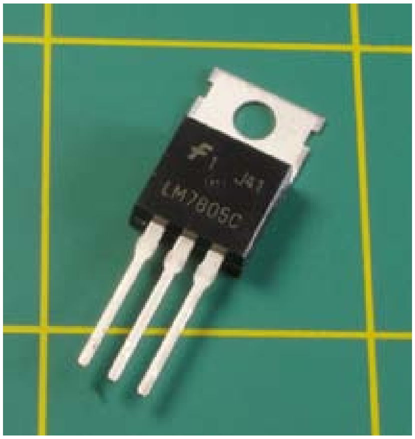

Figure 4-8. *Many integrated circuit chips require a controlled power supply of 5 volts, which can be delivered by this regulator when you apply 7.5 to 9 volts to it. The lefthand pin is for positive input, the center pin is a common ground, and the righthand pin is the 5V output. For currents exceeding 250mA, you should bolt the regulator to a metal heat sink using the hole at the top.*

Tactile switches

These are SPST pushbuttons (momentary switches), usually with four legs. Look for the ALPS part number SKHHAKA010 or any similar item that has pins to fit your breadboard or perforated board. See Figure 4-9.

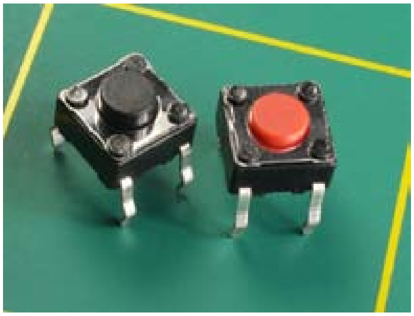

Figure 4-9. *A tactile switch delivers tactile feedback through your fingertip when you press it. They are almost always SPST pushbuttons designed for mounting in circuit boards with standard 1/10-inch hole spacing.*

12-key numeric keypad

Velleman "12 keys keyboard with common output" (no part number, but has been available through All Electronics under catalog code KP-12). Quantity: 1.

This type of keypad has the same layout as an old-fashioned touchtone phone. It should have at least 13 pins or contacts, 12 of which connect with individual pushbuttons, the thirteenth connecting with the other side of all the pushbuttons. In other words, the last pin is "common" to all of them, and this type of keypad is often described as having a "common output." The type of keypad that you don't want is "matrix-encoded," with fewer than 13 contacts, requiring additional external circuitry. See Figures 4-10 and 4-11. If you can't find the Velleman keypad that I suggest, look carefully at keypad descriptions and photographs to make sure that the one you buy is not matrix-encoded and has a common terminal.

Alternatively, you may substitute 12 cheap SPST NO pushbuttons and mount them in a small project box.

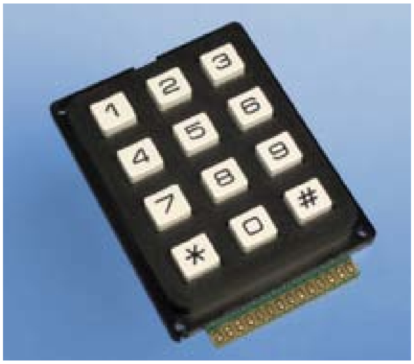

Figure 4-10. *When shopping for a numeric keypad, it should have 12 keys in "touch-tone phone" layout, and should have at least 13 contacts for input/output. The contacts are visible here along the front edge.*

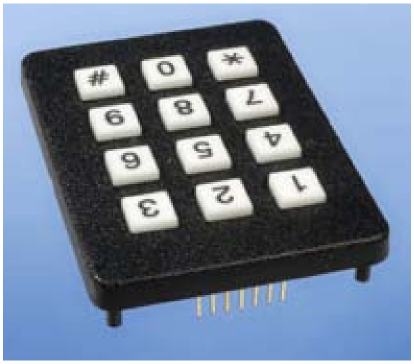

Figure 4-11. *This keypad has insufficient pins and will not work in the circuit in this book.*

BACKGROUND

How chips came to be

The concept of integrating solid-state components into one little package originated with British radar scientist Geoffrey W. A. Dummer, who talked about it for years before he attempted, unsuccessfully, to build one in 1956. The first true integrated circuit wasn't fabricated until 1958 by Jack Kilby, working at Texas Instruments. Kilby's version used germanium, as this element was already in use as a semiconductor. (You'll encounter a germanium diode when I deal with crystal radios in the next chapter of this book.) But Robert Noyce, pictured in Figure 4-12, had a better idea.

Born in 1927 in Iowa, in the 1950s Noyce moved to California, where he found a job working for William Shockley. This was shortly after Shockley had set up a business based around the transistor, which he had coinvented at Bell Labs.

Noyce was one of eight employees who became frustrated with Shockley's management and left to establish Fairchild Semiconductor. While he was the general manager of Fairchild, Noyce invented a silicon-based integrated circuit that avoided the manufacturing problems associated with germanium. He is generally credited as the man who made integrated circuits possible.

Early applications were for military use, as Minuteman missiles required small, light components in their guidance systems. These applications consumed almost all chips produced from 1960 through 1963, during which time the unit price fell from around $1,000 to $25 each, in 1963 dollars.

In the late 1960s, medium-scale integration chips emerged, each containing hundreds of transistors. Large-scale integration enabled tens of thousands of transistors on one chip by the mid-1970s, and today's chips can contain as many as several billion transistors.

Robert Noyce eventually cofounded Intel with Gordon Moore, but died unexpectedly of a heart attack in 1990. You can learn more about the fascinating early history of chip design and fabrication at *http://www.siliconvalleyhistorical.org*.

Figure 4-12. *This picture of Robert Noyce, late in his career, is from the Wikimedia Commons.*

Experiment 16: Emitting a Pulse

I'm going to introduce you to the most successful chip ever made: the 555 timer. As you can find numerous guides to it online, you might question the need to discuss it here, but I have three reasons for doing so:

1. It's unavoidable. You simply have to know about this chip. Some sources estimate that more than 1 billion are still being manufactured annually. It will be used in one way or another in most of the remaining circuits in this book.
2. It provides a perfect introduction to integrated circuits, because it's robust, versatile, and illustrates two functions that we'll be dealing with later: comparators and a flip-flop.
3. After reading all the guides to the 555 that I could find, beginning with the original Fairchild Semiconductor data sheet and making my way through various hobby texts, I concluded that its inner workings are seldom explained very clearly. I want to give you a graphic understanding of what's happening inside it, because if you don't have this, you won't be in a good position to use the chip creatively.

You will need:

- 9-volt power supply.
- Breadboard, jumper wires, and multimeter.
- 5K linear potentiometer. Quantity: 1.
- 555 timer chip. Quantity: 1.
- Assorted resistors and capacitors.
- SPST tactile switches. Quantity: 2.
- LED (any type). Quantity: 1.

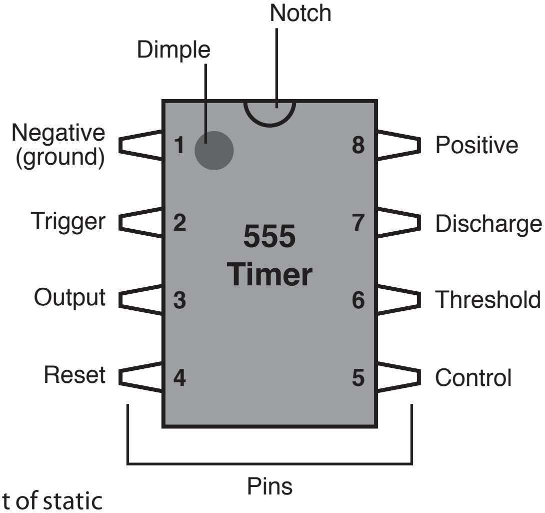

Figure 4-13. *The 555 timer chip, seen from above. Pins on chips are always numbered counterclockwise, from the top-left corner, with a notch in the body of the chip uppermost, or a circular indentation at top-left, to remind you which end is up.*

Procedure

The 555 chip is very robust, but still, in theory, you can zap it with a jolt of static electricity and kill it. Therefore, to be on the safe side, you should ground yourself before handling it. See the "Grounding yourself" warning on page 172 for details. Although this warning primarily refers to the type of chips known as CMOS, which are especially vulnerable, grounding yourself is always a sensible precaution.

Look for a small circular indentation, called the *dimple*, molded into the body of the chip, and turn the chip so that the indentation is at the top-left corner with the pins pointing down. Alternatively, if your chip is of the type with a notch at one end, turn the chip so that the notch is at the top.

The pins on chips are always numbered counterclockwise, starting from the top-left pin (next to the dimple). See Figure 4-13, which also shows the names of the pins on the 555 timer, although you don't need to know most of them just yet.

Insert the chip in your breadboard so that its pins straddle the channel down the center. Now you can easily feed voltages to the pins on either side, and read signals out of them. See Figure 4-14 for a precise guide to placement, in the first project. The timer is identified as "IC1," because "IC" is the customary abbreviation for "Integrated Circuit."

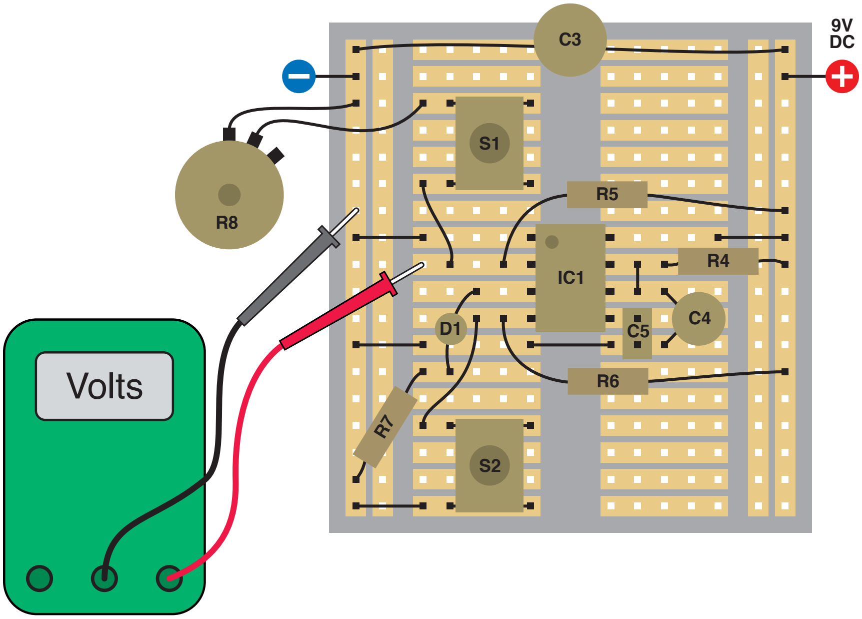

Figure 4-14. *This circuit allows you to explore the behavior of the 555 timer chip. Use your meter to monitor the voltage on pin 2 as shown. There are no resistors labeled R1, R2, or R3 and no capacitors labeled C1 or C2, because they'll be added in a later schematic. Component values in this schematic:*

R4: 100K
R5: 2K2
R6: 10K
R7: 1K
R8: 5K linear potentiometer
C3: 100 µF electrolytic
C4: 47 µF electrolytic
C5: 0.1 µF ceramic
IC1: 555 timer
S1, S2: SPST tactile switches (pushbuttons)
D1: Generic LED

R5 holds the trigger (pin 2) positive until S1 is pressed, which lowers the voltage depending on the setting of potentiometer R8. When the trigger voltage falls below 1/3 of the power supply, the chip's output (pin 3) goes high for a period determined by the values of R4 and C4. S2 resets (zeros) the timer, by reducing the voltage to pin 4, the Reset. C3 smoothes the power supply, and C5 isolates pin 5, the control, so that it won't interfere with the functioning of this test circuit. (We'll use the control pin in a future experiment.)

All integrated circuit chips require a power supply. The 555 is powered with negative voltage applied to pin 1 and positive to pin 8. If you reverse the voltage accidentally, this can permanently damage the chip, so place your jumper wires carefully.

Set your power supply to deliver 9 volts. It will be convenient for this experiment if you supply positive down the righthand side and negative down the lefthand side of the breadboard, as suggested in Figure 4-14. C3 is a large capacitor, at least 100 µF, which is placed across the power supply to smooth it out and provide a local store of charge to fuel fast-switching circuits, as well as to guard against other transient dips in voltage. Although the 555 isn't especially fast-switching, other chips are, and you should get into the habit of protecting them.

Begin with the potentiometer turned all the way counterclockwise to maximize the resistance between the two terminals that we're using, and when you apply the probe from your meter to pin 2, you should measure about 6 volts when you press S1.

Now rotate the potentiometer clockwise and press S1 again. If the LED doesn't light up, keep turning the potentiometer and pressing and releasing the button. When you've turned the potentiometer about two-thirds of the way, you should see the LED light up for just over 5 seconds when you press and release the button. Here are some facts that you should check for yourself:

- The LED will keep glowing after you release the button.
- You can press the button for any length of time (less than the timer's cycle time) and the LED always emits the same length of pulse.
- The timer is triggered by a fall in voltage on pin 2. You can verify this with your meter.
- The LED is either fully on or fully off. You can't see a faint glow when it's off, and the transition from off to on and on to off is very clean and precise.

Check Figure 4-16 to see how the components should look on your breadboard, and then look at the schematic in Figure 4-15 to understand what's happening. I will be adding more components later, which I will be labeling R1, R2, C1, and C2 to be consistent with data sheets that you may see for the 555 timer. Therefore, in this initial circuit the resistors are labeled R4 and up, and capacitors C3 and up.

When S1 (the tactile switch) is open, pin 2 of the 555 timer receives positive power through R5, which is 2K2. Because the input resistance of the timer is very high, the voltage on pin 2 is almost the full 9 volts.

When you press the button, it connects negative voltage through R8, the 5K potentiometer to pin 2. Thus, R8 and R5 form a voltage divider with pin 2 in the middle. You may remember this concept from when you were testing transistors. The voltage between the resistances will change, depending on the values of the resistances.

If R8 is turned up about halfway, it is approximately equal to R5, so the midpoint, connected to pin 2, has about half the 9-volt power supply. But when you turn the potentiometer so that its resistance falls farther, the negative voltage outweighs the positive voltage, so the voltage on pin 2 gradually drops.

If you have clips on your meter leads, you can hook them onto the nearest jumper wires and then watch the meter while you turn the potentiometer up and down and press the button.

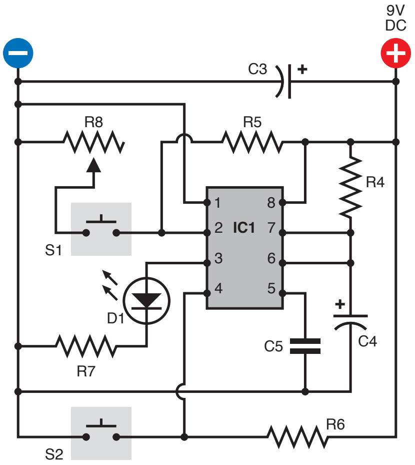

Figure 4-15. *A schematic view of the circuit shown in Figure 4-14. Throughout this chapter, the schematics will be laid out to emulate the most likely placement of components on a breadboard. This is not always the simplest layout, but will be easiest for you to build. Refer to Figure 4-14 for the values of the components.*

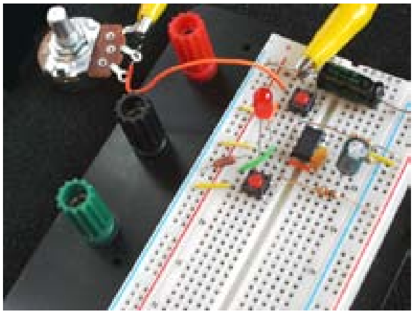

Figure 4-16. *This is how the components look when installed on the breadboard. The alligator clips are attached to a patch cord that links the 100 µF capacitor to the potentiometer. The power supply input is not shown.*

The graphs in Figure 4-17 illustrate what is happening. The upper graph shows the voltage applied to pin 2 by random button-presses, with the potentiometer turned to various values. The lower graph shows that the 555 is triggered if, and only if, the voltage on pin 2 actively drops from above 3 volts to below 3 volts. What's so special about 3 volts? It's one-third of our 9-volt power supply.

Here's the take-home message:

- The output of the 555 (pin 3) emits a *positive* pulse when the trigger (pin 2) drops *below* one-third of the supply voltage.
- The 555 delivers the *same duration* of positive pulse every time (so long as you don't supply a prolonged low voltage on pin 2).
- A *larger* value for R4 or for C4 will *lengthen* the pulse.
- When the output (pin 3) is high, the voltage is almost equal to the supply voltage. When the output goes low, it's almost zero.

The 555 converts the imperfect world around it into a precise and dependable output. It doesn't switch on and off absolutely instantly, but is fast enough to *appear* instant.

Now here's another thing to try. Trigger the timer so that the LED lights up. While it is illuminated, press S2, the second button, which grounds pin 4, the reset. The LED should go out immediately.

When the reset voltage is pulled *low*, the output goes *low*, regardless of what voltage you apply to the trigger.

There's one other thing I want you to notice before we start using the timer for more interesting purposes. I included R5 and R6 so that when you first switch on the timer, it is not emitting a pulse—but is ready to do so. These resistors apply a positive voltage to the trigger and the reset pin, to make sure that the 555 timer is ready to run when you first apply power to it.

As long as the *trigger* voltage is *high*, the timer *will not* emit a pulse. (It emits a pulse when the trigger voltage drops.)

As long as the *reset* voltage is *high*, the timer is *able* to emit a pulse. (It shuts down when the reset voltage drops.)

R5 and R6 are known as "pull-up resistors" because they pull the voltage up. You can easily overwhelm them by adding a direct connection to the negative side of the power supply. A typical pull-up resistor for the 555 timer is 10K. With a 9-volt power supply, it only passes 0.9mA (by Ohm's Law).

Finally, you may be wondering about the purpose of C5, attached to pin 5. This pin is known the "control" pin, which means that if you apply a voltage to it, you can control the sensitivity of the timer. I'll get to this in more detail a little later. Because we are not using this function right now, it's good practice to put a capacitor on pin 5 to protect it from voltage fluctuations and prevent it from interfering with normal functioning.

Make sure you become familiar with the basic functioning of the 555 timer before you continue.

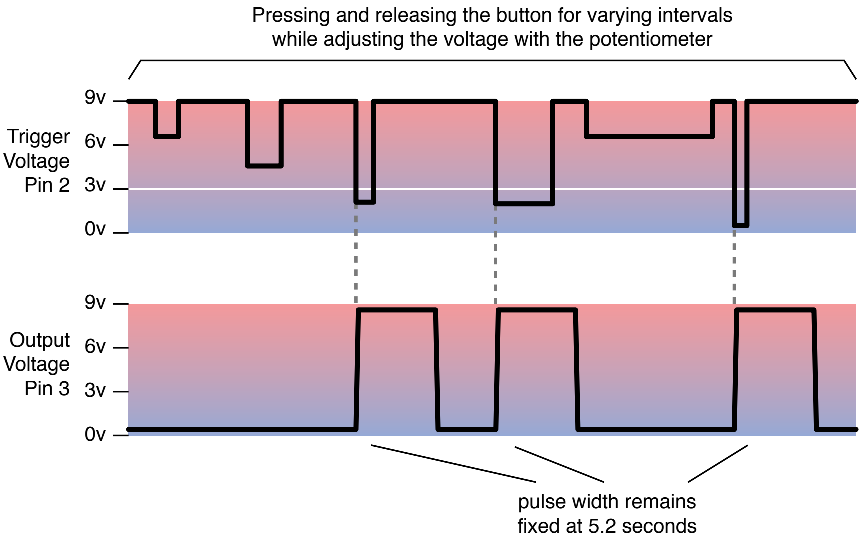

Figure 4-17. *The top graph shows voltage on the trigger (pin 2) when the pushbutton is pressed, for different intervals, at different settings of the potentiometer. The lower graph shows the output (pin 3), which rises until it is almost equal to the power supply, when the voltage on pin 2 drops below 1/3 the full supply voltage.*

FUNDAMENTALS

The following table shows 555 pulse duration in monostable mode:

- Duration is in seconds, rounded to two figures.
- The horizontal scale shows common resistor values between pin 7 and positive supply voltage.
- The vertical scale shows common capacitor values between pin 6 and negative supply voltage.

To calculate a different pulse duration, multiply resistance × capacitance × 0.0011 where resistance is in kilohms, capacitance is in microfarads, and duration is in seconds.

47 µF	0.05	0.11	0.24	0.52	1.1	2.4	5.2	11	24	52

THEORY

Inside the 555 timer: monostable mode

The plastic body of the 555 timer contains a wafer of silicon on which are etched dozens of transistor junctions in a pattern that is far too complex to be explained here. However, I can summarize their function by dividing them into groups, as shown in Figure 4-18. An external resistor and two external capacitors are also shown, labeled the same way as in Figure 4-15.

The negative and positive symbols inside the chip are power sources which actually come from pins 1 and 8, respectively. I omitted the internal connections to those pins for the sake of clarity.

The two yellow triangles are "comparators." Each comparator compares two inputs (at the base of the triangle) and delivers an output (from the apex of the triangle) depending on whether the inputs are similar or different. We'll be using comparators for other purposes later in this book.

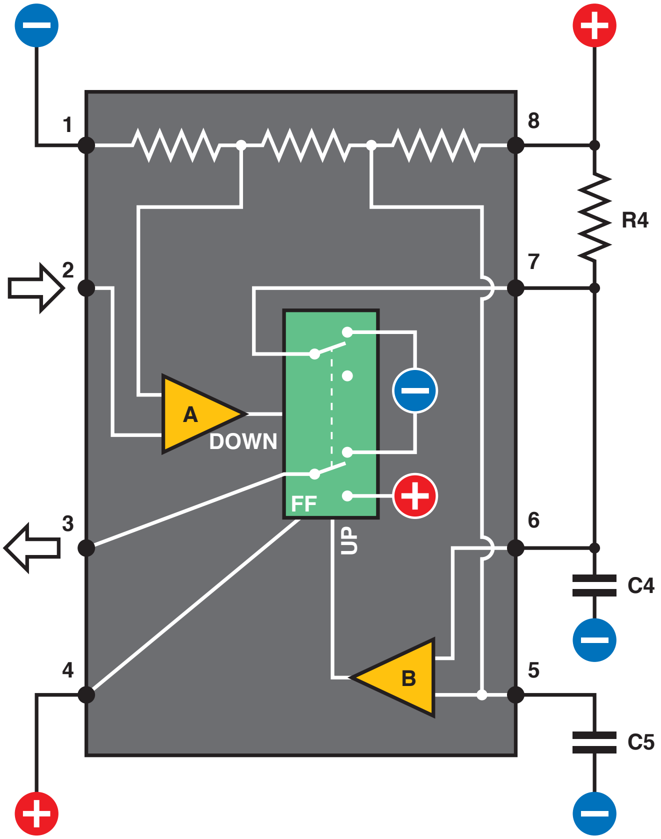

Figure 4-18. *Inside the 555 timer. White lines indicate connections inside the chip. A and B are comparators. FF is a flip-flop which can rest in one state or the other, like a double-throw switch. A drop in voltage on pin 2 is detected by comparator A, which triggers the flip-flop into its "down" position and sends a positive pulse out of pin 3. When C4 charges to 2/3 of supply voltage, this is detected by comparator B, which resets the flip-flop to its "up" position. This discharges C4 through pin 7.*

THEORY

Inside the 555 timer: monostable mode (continued)

The green rectangle, identified as "FF," is a "flip-flop." I have depicted it as a DPDT switch, because that's how it functions here, although of course it is really solid-state.

Initially when you power up the chip, the flip-flop is in its "up" position which delivers low voltage through the output, pin 3. If the flip-flop receives a signal from comparator A, it flips to its "down" state, and flops there. When it receives a signal from comparator B, it flips back to its "up" state, and flops there. The "UP" and "DOWN" labels on the comparators will remind you what each one does when it is activated.

Flip-flops are a fundamental concept in digital electronics. Computers couldn't function without them.

Notice the external wire that connects pin 7 with capacitor C4. As long as the flip-flop is "up," it sinks the positive voltage coming through R4 and prevents the capacitor from charging positively.

If the voltage on pin 2 drops to 1/3 of the supply, comparator A notices this, and flips the flip-flop. This sends a positive pulse out of pin 3, and also disconnects the negative power through pin 7. So now C4 can start charging through R4. While this is happening, the positive output from the timer continues.

As the voltage increases on the capacitor, comparator B monitors it through pin 6, known as the threshold. When the capacitor accumulates 2/3 of the supply voltage, comparator B sends a pulse to the flip-flop, flipping it back into its original state. This discharges the capacitor through pin 7, appropriately known as the discharge pin. Also, the flip-flop ends the positive output through pin 3 and replaces it with a negative voltage. This way, the 555 returns to its original state.

I'll sum up this sequence of events very simply:

1. Initially, the flip-flop grounds the capacitor and grounds the output (pin 3).
2. A drop in voltage on pin 2 to 1/3 the supply voltage or less makes the output (pin 3) positive and allows capacitor C4 to start charging through R4.
3. When the capacitor reaches 2/3 of supply voltage, the chip discharges the capacitor, and the output at pin 3 goes low again.

In this mode, the 555 timer is "monostable," meaning that it just gives one pulse, and you have to trigger it again to get another.

You adjust the length of each pulse by changing the values of R4 and C4. How do you know which values to choose? Check the table on page 157, which gives an approximate idea and also includes a formula so that you can calculate values of your own.

I didn't bother to include pulses shorter than 0.01 second in the table, because a single pulse of this length is usually not very useful. Also I rounded the numbers in the table to 2 significant figures, because capacitor values are seldom more accurate than that.

BACKGROUND

How the timer was born

Back in 1970, when barely a half-dozen corporate seedlings had taken root in the fertile ground of Silicon Valley, a company named Signetics bought an idea from an engineer named Hans Camenzind. It wasn't a huge breakthrough concept—just 23 transistors and a bunch of resistors that would function as a programmable timer. The timer would be versatile, stable, and simple, but these virtues paled in comparison to its primary selling point. Using the emerging technology of integrated circuits, Signetics could reproduce the whole thing on a silicon chip.

This entailed some trial and error. Camenzind worked alone, building the whole thing initially on a large scale, using off-the-shelf transistors, resistors, and diodes on a breadboard. It worked, so then he started substituting slightly different values for the various components to see whether the circuit would tolerate variations during production and other factors such as changes in temperature when the chip was in use. He made at least 10 different versions of the circuit. It took months.

Next came the crafts work. Camenzind sat at a drafting table and used a specially mounted X-Acto knife to scribe his circuit into a large sheet of plastic. Signetics then reduced this image photographically by a ratio of about 300:1. They etched it into tiny wafers, and embedded each of them in a half-inch rectangle of black plastic with the product number printed on top. Thus, the 555 timer was born.

It turned out to be the most successful chip in history, both in the number of units sold (tens of billions and counting) and the longevity of its design (unchanged in almost 40 years). The 555 has been used in everything from toys to spacecraft. It can make lights flash, activate alarm systems, put spaces between beeps, and create the beeps themselves.

Today, chips are designed by large teams and tested by simulating their behavior using computer software. Thus, chips inside a computer enable the design of more chips. The heyday of solo designers such as Hans Camenzind is long gone, but his genius lives inside every 555 timer that emerges from a fabrication facility. (If you'd like to know more about chip history, see *http://www.semiconductormuseum.com/Museum_Index.htm*.)

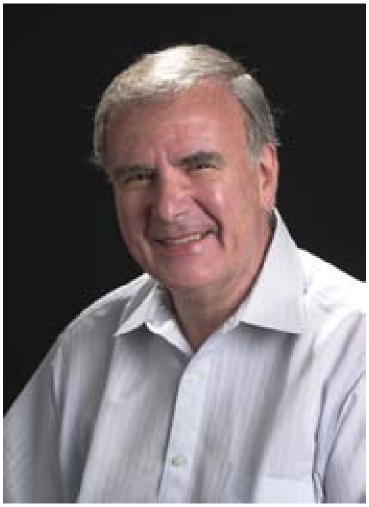

Figure 4-13. *Hans Camenzind, inventor and developer of the 555 timer chip for Signetics.*

FUNDAMENTALS

Why the 555 is useful

In its monostable mode (which is what you just saw), the 555 will emit a single pulse of fixed (but programmable) length. Can you imagine some applications? Think in terms of the pulse from the 555 controlling some other component. A motion sensor on an outdoor light, perhaps. When an infra-red detector "sees" something moving, the light comes on for a specific period—which can be controlled by a 555.

Another application could be a toaster. When someone lowers a slice of bread, a switch will close that triggers the toasting cycle. To change the length of the cycle, you could use a potentiometer instead of R4 and attach it to the external lever that determines how dark you want your toast. At the end of the toasting cycle, the output from the 555 would pass through a power transistor, to activate a solenoid (which is like a relay, except that it has no switch contacts) to release the toast.

Intermittent windshield wipers could be controlled by a 555 timer—and on earlier models of cars, they actually were.

And what about the burglar alarm that was described at the end of Chapter 3? One of the features that I listed, which has not been implemented yet, is that it should shut itself off after a fixed interval. We can use the change of output from a 555 timer to do that.

The experiment that you just performed seemed trivial, but really it implies all kinds of possibilities.

555 timer limits

1. The timer can run from a stable voltage source ranging from 5 to 15 volts.
2. Most manufacturers recommend a range from 1K to 1M for the resistor attached to pin 7.
3. The capacitor value can go as high as you like, if you want to time really long intervals, but the accuracy of the timer will diminish.
4. The output can deliver as much as 100mA at 9 volts. This is sufficient for a small relay or miniature loudspeaker, as you'll see in the next experiment.

Beware of Pin-Shuffling!

In all of the schematics in this book, I'll show chips as you'd see them from above, with pin 1 at top left. Other schematics that you may see, on websites or in other books, may do things differently. For convenience in drawing circuits, people shuffle the pin numbers on a chip so that pin 1 isn't necessarily shown adjacent to pin 2.

Look at the schematic in Figure 4-20 and compare it with the one in Figure 4-15. The connections are the same, but the one in Figure 4-20 groups pins to reduce the apparent complexity of the wiring.

"Pin shuffling" is common because circuit-drawing software tends to do it, and on larger chips, it is necessary for functional clarity of the schematic (i.e., logical groupings of pin names versus physical groupings on memory chips, for example). When you're first learning to use chips, I think it's easier to understand a schematic that shows the pins in their actual positions. So that's the practice I will be using here.

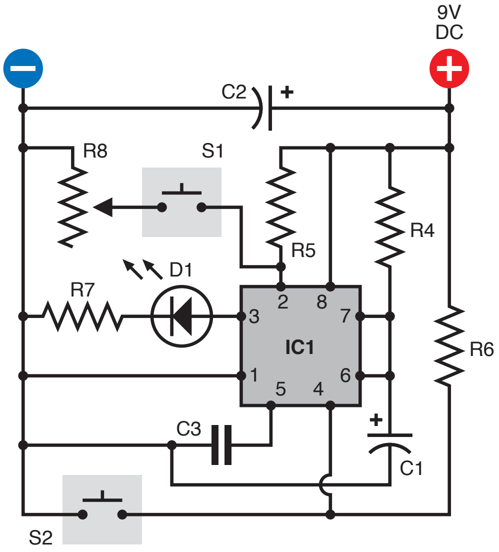

Figure 4-20. *Many people draw schematics in which the pin numbers on a chip are shuffled around to make the schematic smaller or simpler. This is not helpful when you try to build the circuit. The schematic here is for the same circuit as in Figure 4-15. This version would be harder to recreate on a breadboard.*

Experiment 17: Set Your Tone

I'm going to show you two other ways in which the 555 timer can be used.

You will need the same items as in Experiment 16, plus:

- Additional 555 timer chip. Quantity: 1.
- Miniature loudspeaker. Quantity: 1.
- 100K linear potentiometer. Quantity: 1.

Procedure

Leave the components from Experiment 16 where they are on the breadboard, and add the next section below them, as shown in Figures 4-21 and 4-22. Resistor R2 is inserted between pins 6 and 7, instead of the jumper wire that shorted the pins together in the previous circuit, and there's no external input to pin 2 anymore. Instead, pin 2 is connected via a jumper wire to pin 6. The easiest way to do this is by running the wire across the top of the chip.

I have omitted the smoothing capacitor from the schematic in Figure 4-22, because I'm assuming that you're running this circuit on the same breadboard as the first, where the previous smoothing capacitor is still active.

A loudspeaker in series with a 100Ω resistor (R3) has been substituted for the LED to show the output from the chip. Pin 4, the reset, is disabled by connecting it to the positive voltage supply, as I'm not expecting to use the reset function in this circuit.

Now what happens when you apply power? Immediately, you should hear noise through the loudspeaker. If you don't hear anything, you almost certainly made a wiring error.

Notice that you don't have to trigger the chip with a pushbutton anymore. The reason is that when C1 charges and discharges, its fluctuating voltage is connected via a jumper wire across the top of the chip to pin 2, the trigger. In this way, the 555 timer now triggers itself. I'll describe this in more detail in the next section "Theory: Inside the 555 timer: astable mode," if you want to see exactly what is going on.

In this mode, the chip is "astable," meaning that it is not stable, because it flips to and fro endlessly, sending a stream of pulses for as long as the power is connected. The pulses are so rapid that the loudspeaker reproduces them as noise.

In fact, with the component values that I specified for R1, R2, and C1, the 555 chip is emitting about 1,500 pulses per second. In other words, it creates a 1.5 KHz tone.

Check the table on page 166 to see how different values for R2 and C1 can create different pulse frequencies with the chip in this astable mode. Note that the table assumes a fixed value of 1K for R1!

THEORY

Inside the 555 timer: astable mode

Here's what is happening now, illustrated in Figure 4-23. Initially, the flip-flop grounds C1 as before. But now the low voltage on the capacitor is connected from pin 7 to pin 2 through an external wire. The low voltage tells the chip to trigger itself. The flip-flop obediently flips to its "on" position and sends a positive pulse to the loudspeaker, while removing the negative voltage from pin 7.

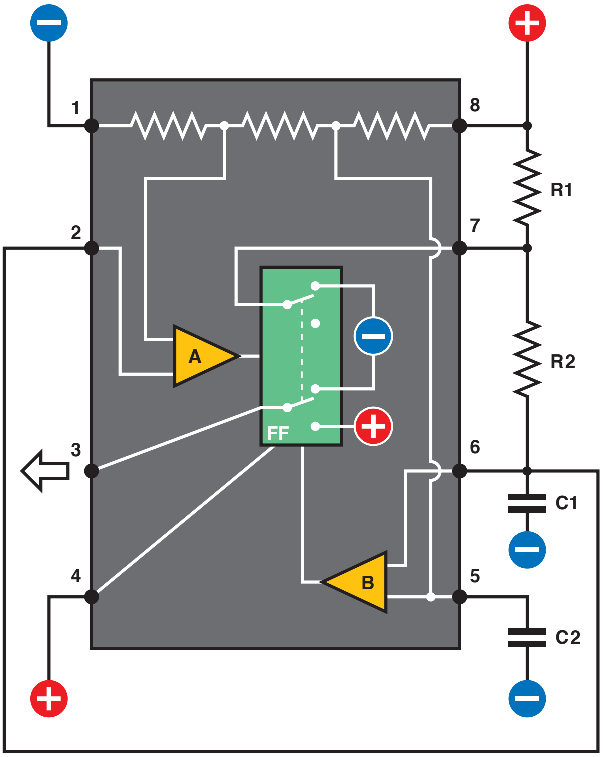

Figure 4-23. *When the 555 timer is used in astable mode, resistor R2 is placed between pin 6 and pin 7, and pin 6 is connected via an external wire to pin 2, so that the timer triggers itself.*

Now C1 starts charging, as it did when the timer was in monostable mode, except that it is being charged through R1 + R2 in series. Because the resistors have low values, and C1 is also small, C1 charges quickly. When it reaches 2/3 full voltage, comparator B takes action as before, discharging the capacitor and ending the output pulse from pin 3.

The capacitor takes longer to discharge than before, because R2 has been inserted between it and pin 7, the discharge pin. While the capacitor is discharging, its voltage diminishes, and is still linked to pin 2. When the voltage drops to 1/3 of full power or less, comparator A kicks in and sends another pulse to the flip-flop, starting the process all over again.

Summing up:

1. In astable mode, as soon as power is connected, the flip-flop pulls down the voltage on pin 2, triggering comparator A, which flips the flip-flop to its "down" position.
2. Pin 3, the output, goes high. The capacitor charges through R1 and R2 in series.
3. When the capacitor reaches 2/3 of supply voltage, the flip-flop goes "up" and the output at pin 3 goes low. The capacitor starts to discharge through R2.
4. When the charge on the capacitor diminishes to 1/3 of full voltage, the pull-down on pin 2 flips the flip-flop again and the cycle repeats.

Unequal on/off cycles

When the timer is running in astable mode, C1 charges through R1 and R2 in series. But when C1 discharges, it dumps its voltage through R2 only. This means that the capacitor charges more slowly than it discharges. While it is charging, the output on pin 3 is high; while it is discharging, the output on pin 3 is low. Consequently the "on" cycle is always longer than the "off" cycle. Figure 4-24 shows this as a simple graph.

If you want the on and off cycles to be equal, or if you want to adjust the on and off cycles independently (for example, because you want to send a very brief pulse to another chip, followed by a longer gap until the next pulse), all you need to do is add a diode, as shown in Figure 4-25.

Now when C1 charges, the electricity flows through R1 as before but takes a shortcut around R2, through diode D1. When C1 discharges, the diode blocks the flow of electricity in that direction, and so the discharge goes back through R2.

THEORY

Inside the 555 timer: astable mode (continued)

R1 now controls the charge time on its own, while R2 controls the discharge time. The formula for calculating the frequency is now:

Frequency = 1440 / ((R1 + R2) × C1)

If you set R1 = R2, you should get almost equal on/off cycles ("almost" because the diode itself imposes a small internal voltage drop of about 0.6V). The exact value depends primarily on the manufacturing process used to make the diode.

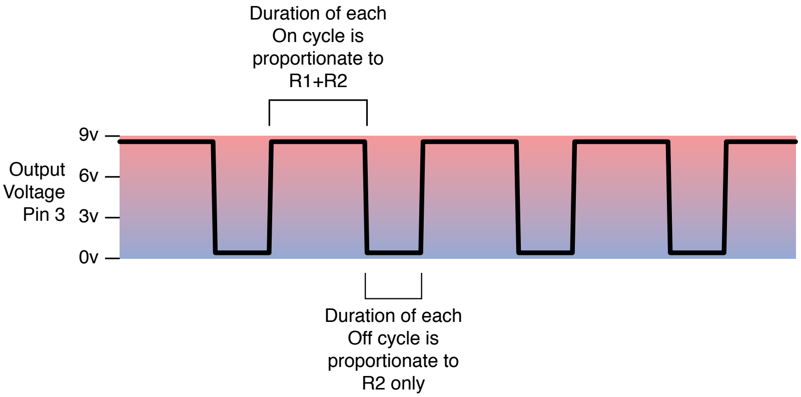

Figure 4-24. *In its usual astable configuration, the timer charges a capacitor through R1+R2 and discharges the capacitor through R2 only. Therefore its output on cycles are longer than its output off cycles.*

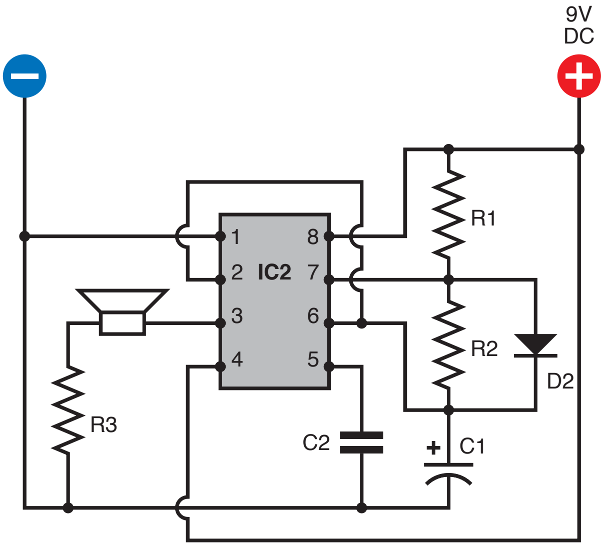

Figure 4-25. *This is a modification of the schematic shown in Figure 4-22. By adding a diode to a 555 timer running in astable mode, we eliminate R2 from the charging cycle of capacitor C1. Now we can adjust the output on cycle with the value of R1, and the output off cycle with the value of R2, so that the on and off durations are independent of each other.*

FUNDAMENTALS

The following table shows 555 timer frequency in astable mode:

- Frequency is in pulses per second, rounded to two figures.
- The horizontal scale shows common resistor values for R2.
- The vertical scale shows common capacitor values for C1. Resistor R1 is assumed to be 1K.
- Resistor R1 is assumed to be 1K.

To calculate a different frequency: double R2, add the product to R1, multiply the sum by C1, and divide the result into 1440. Like this:

Frequency = 1440 / ((R1 + 2R2) × C1) cycles per second

In this formula, R1 and R2 are in kilohms, C1 is in microfarads, and the frequency is in hertz (cycles per second). Note that the frequency is measured from the start of one pulse to the start of the next. The duration of each pulse is not the same as the length of time between each pulse. This issue is discussed in the previous section.

Astable Modifications

In the circuits shown in Figures 4-22 or 4-25, if you substitute a 100K potentiometer for R2, you can adjust the frequency up and down by turning the shaft.

Another option is to “tune” the timer by using pin 5, the control, as shown in the Figure 4-26. Disconnect the capacitor that was attached to that pin and substitute the series of resistors shown. R9 and R11 are both 1K resistors, either side of R10, which is a 100K potentiometer. They ensure that pin 5 always has at least 1K between it and the positive and negative sides of the power supply. Connecting it directly to the power supply won’t damage the timer, but will prevent it from generating audible tones. As you turn the potentiometer to and fro, the frequency will vary over a wide range. If you want to generate a very specific frequency, a trimmer potentiometer can be used instead.

A primary advantage of using pin 5 to adjust frequency is that you can control it remotely. Take the output from pin 3 of another 555 timer running slowly in astable mode, and pipe it through a 2K2 resistor to pin 5. Now you get a two-tone siren effect, as one timer controls the other. If, in addition, you add a 100 µF capacitor between pin 5 and ground, the charging and discharging of the capacitor will make the tone slide up and down instead of switching abruptly. I'll describe this in more detail shortly. This leads me to the whole topic of one chip controlling another chip, which will be our last variation on this experiment.

Chaining Chips

Generally speaking, chips are designed so that they can talk to each other. The 555 couldn't be easier in this respect:

- Pin 3, the output, from one 555 can be connected directly to pin 2, the trigger, of a second 555.
- Alternatively, the output can be sufficient to provide power to pin 8 of a second 555.
- The output is appropriate to control or power other types of chips too.

Figure 4-27 shows these options.

When the output from the first 555 goes high, it is about 70 to 80% of its supply voltage. In other words, when you're using a 9V supply, the high output voltage is at least 6 volts. This is still above the minimum of 5V that the second chip needs to trigger its comparator, so there's no problem.

Less than 0.5 volts when low
IC2
That's low enough to trigger me!

Figure 4-27. *Three ways to chain 555 timers together. The output of IC1 can power a second timer, or adjust its control voltage, or activate its trigger pin.*

You can chain together the two 555 timers that you already have on your breadboard. Figure 4-28 shows how to connect the two circuits that were shown previously in Figures 4-15 and 4-22. Run a wire from pin 3 (the output) of the first chip to pin 8 (the positive power supply) of the second chip, and disconnect the existing wire connecting pin 8 to your power supply. The new wire is shown in red. Now when you press the button to activate the first chip, its output powers the second chip.

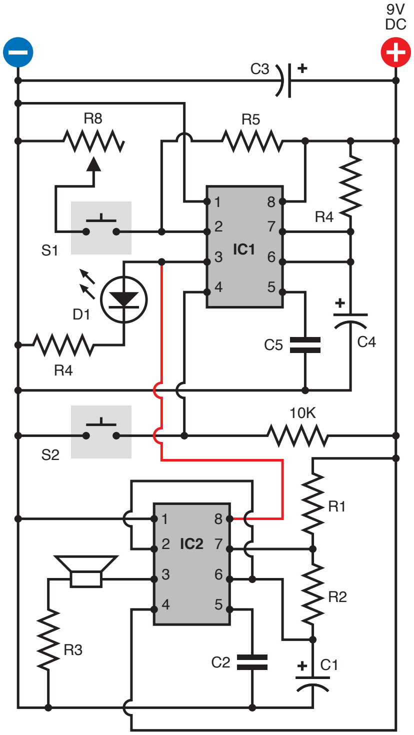

Figure 4-28. *You can combine the two circuits shown in Figures 4-15 and 4-22 simply by disconnecting the wire that provides power to pin 8 of the second timer, and running a substitute wire (shown in red).*

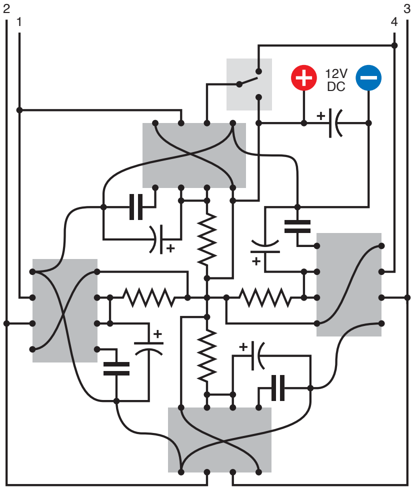

Figure 4-29. *Four 555 timers, chained together in a circle, can flash a series of four sets of LEDs in sequence, like Christmas lights or a movie marquee.*

You can also use the output from one chip to trigger another (i.e., you can connect pin 3 from the first chip to pin 2 of the second). When the output from the first chip is low, it's less than half a volt. This is well below the threshold that the second chip requires to be activated. Why would you want to do this? Well, you might want to have both timers running in monostable mode, so that the end of a high pulse from the first one triggers the start of a high pulse in the second one. In fact, you could chain together as many timers as you like in this way, with the last one feeding back and triggering the first one, and they could flash a series of LEDs in sequence, like Christmas lights. Figure 4-29 shows how four timers could be linked this way, in a configuration that would occupy minimal space (and would be wired point-to-point on perforated board, not on breadboard-format board). Each of the outputs numbered 1 through 4 would have about enough power to run maybe 10 LEDs, if you used relatively high load resistors to limit their current.

Incidentally, you can reduce the chip count (the number of chips) by using two 556 timers instead of four 555 timers. The 556 contains a pair of 555 timers in one package. But because you have to make the same number of external connections (other than the power supply), I haven't bothered to use this variant.

You can even get a 558 timer that contains four 555 circuits, all preset to function in astable mode. I decided not to use this chip, because its output behaves differently from a normal 555 timer. But you can buy a 558 timer and play with it if you wish. It is ideal for doing the "chain of four timers" that I suggested previously. The data sheet even suggests this.

Lastly, going back to the idea of modifying the frequency of a 555 timer in astable mode, you can chain two timers, as shown in Figure 4-30. The red wire shows the connection from the output of the first timer to the control pin of the second. The first timer has now been rewired in astable mode, so that it creates an oscillating on/off output around four times per second. This output flashes the LED (to give you a visual check of what's going on) and feeds through R7 to the control pin of the second timer.

But C2 is a large capacitor, which takes time to charge through R7. While this happens, the voltage detected by pin 5 slowly rises, so that the tone generated by IC2 gradually rises in pitch. Then IC1 reaches the end of its on cycle and switches itself off, at which point C2 discharges and the pitch of the sound generated by IC2 falls again.

You can tweak this circuit to create all kinds of sounds, much more controllably then when you were using PUT transistors to do the same kind of thing. Here are some options to try:

- Double or halve the value of C2.
- Omit C2 completely, and experiment with the value of R7.
- Substitute a 10K potentiometer for R7.
- Change C4 to increase or decrease the cycle time of IC1.

- Halve the value of R5 while doubling the value of C4, so that the cycle time of IC1 stays about the same, but the On time becomes significantly longer than the Off time.
- Change the supply voltage in the circuit from 9 volts to 6 volts or 12 volts.

Remember, you can't damage a 555 timer by making changes of this kind. Just make sure that the negative side of your power supply goes to pin 1 and the positive side to pin 8.

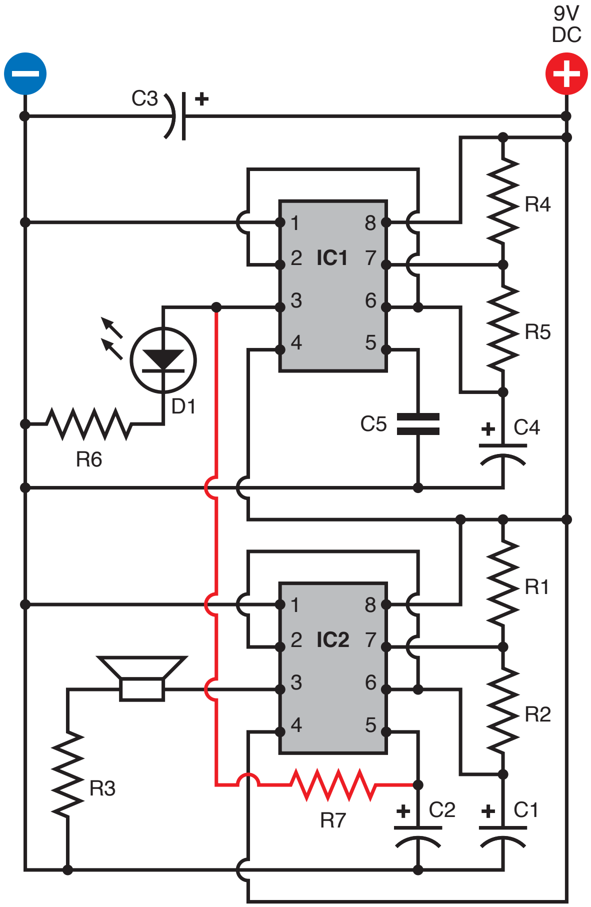

Figure 4-30. *When both timers are astable, but IC1 runs much more slowly than IC2, the output from IC1 can be used to modulate the tone generated by IC2. Note that as this is a substantial modification to the previous schematics, several components have been relabeled. To avoid errors, you may need to remove the old circuit from your breadboard and build this version from scratch. Try these values initially:*

R1, R4, R6, R7: 1K
R2, R5: 10K
R3: 100 ohms
C1: 0.047 µF
C2, C3: 100 µF
C4: 68 µF
C5: 0.1 µF

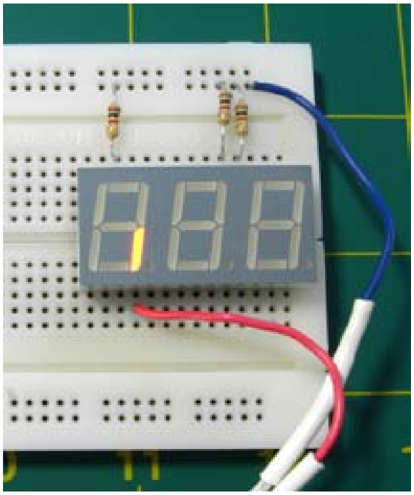

Figure 4-31. *After putting a 1K resistor between the common cathode of the display and the negative supply voltage, you can use the positive supply voltage to illuminate each segment in turn.*

Experiment 18: Reaction Timer

Because the 555 can easily run at thousands of cycles per second, we can use it to measure human reactions. You can compete with friends to see who has the fastest response—and note how your response changes depending on your mood, the time of day, or how much sleep you got last night.

Before going any further, I have to warn you that this circuit will have more connections than others you've tackled so far. It's not conceptually difficult, but requires a lot of wiring, and will only just fit on a breadboard that has 63 rows of holes. Still, we can build it in a series of phases, which should help you to detect any wiring errors as you go.

You will need:

- 4026 chip. Quantity: 4 (really you need only 3, but get another one in case you damage the others).
- 555 timers. Quantity: 3.
- Tactile switches (SPST momentary switches). Quantity: 3.
- Three numeric LEDs, or one 3-digit LED display (see the shopping list at the beginning of this chapter). Quantity: 1.
- Breadboard, resistors, capacitors, and meter, as usual.

Step 1: Display

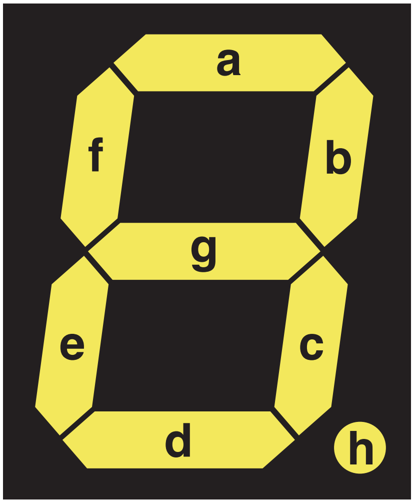

Figure 4-32. *The most basic and common digital numeral consists of seven LED segments identified by letters, as shown here, plus an optional decimal point.*

You can use three separate LED numerals for this project, but I suggest that you buy the Kingbright BC56-11EWA on the shopping list at the beginning of this chapter. It contains three numerals in one big package.

You should be able to plug it into your breadboard, straddling the center channel. Put it all the way down at the bottom of the breadboard, as shown in Figure 4-31. Don't put any other components on the breadboard yet.

Now set your power supply to 9 volts, and apply the *negative* side of it to the row of holes running up the breadboard on the *righthand* side. Insert a 1K resistor between that negative supply and each of pins 18, 19, and 26 of the Kingbright display, which are the "common cathode," meaning the negative connection shared by each set of LED segments in the display. (The pin numbers of the chip are shown in Figure 4-33. If you're using another model of display, you'll have to consult a data sheet to find which pin(s) are designed to receive negative voltage.)

Switch on the power supply and touch the free end of the positive wire to each row of holes serving the display on its left and right sides. You should see each segment light up, as shown in Figure 4-31.

Each numeral from 0 to 9 is represented by a group of these segments. The segments are always identified with lowercase letters *a* through *g*, as shown in Figure 4-32. In addition, there is often a decimal point, and although we won't be using it, I've identified it with the letter *h*.

Check Figure 4-33 showing the Kingbright display, and you'll see I have annotated each pin with its function. You can step down the display with the positive wire from your power supply, making sure that each pin lights an appropriate segment.

Incidentally, this display has two pins, numbered 3 and 26, both labeled to receive negative voltage for the first of the digits. Why two pins instead of one? I don't know. You need to use only one, and as this is a passive chip, it doesn't matter if you leave the unused one unconnected. Just take care not to apply positive voltage to it, which would create a short circuit.

A numeric display has no power or intelligence of its own. It's just a bunch of light-emitting diodes. It's not much use, really, until we can figure out a way to illuminate the LEDs in appropriate groups—which will be the next step.

Step 2: Counting

Fortunately, we have a chip known as the 4026, which receives pulses, counts them, and creates an output designed to work with a seven-segment display so that it shows numbers 0–9. The only problem is that this is a rather old-fashioned CMOS chip (meaning, Complementary Metal Oxide Semiconductor) and is thus sensitive to static electricity. Check the caution on page 172 before continuing.

Switch off your power supply and connect its wires to the top of the breadboard, noting that for this experiment, we're going to need positive and negative power on both sides. See Figure 4-34 for details. If your breadboard does not already have the columns of holes color-coded, I suggest you use Sharpie markers to identify them, to avoid polarity errors that can fry your components.

The 4026 counter chip is barely powerful enough to drive the LEDs in our display when powered by 9 volts. Make sure you have the chip the right way up, and insert it into the breadboard immediately above your three-digit display, leaving just one row of holes between them empty.

The schematic in Figure 4-35 shows how the pins of the 4026 chip should be connected. The arrows tell you which pins on the display should be connected with pins on the counter.

Figure 4-36 shows the "pinouts" (i.e., the functions of each pin) of a 4026 counter chip. You should compare this with the schematic in Figure 4-35.

Include a tactile switch between the positive supply and pin 1 of the 4026 counter, with a 10K resistor to keep the input to the 4026 counter negative until the button is pressed. Make sure all your positives and negatives are correct, and turn on the power. You should find that when you tap the tactile switch lightly, the counter advances the numeric display from 0 through 9 and then begins all over again from 0. You may also find that the chip sometimes misinterprets your button-presses, and counts two or even three digits at a time. I'll deal with this problem a little further on.

The LED segments will not be glowing very brightly, because the 1K series resistors deprive of them of the power they would really like to receive. Those resistors are necessary to avoid overloading the outputs from the counter.

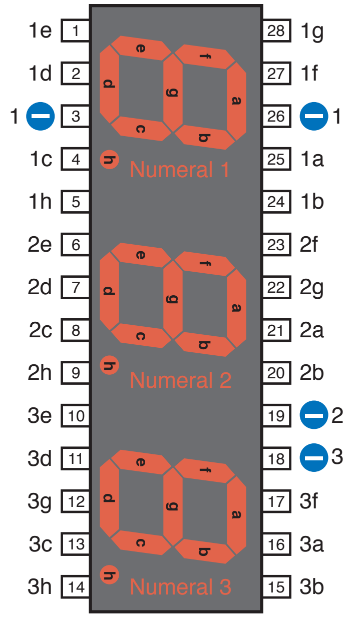

Figure 4-33. *This Kingbright unit incorporates three seven-segment numeric displays in one package, and can be driven by three chained 4026 decade counters. The pin numbers are shown close to the chip. Segments a through g of numeral 1 are identified as 1a through 1g. Segments a through g of numeral 2 are identified as 2a through 2g. Segments a through g of numeral 3 are identified as 3a through 3g.*

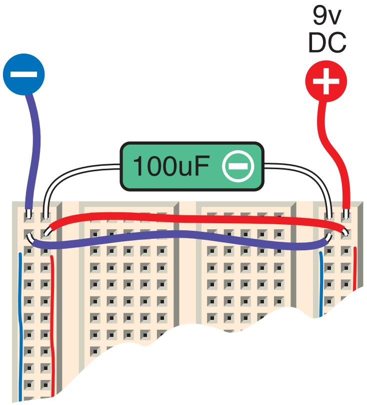

Figure 4-34. *When building circuits around chips, it's convenient to have a positive and negative power supply down each side of your breadboard. For the reaction timer circuit, a 9V supply with a 100 µF smoothing capacitor can be set up like this. If your breadboard doesn't color-code the columns of holes on the left and right sides, I suggest you do that yourself with a permanent marker.*

Grounding Yourself

To avoid the frustration that occurs when you power up a circuit and nothing happens, be sure to take these precautions when you use the older generation of CMOS chips (which often have part numbers from 4000 upward, such as 4002, 4020, and so on):

Chips are often shipped with their legs embedded in black foam. This is electrically conductive foam, and you should keep the chips embedded in it until you are ready to use them.

If the chips are supplied to you in plastic tubes, you can take them out and poke their legs into pieces of conductive foam or, if you don't have any, use aluminum foil. The idea is to avoid one pin on a chip acquiring an electric potential that is much higher than another pin.

While handling CMOS components, grounding yourself is important. I find that in dry weather, I accumulate a static charge merely by walking across a plastic floor-protecting mat in socks that contain some synthetic fibers. You can buy a wrist strap to keep yourself grounded, or simply touch a large metal object, such as a file cabinet, before you touch your circuit board. I am in the habit of working with my socked foot touching a file cabinet, which takes care of the problem.

Never solder a CMOS chip while there is power applied to it.

Grounding the tip of your soldering iron is a good idea.

Better still, don't solder CMOS chips at all. When you're ready to immortalize a project by moving it from a breadboard into perforated board, solder a socket into your perforated board, then push the chip into the socket. If there's a problem in the future, you can unplug the chip and plug in another.

Use a grounded, conductive surface on your workbench. The cheapest way to do this is to unroll some aluminum foil and ground it (with an alligator clip and a length of wire) to a radiator, a water pipe, or a large steel object. I like to use an area of conductive foam to cover my workbench—the same type of foam that is used for packaging chips. However, this foam is quite expensive.

Counter

Figure 4-36. *The 4026 decade counter is a CMOS chip that accepts clock pulses on pin 1, maintains a running total from 0 to 9, and outputs this total via pins designed to interface with a seven-segment LED numeric display.*

FUNDAMENTALS

Counters and seven-segment displays

Most counters accept a stream of pulses and distribute them to a series of pins in sequence. The 4026 decade counter is unusual in that it applies power to its output pins in a pattern that is just right to illuminate the segments of a 7-segment numeric display.

Some counters create positive outputs (they "source" current) while others create negative outputs (they "sink" current). Some seven-segment displays require positive input to light up the numbers. These are known as "common cathode" displays. Others require negative input and are known as "common anode" displays. The 4026 delivers positive outputs and requires a common cathode display.

Check the data sheet for any counter chip to find out how much power it requires, and how much it can deliver. CMOS chips are becoming dated, but they are very useful to hobbyists, because they will tolerate a wide range of supply voltage—from 5 to 15 volts in the case of the 4026. Other types of chips are much more limited.

Most counters can source or sink only a few milliamps of output power. When the 4026 is running on a 9-volt power supply, it can source about 4mA of power from each pin. This is barely enough to drive a seven-segment display.

You can insert a series resistor between each output pin of the counter and each input pin of the numeric display, but a simpler, quicker option is to use just one series resistor for each numeral, between the negative-power pin and ground. The experiment that I'm describing uses this shortcut. Its disadvantage is that digits that require only a couple of segments (such as numeral 1) will appear brighter than those that use many segments (such as numeral 8).

If you want your display to look bright and professional, you really need a transistor to drive each segment of each numeral. An alternative is to use a chip containing multiple "op amps" to amplify the current.

When a decade counter reaches 9 and rolls over to 0, it emits a pulse from its "carry" pin. This can drive another counter that will keep track of tens. The carry pin on that counter can be chained to a third counter that keeps track of hundreds, and so on. In addition to decade counters, there are hexadecimal counters (which count in 16s), octal counters (in 8s), and so on.

Why would you need to count in anything other than tens? Consider that the four numerals on a digital clock each count differently. The rightmost digit rolls over when it reaches 10. The next digit to the left counts in sixes. The first hours digit counts to 10, gives a carry signal, counts to 2, and gives another carry signal. The leftmost hours digit is either blank or 1, when displaying time in 12-hour format. Naturally there are counters specifically designed to do all this.

Counters have control pins such as "clock disable," which tells the counter to ignore its input pulses and freeze the display, "enable display," which enables the output from the chip, and "reset," which resets the count to zero.

The 4026 requires a positive input to activate each control pin. When the pins are grounded, their features are suppressed.

To make the 4026 count and display its running total you must ground the "clock disable" and "reset" pins (to suppress their function) and apply positive voltage to the "enable display" pin (to activate the output). See Figure 4-36 to see these pins identified.

Assuming that you succeed in getting your counter to drive the numeric display, you're ready to add two more counters, which will control the remaining two numerals. The first counter will count in ones, the second in tens, and the third in hundreds.

In Figure 4-37, I've continued to use arrows and numbers to tell you which pins of the counters should be connected to which pins of the numeric display. Otherwise, the schematic would be a confusing tangle of wires crossing each other.

At this point, you can give up in dismay at the number of connections—but really, using a breadboard, it shouldn't take you more than half an hour to complete this phase of the project. I suggest you give it a try, because there's

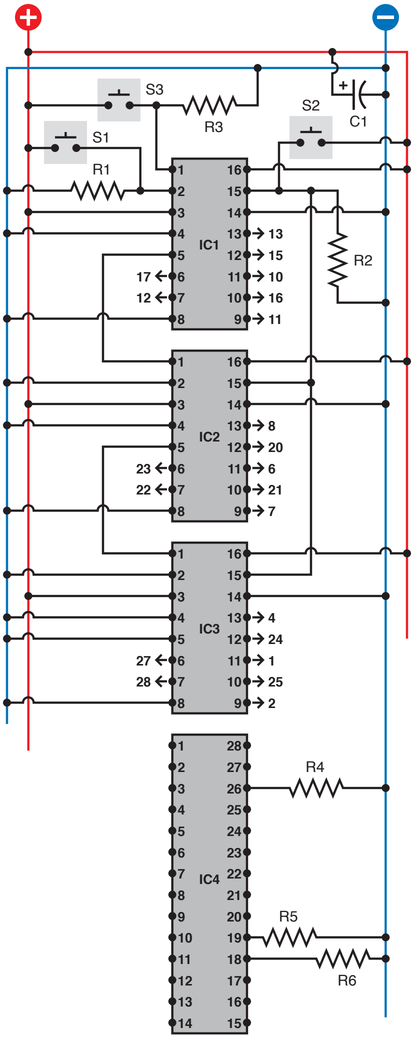

Figure 4-37. *This test circuit, laid out as you would be likely to place it on a breadboard, allows you to trigger a counter manually to verify that the display increments from 000 upward to 999.*

Component values:

All resistors are 1K.
S1, S2, S3: SPST tactile switches, normally open
IC1, IC2, IC3: 4026 decade counter chips
IC4: Kingbright 3-digit common-cathode display
C1: 100 µF (minimum) smoothing capacitor

Wire the output pins on IC1, IC2, and IC3 to the pins on IC4, according to the numbers preceded by arrows. The actual wires have been omitted for clarity. Check for the pinouts of IC4.

something magical about seeing a display count from 000 through 999 "all by itself," and I chose this project because it also has a lot of instructional value.

S1 is attached to the "clock disable" pin of IC1, so that when you hold down this button, it should stop that counter from counting. Because IC1 controls IC2, and IC2 controls IC3, if you freeze IC1, the other two will have to wait for it to resume. Therefore you won't need to make use of their "clock disable" features.

S2 is connected to the "reset" pins of all three counters, so that when you hold down this button, it should set them all to zero.

S3 sends positive pulses manually to the "clock input" pin of the first counter.

S1, S2, and S3 are all wired in parallel with 1K resistors connected to the negative side of the power supply. The idea is that when the buttons are not being pressed, the "pull-down" resistors keep the pins near ground (zero) voltage. When you press one of the buttons, it connects positive voltage directly to the chip, and easily overwhelms the negative voltage. This way, the pins remain either in a definitely positive or definitely negative state. If you disconnect one of these pull-down resistors you are likely to see the numeric display "flutter" erratically. (The numeric display chip has some unconnected pins, but this won't cause any problem, because it is a passive chip that is just a collection of LED segments.)

Always connect input pins of a CMOS chip so that they are either positive or negative. See the "No Floating Pins" warning on the next page.

I suggest that you connect all the wires shown in the schematic first. Then cut lengths of 22-gauge wire to join the remaining pins of the sockets from IC1, IC2, and IC3 to IC4.

Switch on the power and press S2. You'll see three zeros in your numeric display.

Each time you press S3, the count should advance by 1. If you press S2, the count should reset to three zeros. If you hold down S1 while you press S3 repeatedly, the counters should remain frozen, ignoring the pulses from S3.

FUNDAMENTALS

Switch bounce

When you hit S3, I think you'll find that the count sometimes increases by more than 1. This does not mean that there's something wrong with your circuit or your components; you are just observing a phenomenon known as "switch bounce."

On a microscopic level, the contacts inside a pushbutton switch do not close smoothly, firmly, and decisively. They vibrate for a few microseconds before settling; the counter chip detects this vibration as a series of pulses, not just one.

Various circuits are available to "debounce" a switch. The simplest option is to put a small capacitor in parallel with the switch, to absorb the fluctuations; but this is less than ideal. I'll come back to the topic of debouncing later in the book. Switch bounce is not a concern in this circuit, because we're about to get rid of S3 and substitute a 555 timer that generates nice clean bounceless pulses.

Pulse Generation

A 555 timer is ideal for driving a counter chip. You've already seen how to wire a 555 to create a stream of pulses that made noise through a loudspeaker. I'm reproducing the same circuit in Figure 4-38 in simplified form, using the positive and negative supply configuration in the current project. Also I'm showing the connection between pins 2 and 6 in the way that you're most likely to make it, via a wire that loops over the top of the chip.

For the current experiment, I'm suggesting initial component values that will generate only four pulses per second. Any faster than that, and you won't be able to verify that your counters are counting properly.

Install IC5 and its associated components on your breadboard immediately above IC1. Don't leave any gap between the chips. Disconnect S3 and R3 and connect a wire directly between pin 3 (output) of IC5 and pin 1 (clock) of IC1, the topmost counter. Power up again, and you should see the digits advancing rapidly in a smooth, regular fashion. Press S1, and while you hold it, the count should freeze. Release S1 and the count will resume. Press S2 and the counter should reset, even if you are pressing S1 at the same time.

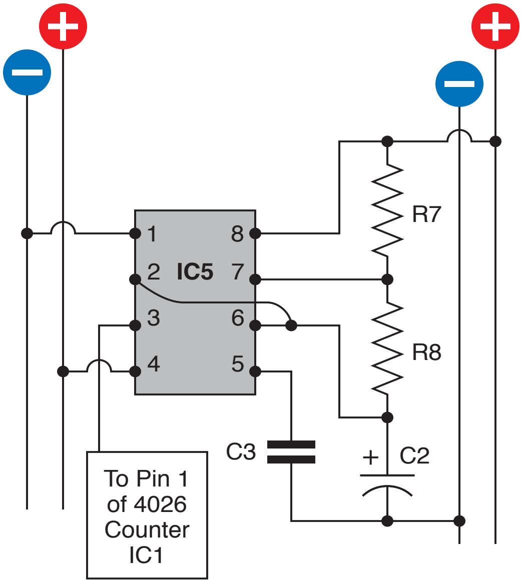

Figure 4-38. *A basic astable circuit to drive the decade counter in the previous schematic. Output is approximately 4 pulses per second.*

C3: 0.1 µF
IC5: 555 timer

No Floating Pins!

A CMOS chip is hypersensitive. Any pin that is not wired either to the supply voltage or to ground is said to be "floating" and may act like an antenna, sensitive to the smallest fluctuations in the world around it.

The 4026 counter chip has a pin labeled "clock disable." The manufacturer's data sheet helpfully tells you that if you give this pin a positive voltage, the chip stops counting and freezes its display. As you don't want to do that, you may just ignore that pin and leave it unconnected, at least while you test the chip. This is a very bad idea!

What the data sheet doesn't bother to tell you (presumably because "everyone knows" such things) is that if you want the clock to run normally, the clock-disable feature itself has to be disabled, by wiring it to negative (ground) voltage. If you leave the pin floating (and I speak from experience), the chip will behave erratically and uselessly.

All input pins must be either positively or negatively wired, unless otherwise specified.

Refinements

Now it's time to remember that what we really want this circuit to do is test a person's reflexes. When the user starts it, we want an initial delay, followed by a signal—probably an LED that comes on. The user responds to the signal by pressing a button as quickly as possible. During the time it takes for the person to respond, the counter will count milliseconds. When the person presses the button, the counter will stop. The display then remains frozen indefinitely, displaying the number of pulses that were counted before the person was able to react.

How to arrange this? I think we need a flip-flop. When the flip-flop gets a signal, it starts the counter running—and keeps it running. When the flip-flop gets another signal (from the user pressing a button), it stops the counter running, and keeps it stopped.

How do we build this flip-flop? Believe it or not, we can use yet another 555 timer, in a new manner known as bistable mode.

FUNDAMENTALS

The bistable 555 timer

Figure 4-39 shows the internal layout of a 555 timer, as before, but the external components on the righthand side have been eliminated. Instead, I'm applying a constant negative voltage to pin 6. Can you see the consequences? Suppose you apply a negative pulse to the trigger (pin 2). Normally when you do this and the 555 starts running, it generates a positive output while charging a capacitor attached to pin 6. When the capacitor reaches 2/3 of the full supply voltage, this tells the 555 to ends its positive output, and it flips back to negative.

Well, if there's no capacitor, there's nothing to stop the timer. Its positive output will just continue indefinitely. However, pin 4 (the reset) can still override everything, so if you apply negative voltage to pin 4, it flips the output to negative. After that, the output will stay negative indefinitely, as it usually does, until you trigger the timer by dropping the voltage to pin 2 again. This will flip the timer back to generating its positive output.

Here's a quick summary of the bistable configuration:

- A negative pulse to pin 2 turns the output positive.
- A negative pulse to pin 4 turns the output negative.
- The timer is stable in each of these states. Its run-time has become infinite.

It's OK to leave pins 5 and 7 of the timer unconnected, because we're pushing it into extreme states where any random signals from those pins will be ignored.

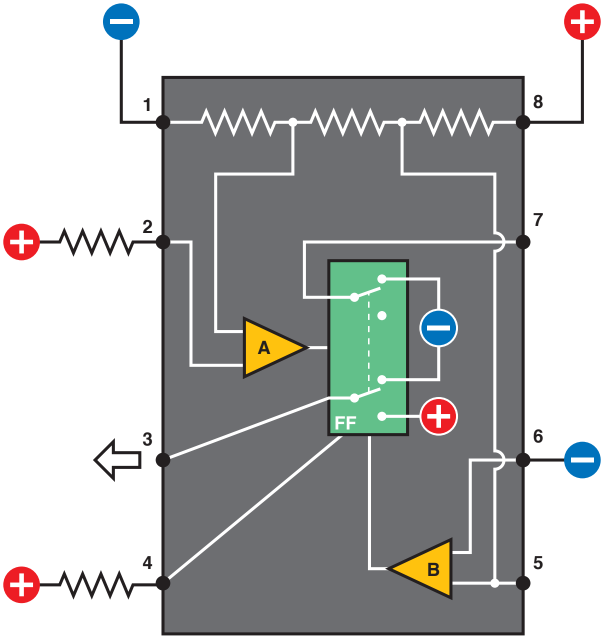

Figure 4-39. *In the bistable configuration, pin 6 of a 555 timer is perpetually negative, so the timer cycle never ends, unless you force it to do so by applying a negative pulse to pin 4 (the reset).*

In bistable mode, the 555 has turned into one big flip-flop. To avoid any uncertainty, we keep pins 2 and 4 normally positive via pull-up resistors, but negative pulses on those pins can overwhelm them when we want to flip the 555 into its opposite state. The schematic for running a 555 timer in bistable mode, controlled by two pushbuttons, is shown in Figure 4-40. You can add this above your existing circuit. Because you're going to attach the output from IC6 to pin 2 of IC1, the topmost counter, you can disconnect S1 and R1 from that pin. See Figure 4-41.

Now, power up the circuit again. You should find that it counts in the same way as before, but when you press S4, it freezes. This is because your bistable 555 timer is sending its positive output to the "clock disable" pin on the counter. The counter is still receiving a stream of pulses from the astable 555 timer, but as long as pin 2 is positive on the counter, the counter simply ignores the pulses.

Now press S5, which flips your bistable 555 back to delivering a negative output, at which point the count resumes.

We're getting close to a final working circuit here. We can reset the count to zero (with S3), start the count (with S5), and wait for the user to stop the count (with S4). The only thing missing is a way to start the count unexpectedly.

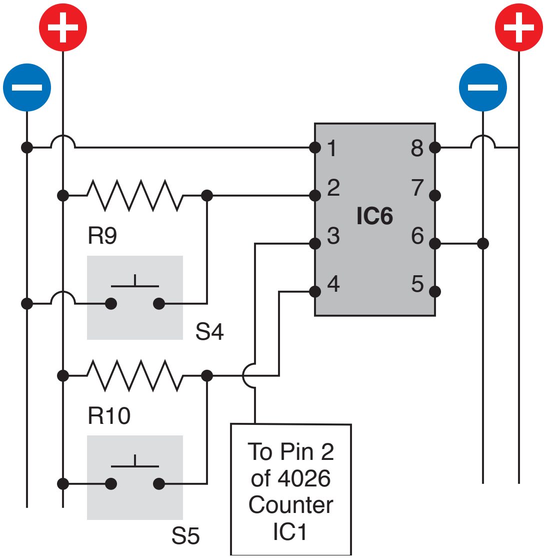

Figure 4-40. *Adding a bistable 555 timer to the reflex tester will stop the counter with a touch of a button, and keep it stopped.*

IC5, IC6, IC7: 555 timers

The Delay

Suppose we set up yet another 555 in monostable mode. Trigger its pin 2 with a negative pulse, and the timer delivers a positive output that lasts for, say, 4 seconds. At the end of that time, its output goes back to being negative. Maybe we can hook that positive-to-negative transition to pin 4 of IC6. We can use this instead of switch S5, which you were pressing previously to start the count.

Check the new schematic in Figure 4-41 which adds another 555 timer, IC7 above IC6. When the output from IC7 goes from positive to negative, it will trigger the reset of IC6, flipping its output negative, which allows the count to begin. So IC7 has taken the place of the start switch, S4. You can get rid of S4, but keep the pull-up resistor, R9, so that the reset of IC6 remains positive the rest of the time.

This arrangement works because I have used a capacitor, C4, to connect the output of IC7 to the reset of IC6. The capacitor communicates the sudden change from positive to negative, but the rest of the time it blocks the steady voltage from IC7 so that it won't interfere with IC6.

The final schematic in Figure 4-41 shows the three 555 timers all linked together, as you should insert them above the topmost counter, IC1. I also added an LED to signal the user. Figure 4-42 is a photograph of my working model of the circuit.

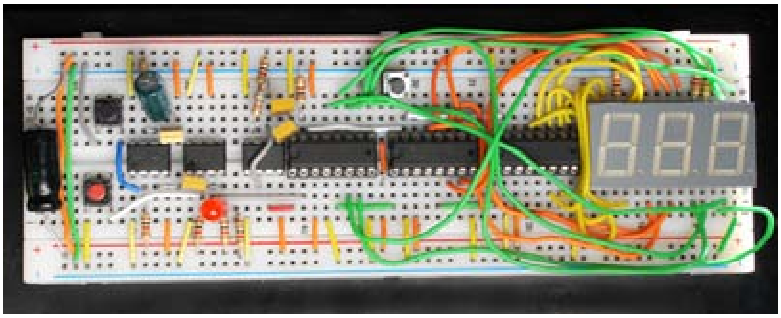

Figure 4-42. *The complete reaction-timer circuit barely fits on a 63-row breadboard.*

Because this circuit is complicated, I'll summarize the sequence of events when it's working. Refer to Figure 4-41 while following these steps:

1. User presses Start Delay button S4, which triggers IC7.
2. IC7 output goes high for a few seconds while C5 charges.
3. IC7 output drops back low.
4. IC7 communicates a pulse of low voltage through C4 to IC6, pin 4.
5. IC 6 output flips to low and flops there.
6. Low output from IC6 sinks current through LED and lights it.
7. Low output from IC6 also goes to pin 2 of IC1.

8. Low voltage on pin 2 of IC1 allows IC1 to start counting.
9. User presses S3, the "stop" button.
10. S3 connects pin 2 of IC6 to ground.
11. IC6 output flips to high and flops there.
12. High output from IC6 turns off the LED.
13. High output from IC6 also goes to pin 2 of IC1.
14. High voltage on pin 2 of IC1 stops it from counting.
15. After assessing the result, user presses S2.
16. S2 applies positive voltage to pin 15 of IC1, IC2, IC3.
17. Positive voltage resets counters to zero.
18. The user can now try again.
19. Meanwhile, IC5 is running continuously throughout.

In case you find a block diagram easier to understand, I've included that, too, in Figure 4-43.

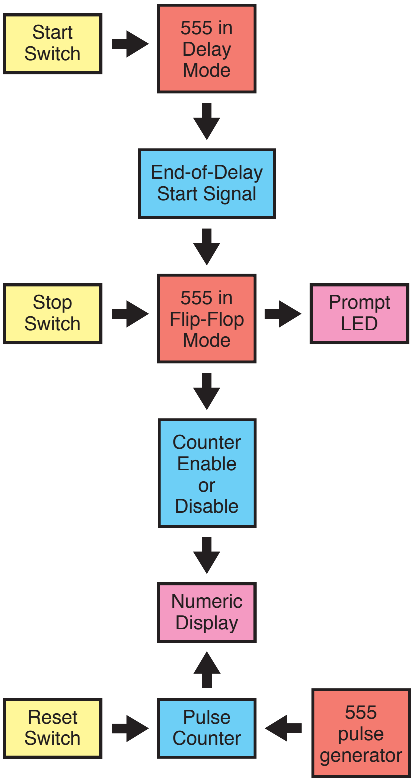

Figure 4-43. *The functions of the reflex tester, summarized as a block diagram.*

Using the Reflex Tester

At this point, you should be able to test the circuit fully. When you first switch it on, it will start counting, which is slightly annoying, but easily fixed. Press S3 to stop the count. Press S2 to reset to zero.

Now press S4. Nothing seems to happen—but that's the whole idea. The delay cycle has begun in stealth mode. After a few seconds, the delay cycle ends, and the LED lights up. Simultaneously, the count begins. As quickly as possible, the user presses S3 to stop the count. The numerals freeze, showing how much time elapsed.

There's only one problem—the system has not yet been calibrated. It is still running in slow-motion mode. You need to change the resistor and capacitor attached to IC5 to make it generate 1,000 pulses per second instead of just three or four.

Substitute a 10K trimmer potentiometer for R8 and a 1 μF capacitor for C2. This combination will generate about 690 pulses per second when the trimmer is presenting maximum resistance. When you turn the trimmer down to decrease its resistance, somewhere around its halfway mark the timer will be running at 1,000 pulses per second.

How will you know exactly where this point is? Ideally, you would attach an oscilloscope probe to the output from IC5. But, most likely, you don't have an oscilloscope, so here are a couple other suggestions.

First remove the 1 μF capacitor at C2 and substitute a 10 μF capacitor. Because you are multiplying the capacitance by 10, you will reduce the speed by 10. The leftmost digit in your display should now count in seconds, reaching 9 and rolling over to 0 every 10 seconds. You can adjust your trimmer potentiometer while timing the display with a stopwatch. When you have it right, remove the 10 μF capacitor and replace the 1 μF capacitor at C2.

The only problem is, the values of capacitors may be off by as much as 10%. If you want to fine-tune your reflex timer, you can proceed as follows.

Disconnect the wire from pin 5 of IC3, and substitute an LED with a 1K series resistor between pin 5 and ground. Pin 5 is the “carry” pin, which will emit a positive pulse whenever IC3 counts up to 9 and rolls over to start at 0 again. Because IC3 is counting tenths of a second, you want its carry output to occur once per second.

Now run the circuit for a full minute, using your stopwatch to see if the flashing LED drifts gradually faster or slower than once per second. If you have a camcorder that has a time display in its viewfinder, you can use that to observe the LED.

If the LED flashes too briefly to be easily visible, you can run a wire from pin 5 to another 555 timer that is set up in monostable mode to create an output lasting for around 1/10 of a second. The output from that timer can drive an LED.

Enhancements

It goes without saying that anytime you finish a project, you see some opportunities to improve it. Here are some suggestions:

1. No counting at power-up. It would be nice if the circuit begins in its “ready” state, rather than already counting. To achieve this you need to send a negative pulse to pin 2 of IC6, and maybe a positive pulse to pin 15 of IC1. Maybe an extra 555 timer could do this. I’m going to leave you to experiment with it.
2. Audible feedback when pressing the Start button. Currently, there’s no confirmation that the Start button has done anything. All you need to do is buy a piezoelectric beeper and wire it between the righthand side of the Start button and the positive side of the power supply.
3. A random delay interval before the count begins. Making electronic components behave randomly is very difficult, but one way to do it would be to require the user to hold his finger on a couple of metal contacts. The skin resistance of the finger would substitute for R11. Because the finger pressure would not be exactly the same each time, the delay would vary. You’d have to adjust the value of C5.

Summing Up

This project demonstrated how a counter chip can be controlled, how counter chips can be chained together, and three different functions for 555 timers. It also showed you how chips can communicate with each other, and introduced you to the business of calibrating a circuit after you've finished building it.

Naturally, if you want to get some practical use from the circuit, you should build it into an enclosure with heavier-duty pushbuttons—especially the button that stops the count. You'll find that when people's reflexes are being tested, they are liable to hit the stop button quite hard.

Because this was a major project, I'll follow it up here with some quicker, easier ones as we move into the fascinating world of another kind of integrated circuit: logic chips.

Experiment 19: Learning Logic

You will need:

- Assorted resistors and capacitors.
- 74HC00 quad 2-input NAND chip, 74HC08 quad 2-input AND chip, and LM7805 voltage regulator. Quantity: 1 of each.
- Signal diode, 1N4148 or similar. Quantity: 1.
- Low-current LED. Quantity: 1.
- SPST tactile switches. Quantity: 2.

You're going to be entering the realm of pure digital electronics, using "logic gates" that are fundamental in every electronic computing device. When you deal with them individually, they're extremely easy to understand. When you start chaining them together, they can seem intimidatingly complex. So let's start with them one at a time.

Logic gates are much fussier than the 555 timer or the 4026 counter that you used previously. They demand an absolutely precise 5 volts DC, with no fluctuations or "spikes" in the flow of current. Fortunately, this is easy to achieve: just set up your breadboard with an LM7805 voltage regulator, as shown in the schematic in Figure 4-44 and the photograph in Figure 4-45. The regulator receives 9 volts from your usual voltage supply, and reduces it to 5 volts, with the help of a couple of capacitors. You apply the 9 volts to the regulator, and distribute the 5 volts down the sides of your breadboard instead of the unregulated voltage that you used previously. Use your meter to verify the voltage, and make sure you have the polarity clearly marked.

After installing your regulator, take a couple of tactile switches, two 10K resistors, a low-current LED, and a 1K resistor, and set them around a 74HC00 logic chip as shown in Figure 4-46. You may notice that many of the pins of the chip are shorted together and connected to the negative side of the power supply. I'll explain that in a moment.

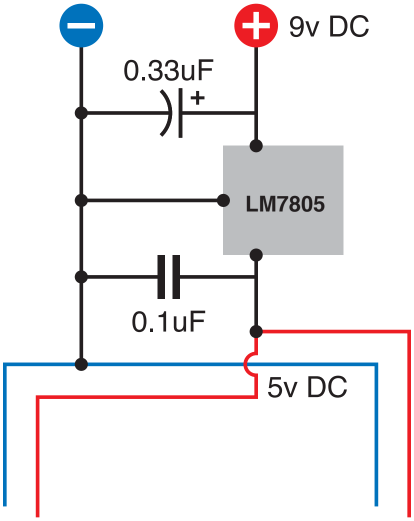

Figure 4-44. *This simple circuit is essential to provide a regulated 5V DC supply for logic chips.*

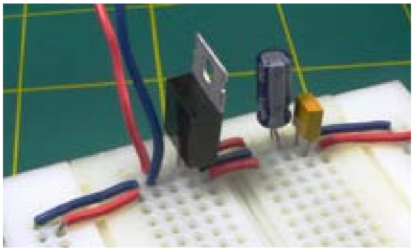

Figure 4-45. *The voltage regulator and its two capacitors can fit snugly at the top of a breadboard. Remember to apply the 9V input voltage at the left pin of the regulator, and distribute the 5V output down the sides of the breadboard.*

FUNDAMENTALS

Voltage regulators

The simplest versions of these little semiconductors accept a higher DC voltage on one pin and deliver a lower DC voltage on another pin, with a third pin (usually in the middle) serving as a common negative, or ground. You should also attach a couple of capacitors to smooth the current, as shown in Figure 4-46.

Typically you can put a 7.5-volt or 9-volt supply on the "input" side of a 5-volt regular, and draw a precise 5 volts from the "output" side. If you're wondering where the extra voltage goes, the answer is, the regulator turns the electricity into heat. For this reason, small regulators (such as the one in Figure 4-8) often have a metal back with a hole in the top. Its purpose is to radiate heat, which it will do more effectively if you bolt it to a piece of aluminum, since aluminum conducts heat very effectively. The aluminum is known as a heat sink, and you can buy fancy ones that have multiple cooling fins.

For our purposes, we won't be drawing enough current to require a heat sink.

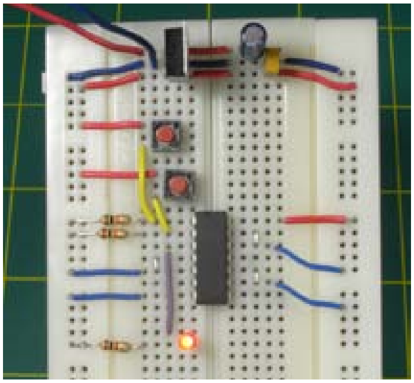

Figure 4-47. *This breadboard layout is exactly equivalent to the schematic in Figure 4-46.*

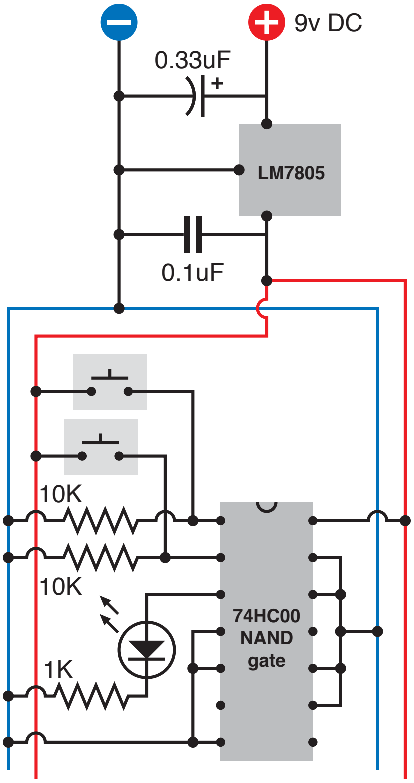

Figure 4-46. *By observing the LED when you press either, both, or neither of the buttons, you can easily figure out the logical function of the NAND gate.*

When you connect power, the LED should light up. Press one of the tactile switches, and the LED remains illuminated. Press the other tactile switch, and again the LED stays on. Now press both switches, and the light should go out.

Pins 1 and 2 are logic inputs for the 74HC00 chip. Initially they were held at negative voltage, being connected to the negative side of the power supply through 10K resistors. But each pushbutton overrides its pull-down resistor and forces the input pin to go positive.

The logic output from the chip, as you saw, is normally positive—but *not* if the first input *and* the second input are positive. Because the chip does a "Not AND" operation, it's known as a NAND logic gate. You can see the breadboard layout in Figure 4-47. Figure 4-48 is a simplified version of the circuit. The U-shaped thing with a circle at the bottom is the logic symbol for a NAND gate. No power supply is shown for it, but in fact all logic chips require a power supply, which enables them to put out more current than they take in. Anytime you see a symbol for a logic chip, try to remember that it has to have power to function.

The 74HC00 actually contains four NAND gates, each with two logical inputs and one output. They are arrayed as shown in Figure 4-49. Because only one gate was needed for the simple test, the input pins of the unused gates were shorted to the negative side of the power supply.

Pin 14 supplies positive power for the chip; pin 7 is its ground pin. Almost all the 7400 family of logic chips use the same pins for positive and negative power, so you can swap them easily.

In fact, let's do that right now. First, disconnect the power. Carefully pull out the 74HC00 and put it away with its legs embedded in conductive foam. Substitute a 74HC08 chip, which is an AND chip. Make sure you have it the right way up, with its notch at the top. Reconnect the power and use the pushbuttons as you did before. This time, you should find that the LED comes on if the first input AND the second input are both positive, but it remains dark otherwise. Thus, the AND chip functions exactly opposite to the NAND chip. Its pinouts are shown in Figure 4-50.

You may be wondering why these things are useful. Soon you'll see that we can put logic gates together to do things such as create an electronic combination lock, or a pair of electronic dice, or a computerized version of a TV quiz show where users compete to answer a question. And if you were really insanely ambitious, you could build an entire computer out of logic gates.

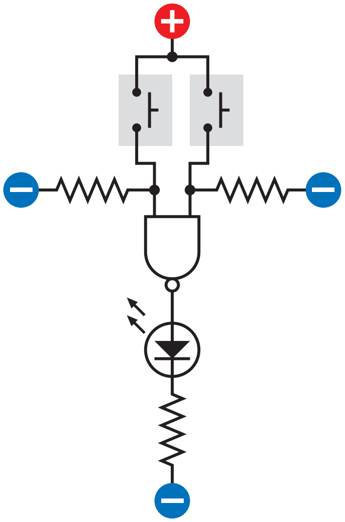

Figure 4-48. *The structure and function of the NAND gate is easier to visualize with this simplified schematic that omits the power supply for the chip and doesn't attempt to place the wires to fit a breadboard layout.*

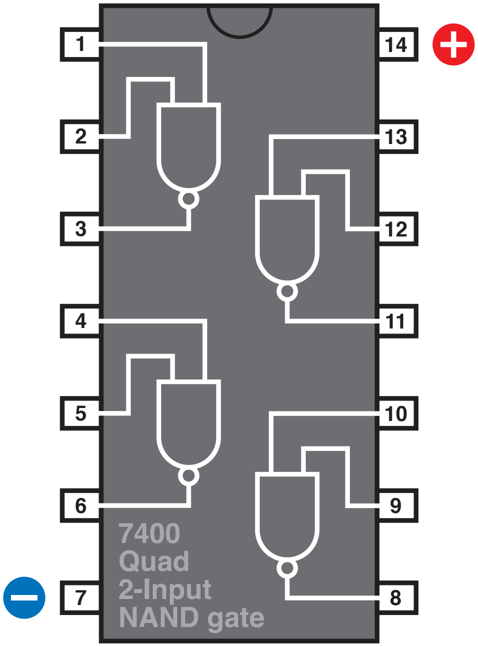

Figure 4-49. *The pinouts of the logic gates in a 74HC00chip.*

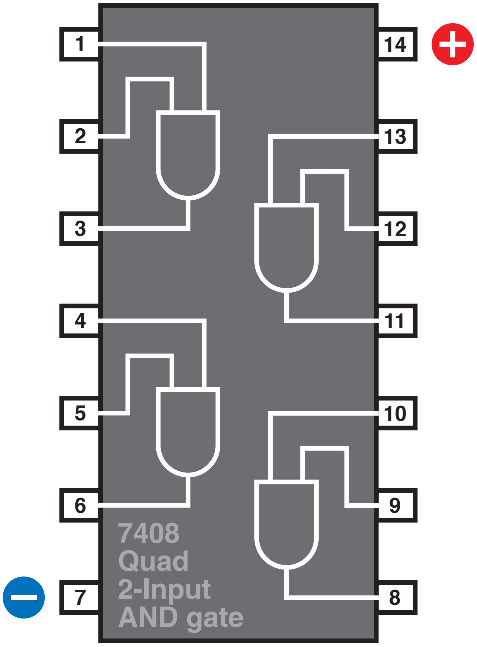

Figure 4-50. *The pinouts of the logic gates in a 74HC08chip.*

BACKGROUND

From Boole to Shannon

George Boole was a British mathematician, born in 1815, who did something that few people are ever lucky enough or smart enough to do: he invented an entirely new branch of mathematics.

Interestingly, it was not based on numbers. Boole had a relentlessly logical mind, and he wanted to reduce the world to a series of true-or-false statements which could overlap in interesting ways. For instance, suppose there is a couple named Ann and Bob who have so little money, they only own one hat. Clearly, if you happen to run into Ann and Bob walking down the street, there are four possibilities: neither of them may be wearing a hat, Ann may be wearing it, or Bob may be wearing it, but they cannot both be wearing it.

The diagram in Figure 4-51 illustrates this. All the states are possible except the one where the circles overlap. (This is known as a Venn diagram. I leave it to you to search for this term if it interests you and you'd like to learn more.) Boole took this concept much further, and showed how to create and simplify extremely complex arrays of logic.

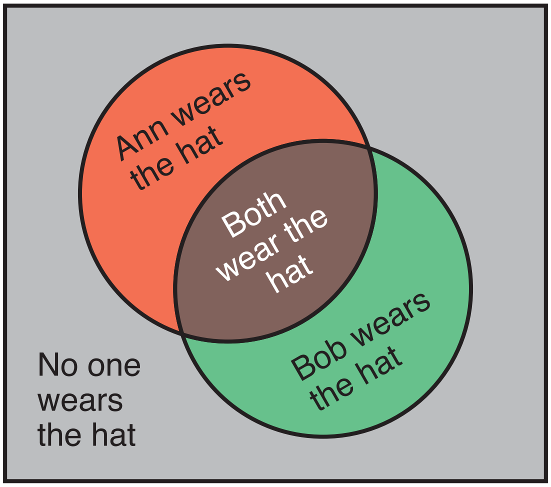

Figure 4-51. *This slightly frivolous Venn diagram illustrates the various possibilities for two people, Ann and Bob, who own only one hat.*

Another way to summarize the hat-wearing situation is to make the "truth table" shown in Figure 4-52. The rightmost column shows whether each combination of propositions can be true. Now check the table in Figure 4-53. It's the same table but uses different labels, which describe the pattern you have seen while using the NAND gate.

Boole published his treatise on logic in 1854, long before it could be applied to electrical or electronic devices. In fact, during his lifetime, his work seemed to have no practical applications at all. But a man named Claude Shannon encountered Boolean logic while studying at MIT in the 1930s, and in 1938 he published a paper describing how Boolean analysis could be applied to circuits using relays. This had immediate practical applications, as telephone networks were growing rapidly, creating complicated switching problems.

BACKGROUND

From Boole to Shannon (continued)

Ann is wearing the hat	Bob is wearing the hat	This combination can be
NO	NO	TRUE
NO	YES	TRUE
YES	NO	TRUE
YES	YES	FALSE

Figure 4-52. *The hat-wearing possibilities can be expressed in a "truth table."*

Input A	Input B	Output
OFF	OFF	ON
OFF	ON	ON
ON	OFF	ON
ON	ON	OFF

Figure 4-53. *The truth-table from can be relabeled to describe the inputs and outputs of a NAND gate.*

A very simple telephone problem could be expressed like this. Suppose two customers in a rural area share one telephone line. If one of them wants to use the line, or the other wants to use it, or neither of them wants to use it, there's no problem. But they cannot both use it at once. You may notice that this is exactly the same as the hat-wearing situation for Ann and Bob.

We can easily draw a circuit using two normally closed relays that creates the desired outcome (see Figure 4-54), but if you imagine a telephone exchange serving many thousands of customers, the situation becomes very complicated indeed. In fact, in Shannon's time, no logical process existed to find the best solution and verify that it used fewer components than some other solution.

Shannon saw that Boolean analysis could be used for this purpose. Also, if you used an "on" condition to represent numeral 1 and an "off" condition to represent numeral 0, you could build a system of relays that could count. And if it could count, it could do arithmetic.

When vacuum tubes were substituted for relays, the first practical digital computers were built. Transistors took the place of vacuum tubes, and integrated circuit chips replaced transistors, leading to the desktop computers that we now take for granted today. But deep down, at the lowest levels of these incredibly complex devices, they still use the laws of logic discovered by George Boole. Today, when you use a search engine online, if you use the words AND and OR to refine your search, you're actually using Boolean operators.

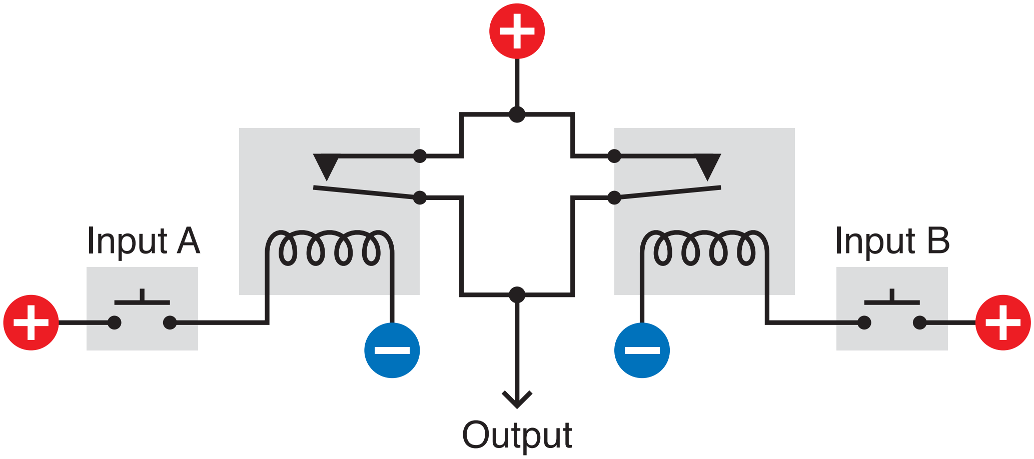

Figure 4-54. *This relay circuit could illustrate the desired logic for two telephone customers wanting to share one line, and its behavior is almost identical to that of the NAND schematic shown in Figure 4-48.*

Figure 4-55. *Ann and Bob attempt to overcome the limitations of Boolean logic.*

ESSENTIALS

Logic gate basics

The NAND gate is the most fundamental building block of digital computers, because (for reasons which I don't have space to explain here) it enables digital addition. If you want to explore more try searching online for topics such as "binary arithmetic" and "half-adder."

Generally, there are seven types of logic gates:

- AND
- NAND
- OR
- NOR
- XOR
- XNOR
- NOT

Of the six two-input gates, the XNOR is hardly ever used. The NOT gate has a single input, and simply gives a negative output when the input is positive or a positive output when the input is negative. The NOT is more often referred to as an "Inverter." The symbols for all seven gates are shown in Figure 4-56.

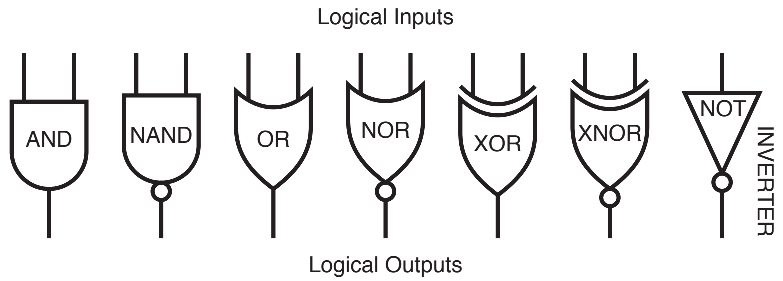

Figure 4-56. *American symbols for the six types of two-input logic gates, and the single-input inverter.*

I've shown the American symbols. Other symbols have been adopted in Europe, but the traditional symbols shown here are the ones that you will usually find, even being used by Europeans. I also show the truth tables, in Figure 4-57, illustrating the logical output (high or low) for each pair of inputs of each type of gate.

The plus signs indicate higher voltage, close to the positive potential of the power supply in the circuit. The exact voltages will vary depending on other components that may be actively connected.*

ESSENTIALS

Logic gate basics (continued)

If you have difficulty visualizing logic gates, a mechanical comparison may help. You can think of them as being like sliding plates with holes in them, in a bubblegum machine. Two people, A and B, can push the plates. These people are the two inputs, which are considered positive when they are doing something. (Negative logic systems also exist, but are uncommon, so I'm only going to talk about positive systems here.)

The flow of bubblegum represents a flow of positive current. The full set of possibilities is shown in Figures 4-58 through 4-63.

BACKGROUND

The confusing world of TTL and CMOS

Back in the 1960s, the first logic gates were built with Transistor-Transistor Logic, abbreviated TTL, meaning that tiny bipolar transistors were etched into a single wafer of silicon. Soon, these were followed by Complementary Metal Oxide Semiconductors, abbreviated CMOS. Each of these chips was a collection of metal-oxide field-effect transistors (known as MOSFETs). The 4026 chip that you used earlier is an old CMOS.

You may remember that bipolar transistors amplify current. TTL circuits are similar: they are sensitive to current, rather than voltage. Thus they require a significant flow of electricity, to function. But CMOS chips are like the programmable unijunction transistor that I featured previously. They are voltage-sensitive, enabling them to draw hardly any current while they are waiting for a signal, or pausing after emitting a signal.

The two families named TTL and CMOS still exist today. The table in Figure 4-64 summarizes their basic advantages and disadvantages. The CMOS series, with part numbers from 4000 upward, were easily damaged by static electricity but were valuable because of their meager power consumption. The TTL series, with part numbers from 7400 upward, used much more power but were less sensitive and very fast. So, if you wanted to build a computer, you used the TTL family, but if you wanted to build a little gizmo that would run for weeks on a small battery, you used the CMOS family.

From this point on everything became extremely confusing, because CMOS manufacturers wanted to grab market share by emulating the advantages of TTL chips. Newer generations of CMOS chips even changed their part numbers to begin with "74" to emphasize their compatibility, and the functions of pins on CMOS chips were swapped around to match the functions of pins on TTL chips. Consequently, the pinouts of CMOS and TTL chips are usually now identical, but the meaning of "high" and "low" states changed in each new generation, and the maximum supply voltages for CMOS chips were revised downward. Note I have included question marks beside two categories in the CMOS column, as modern CMOS chips have overcome those disadvantages—at least to some extent.

Here's a quick summary, which will be useful to you if you look at a circuit that you find online, and you wonder about the chips that have been specified.

Where you see a letter "x," it means that various numbers may appear in that location. Thus "74xx" includes the 7400 NAND gate, the 7402 NOR gate, the 74150 16-bit data selector, and so on. A combination of letters preceding the "74" identifies the chip manufacturer, while letters following the part number may identify the style of package, may indicate whether it contains heavy metals that are environmentally toxic, and other details.

	TTL	CMOS
Part number series	7400	4000 (Later adopted 7400 numbering)
Vulnerable to static electricity	Less	More?
Speed	Faster	Slower?
Power Consumption	Higher	Very Low
Power Supply Range	Narrow 5v	Wider 3v-6v
Input Impedance	Low	Very High

Figure 4-64. *The basic differences between the two families of logic chips. In successive generations, these differences have gradually diminished.*

TTL family:

74xx
The old original generation, now obsolete.

74Sxx
Higher speed "Schottky" series, now obsolete.

74LSxx
Lower power Schottky series, still used occasionally.

74ALSxx
Advanced low-power Schottky.

74Fxx
Faster than the ALS series.

BACKGROUND

The confusing world of TTL and CMOS (continued)

CMOS family:

40xx
The old original generation, now obsolete.

40xxB
The 4000B series was improved but still susceptible to damage from static electricity. Many hobby circuits still use these chips because they will run from relatively high voltages and can power LEDs and even small relays directly.

74HCxx
Higher-speed CMOS, with part numbers matching the TTL family, and pinouts matching the TTL family, but input and output voltages not quite the same as the TTL family. I've used this generation extensively in this book, because it's widely available, and the circuits here have no need for greater speed or power.

74HCTxx
Like the HC series but matching the TTL voltages.

74ACxx
Advanced version of HC series. Faster, with higher output capacity.

74ACTxx
Like the AC series but with the same pin functions and voltages as TTL.

74AHCxx
Advanced higher-speed CMOS.

74AHCTxx
Like the AHC series but with the same pin functions and voltages as TTL.

74LVxx
Lower voltage (3.3v) versions, including LV, LVC, LVT, and ALVC series.

As you can see, these days you have to interpret part numbers very carefully. But which family and generation of chips should you use? Well, that depends! Following are some guidelines.

What you don't need:

1. Speed differences are irrelevant from our point of view, as we're not going to be building circuits running at millions of cycles per second.
2. Price differences are so small as to be inconsequential.
3. Lower-voltage (LV) CMOS chips are not very interesting for our small experimental circuits.
4. Try to avoid mixing different families, and different generations of the same family, in the same circuit. They may not be compatible.
5. Some modern chip varieties may be only available in the surface-mount package format. Because they're so much more difficult to deal with, and their only major advantage is miniaturization, I don't recommend them.
6. In the TTL family, the LS and ALS series cannot handle as much output current as the S series and the F series. You don't need them.

What you should use:

1. The old 74LSxx series of TTL chips was so popular, you'll still find schematics that specify these chips. You should still be able to buy them from sources online, but if not, you can substitute the 74HCTxx chips, which are designed to function identically.
2. The old 4000B series of CMOS chips are still used by hobbyists because their willingness to tolerate high voltages is convenient. While TTL or TTL-compatible chips require a carefully regulated 5 volts, the 4000B chips would handle 15 volts—and also delivered enough power to energize LEDs or even very small relays. Some hobbyists also have a nostalgic affection for the 74Cxx series of chips, which had the same pin connections as the TTL chips but could still tolerate higher voltages and higher output current. The trouble is, some of the 74Cxx chips are almost extinct, and while the 4000B chips are still available, they are considered almost obsolete.

BACKGROUND

The confusing world of TTL and CMOS (continued)

Bottom line: I suggest you use the 4000B chips only if you want to replicate an old circuit, or if a modern equivalent is unavailable (which is why I specified the 4026B chip for the reaction timer—I could not find a modern equivalent that will drive seven-segment numeric displays directly, and I didn't want you to have to deal with more parts than necessary).

If you check online suppliers such as *Mouser.com* you'll find that the HC family is by far the most popular right now. They are all available in through-hole format (to fit your breadboard and perforated board). They have the high input impedance of CMOS (which is useful) and they have the same pin identities as the old 74LSxx series.

Abbreviations

When looking at data sheets, you are likely to encounter some or all of these abbreviations:

- VOH min: Minimum output voltage in high state
- VOL max: Maximum output voltage in low state
- VIH min: Minimum input voltage to be recognized as high
- VIL max: Maximum input voltage recognized as low

BACKGROUND

Logic gate origins

The 7400 family of integrated circuits was introduced by Texas Instruments, beginning with the 7400 NAND gate in 1962. Other companies had sold logic chips previously, but the 7400 series came to dominate the market. The Apollo lunar missions used a computer built with 7400 chips, and they were a mainstay of minicomputers during the 1970s.

RCA introduced its 4000 series of logic chips in 1968, built around CMOS transistors; Texas Instruments had chosen TTL. The CMOS chips used less power, thus generating much less heat and enabling flexible circuit design, as each chip could power many others. CMOS was also tolerant of wide voltage ranges (from 3 to 15 volts) but prohibited switching speeds faster than around 1MHz. TTL was 10 times faster.

Design tweaks gradually eradicated the speed penalty for CMOS, and TTL chips have become relatively rare. Still, some people retain a special nostalgic loyalty to "the logic gates that went to the moon." A hardcore enthusiast named Bill Buzbee has built an entire web server from TTL-type 7400 chips, currently online at *http://magic-1.org*. Figure 4-65 shows just one of the handmade circuit boards that Bill assembled to run his computer.

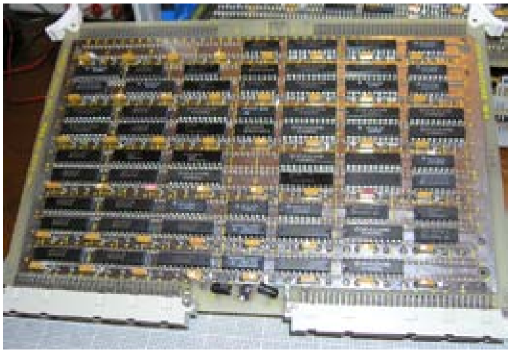

Figure 4-65. *Hobbyist Bill Buzbee built himself a web server entirely from 7400 series logic chips, the oldest of which was fabricated back in 1969. The web server can be found online at http://magic-1.org, displaying pictures of itself and details of its construction. The picture here that Bill took shows just one of the circuit boards of this remarkable project.*

FUNDAMENTALS

Common part numbers

Each 14-pin chip can contain four 2-input gates, three 3-input gates, two 4-input gates, one 8-input gate, or six single-input inverters, as shown in the following table.

	2 input	3 input	4 input	8 input
AND	7408	7411	7421	
NAND	7400	7410	7420	7430
OR	7432			744078*
NOR	7402	7427		744078*
XOR	7486			
XNOR	747266			
Inverter	(1 input) 7404			

*The 744078 has an OR output and a NOR output on the same chip.

Figures 4-66 through 4-74 show the internal connections of the logic chips that you are most likely to use. Note that the 7402 NOR gate has its logical inputs and outputs arranged differently from all the other chips.

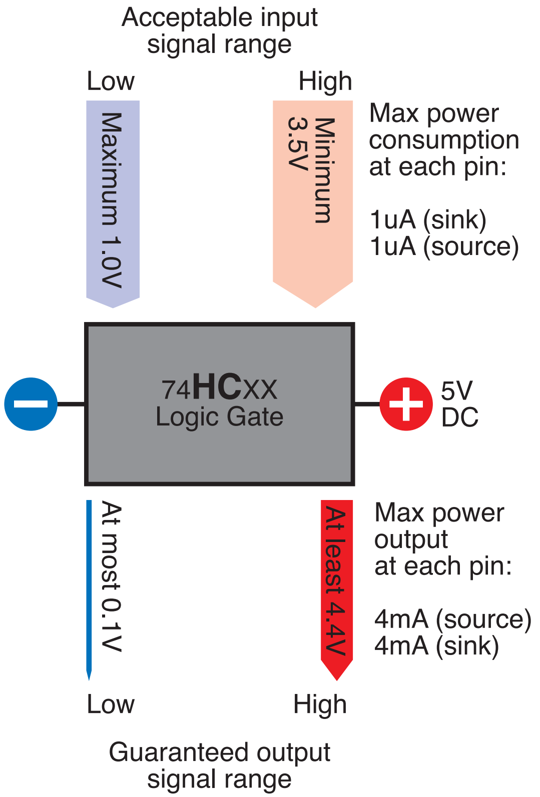
FUNDAMENTALS

Rules for connecting logic gates

Permitted:

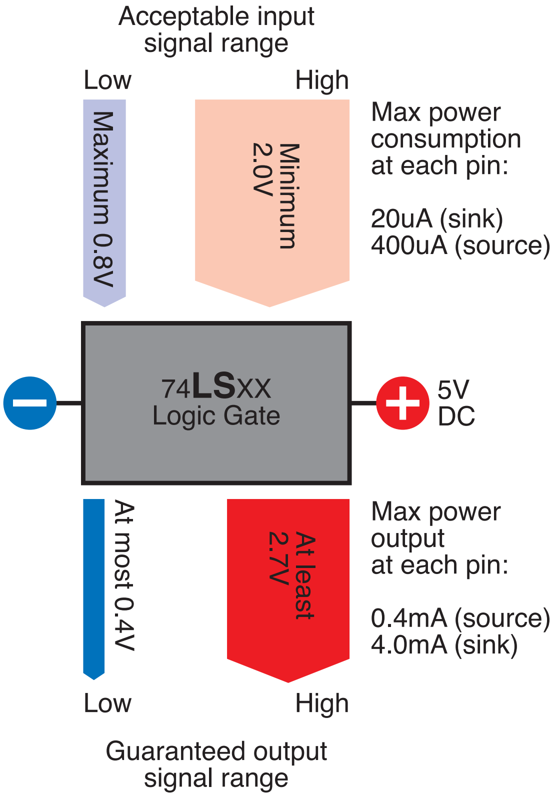
- You can connect the input of a gate directly to your regulated power supply, either positive side or negative side.
- You can connect the output from one gate directly to the input of another gate.
- The output from one gate can power the inputs of many other gates (this is known as "fanout"). The exact ratio depends on the chip, but you can always power at least ten inputs with one logic output. The output from a logic chip can drive the trigger (pin 3) of a 555 timer. The output from the timer can then deliver 100mA, easily enough for half-a-dozen LEDs or a small relay.
- Low input doesn't have to be zero. A 74HCxx logic gate will recognize any voltage up to 1 volt as "low."
- High input doesn't have to be 5 volts. A 74HCxx logic gate will recognize any voltage above 3.5 volts as "high."

See Figures 4-75 and 4-76 for a comparison of permitted voltages on the input and output side of 74HCxx and 74LSxx chips.



Acceptable input signal range
Low
High
Maximum 1.0V
Minimum 3.5V
Max power consumption at each pin:
1uA (sink)
1uA (source)
74HCxx Logic Gate
5V DC
At most 0.1V
At least 4.4V
Max power output at each pin:
4mA (source)
4mA (sink)
Low
High
Guaranteed output signal range

Figure 4-75. *Each family of logic chips, and each generation in each family, has different standards for input and output minimum and maximum voltages. This diagram shows the standards used by the HC generation of the CMOS family, which was chosen for most of the projects in this book. Note that the current required for input is minimal compared with the current available for output. The power supply to the chip makes up the difference.*



Acceptable input signal range
Low
High
Maximum 0.8V
Minimum 2.0V
Max power consumption at each pin:
20uA (sink)
400uA (source)
74LSxx Logic Gate
5V DC
At most 0.4V
At least 2.7V
Max power output at each pin:
0.4mA (source)
4.0mA (sink)
Low
High
Guaranteed output signal range

Figure 4-76. *Because the LS generation of the TTL family has such different tolerances for input voltages and different standards for output voltages, the LS generation of TTL chips should not be mixed in the same circuit as the HC generation of CMOS chips, unless pull-up resistors are used to bring the LS chips into conformance with standards expected by the HC chips. See Experiment 21 for a case study in using LS chips.*

FUNDAMENTALS

Rules for connecting logic gates (continued)

Not permitted:

- No floating-input pins! On CMOS chips such as the HC family, you must always connect all input pins with a known voltage, even if they supply a gate on the chip that you're not using. When you use a SPST switch to control an input, remember that in its "off" position, it leaves the input unconnected. Use a pull-up or pull-down resistor to prevent this situation. See Figure 4-77.
- Don't use an unregulated power supply, or more than 5 volts, to power 74HCxx or 74LSxx logic gates.
- Be careful when using the output from a logic gate to power even a low-current LED. Check how many milliamps are being drawn. Also be careful when "sharing" the output from a logic gate with the input of another gate, at the same time that it is driving an LED. The LED may pull down the output voltage, to a point where the other gate won't recognize it. Always check currents and voltages when modifying a circuit or designing a new one.
- Never apply a significant voltage or current to the output pin of a logic gate. In other words, don't force an input into an output.
- Never link the outputs from two or more logic gates. If they must share a common output wire, use diodes to protect them from each other. See Figure 4-78.

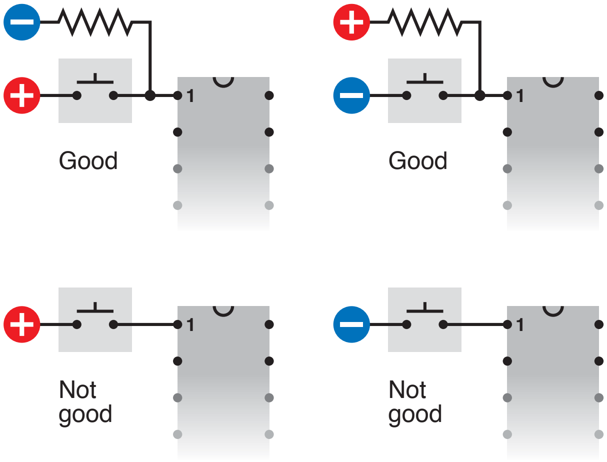


Figure 4-77. *Because a CMOS chip is so sensitive to input fluctuations, a logical input should never be left "floating," or unattached to a defined voltage source. This means that any single-throw switch or pushbutton should be used with a pull-up or pull-down resistor, so that when the contacts are open, the input is still defined.*

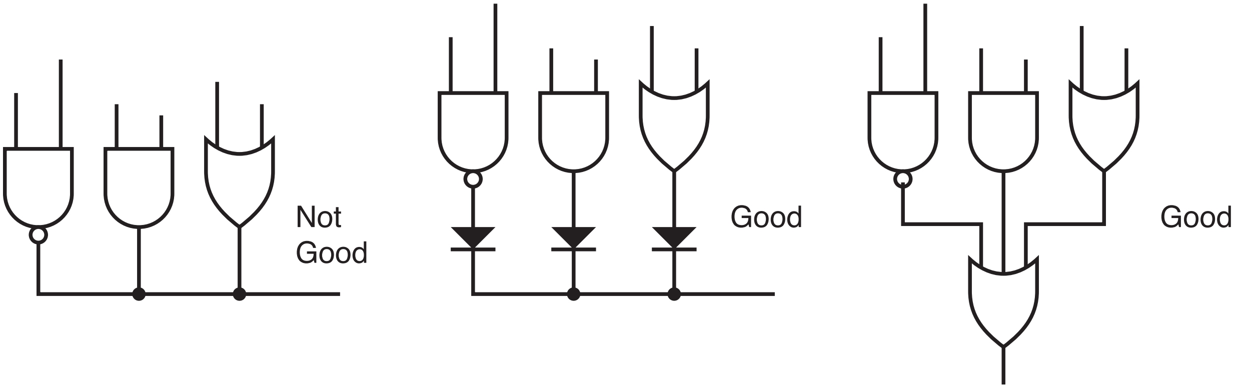

Figure 4-78. *The output from one logic gate must not be allowed to feed back into the output from another logic gate. Diodes can be used to isolate them, or they can be linked via another gate.*

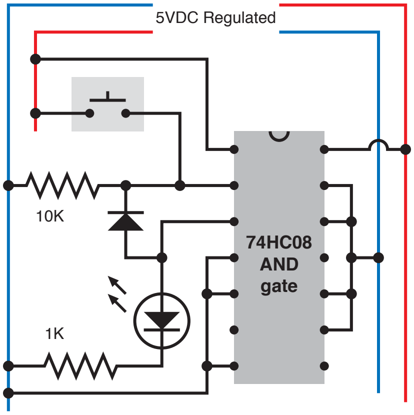

Figure 4-79. *Using a diode, the logical output from a gate can be allowed to feed back to one of its inputs, so that the gate latches after receiving a brief logical input pulse.*

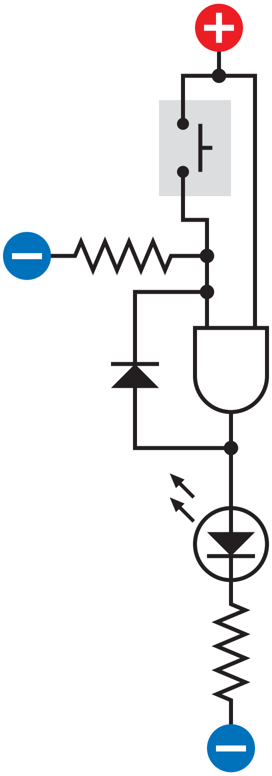

Figure 4-80. *The breadboard-format schematic in is simplified here to show more clearly the way in which a gate can latch itself after receiving an input pulse.*

In the 74HCxx logic family, each input of a logic gate consumes just a microamp, while the output can source 4 milliamps. This seems paradoxical: how can the chip give out more than it takes in? The answer is that it also consumes power from the power supply attached to pins 7 and 14. That's where the additional electricity comes from.

Because the logical output from a chip can be greater than the logical input, we can put the chip in a state where it keeps itself "switched on" in a way which is similar to the way the relay in the alarm project was wired to lock itself on. The simplest way to do this in a logic chip is by feeding some of the output back to one of the inputs.

Figure 4-79 shows an AND gate with one of its inputs wired to positive and its other input held low by a pull-down resistor, with a pushbutton that can make the input high. A signal diode connects the output of the chip back to the pushbutton-controlled input. Remember that the diode has a mark on it indicating the end which should be connected to the *negative* side of the power supply, which in this case will be the end of the 10K resistor.

The schematic in Figure 4-79 shows how the circuit should look in breadboard format. Figure 4-80 shows it in a simpler format.

From this point on, I won't bother to show the power regulator and the capacitors associated with it. Just remember to include them every time you see the power supply labeled as "5V DC Regulated."

When you switch on the power, the LED is dark, as before. The AND gate needs a positive voltage on both of its logical inputs, to create a positive output, but it now has positive voltage only on one of its inputs, while the other input is pulled down by the 10K resistor. Now touch the pushbutton, and the LED comes on. Let go of the pushbutton, and the LED stays on, because the positive output from the AND gate circulates back through the diode and is high enough to overcome the negative voltage coming through the pull-down resistor.

The output from the AND gate is powering its own input, so the LED will stay on until we disconnect it. This arrangement is a simple kind of "latch," and can be very useful when we want an output that continues after the user presses and releases a button.

You can't just connect the output from the gate to one of its inputs using an ordinary piece of wire, because this would allow positive voltage from the tactile switch to flow around and interfere with the output signal. Remember, you must never apply voltage to the output pin of a logic gate. The diode prevents this from happening.

If you've grasped the basics of logic gates, you're ready now to continue to our first real project, which will use all the information that I've set out so far.

Experiment 20: A Powerful Combination

Suppose you want to prevent other people from using your computer. I can think of two ways to do this: using software, or using hardware. The software would be some kind of startup program that intercepts the normal boot sequence and requests a password. You could certainly do it that way, but I think it would be more fun (and more relevant to this book) to do it with hardware. What I'm imagining is a numeric keypad requiring the user to enter a secret combination before the computer can be switched on.

You will need:

- Numeric keypad. As specified in the shopping list at the beginning of this chapter, it must have a "common terminal" or "common output." The schematic in Figure 4-82 shows what I mean. Inside the keypad, one conductor (which I have colored red to distinguish it from the others) connects with one side of every pushbutton. This conductor is "common" to all of them. It emerges from the keypad on an edge connector or set of pins at the bottom, which I've colored yellow.

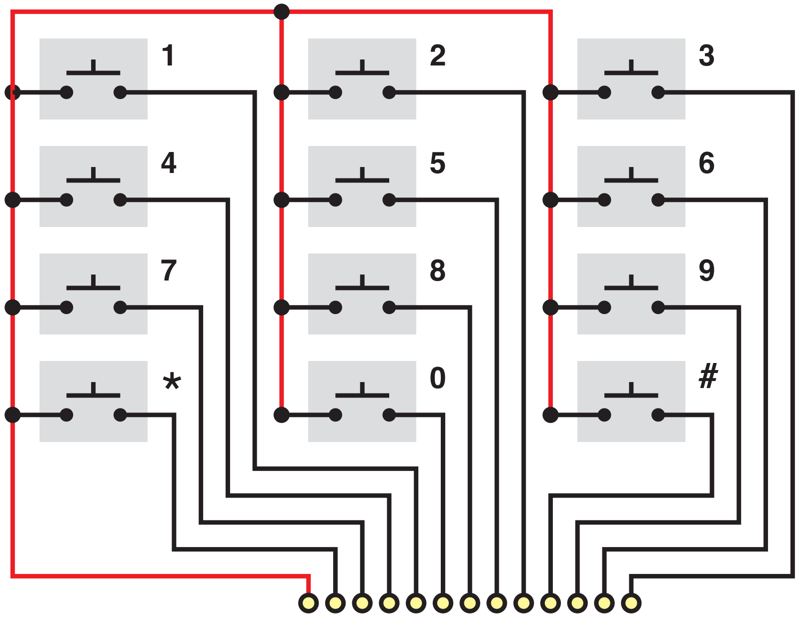

Figure 4-82. *A keypad of the type required for Experiment 20 incorporates a common terminal connected to one side of each of the 12 pushbuttons. The wire from the common terminal is shown red, here, to make it more easily identifiable.*

- Keypads that use "matrix encoding" won't work with the circuit that I'm going to describe. If the Velleman keypad, which I recommend, is unavailable, and you can't find another like it, you can use 12 separate SPST pushbuttons. Of course, that will cost a little more.
- 74HC08 logic chip containing four AND gates. Quantity: 1.
- 74HC04 logic chip containing six inverters. Quantity: 1.
- 555 timer chip. Quantity: 1.

The Warranty Issue

If you follow this project all the way to its conclusion, you'll open your desktop computer, cut a wire, and saw a hole in the cabinet. Without a doubt, this will void your warranty. If this makes you nervous, here are three options:

1. Breadboard the circuit for fun, and leave it at that.

2. Use the numeric keypad on some other device.

3. Use it on an old computer.

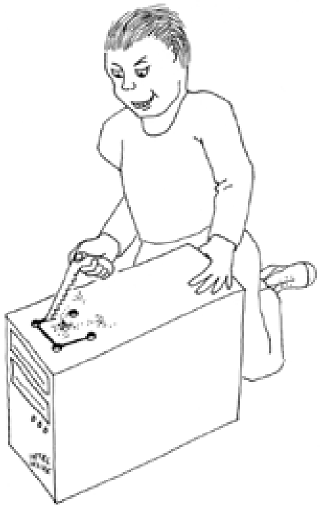

Figure 4-81. *Caution: This just might void your warranty.*

- Latching relay, 5 volt, DPST or DPDT, "2 form C" package, Panasonic DS2E-SL2-DC5V or similar. Must have two separate coils (one to latch, one to unlatch) with separate inputs. Quantity: 1.
- LEDs, 5mm generic, your choice of colors. Quantity: 3.
- Ribbon cable, with six conductors minimum, if you want to do a really neat job. You can use a cable of the type sold for hard drives, and split off the six conductors that you need, or shop around on eBay.
- Tools to open your computer, drill four holes, and make saw cuts between the holes, to create a rectangular opening for the keypad (if you want to take this project to its conclusion). Also, four small bolts to attach the keypad to the computer cabinet after you create the opening for it.

The Schematic

This time I'd like you to study the schematic before building anything. Let's start with the simplified version, shown in Figure 4-83.

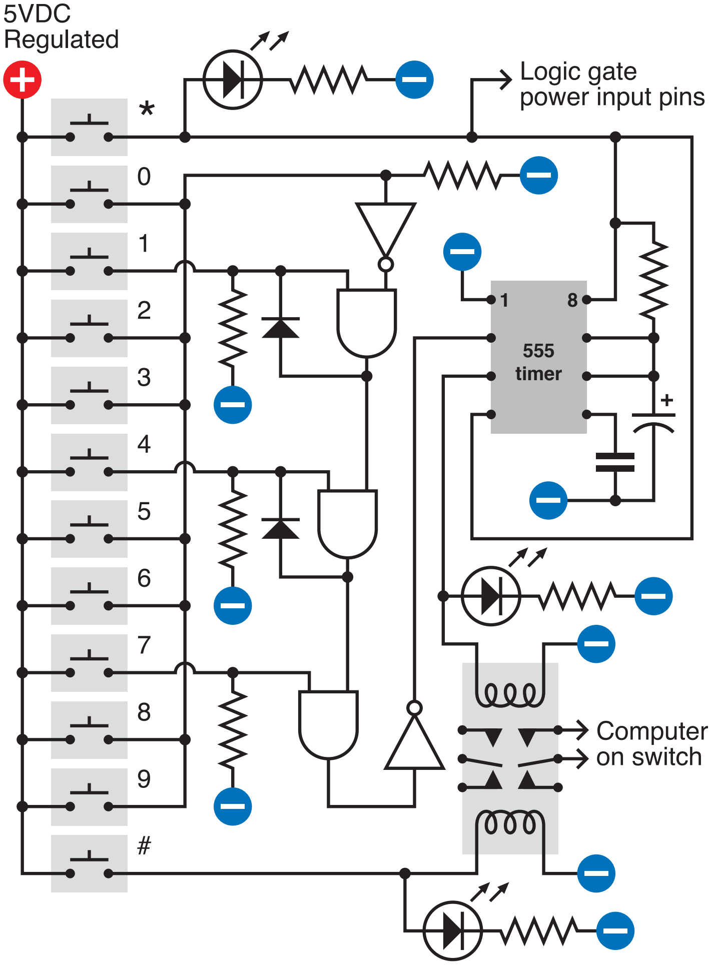

Figure 4-83. *A simplified schematic showing the basic structure of the combination lock circuit.*

I want this to be a battery-powered circuit, so that you don't have to run a separate power supply to it or (worse) try to tap into your computer's 5-volt bus. Battery power means that the circuit has to be "off" most of the time, to prevent the battery from running down. Because the keypad has two spare buttons (the asterisk and the pound sign), I'm going to use the asterisk as the "power on" button. When you press it, the LED at the top of the schematic lights up to confirm that everything's working, and the button sends power to the two logic chips and the 555 timer. You have to hold down the asterisk button while you punch in a three-digit code to unlock the computer.

Arbitrarily, I've chosen 1-4-7 as the three-digit code. Let's track what happens when you enter this sequence. (Naturally, if you build the circuit, you can wire it to choose any three digits you prefer.)

Pressing the 1 button sends positive power to one logical input of the first AND gate. The other logical input of this gate is also positive, because an inverter is supplying it, and the input of the inverter is being held negative by a pull-down resistor. When an inverter has a negative input, it gives a positive output, so pressing the 1 button activates the AND gate, and makes its output positive. The AND gate locks itself on, as its output cycles back to its switched input via a diode. So the gate output remains high even after you let go of the 1 button.

The output from the first AND gate also supplies one logical input of the second AND gate. When you press the 4 button, you send positive voltage to the other logical input of this AND gate, so its output goes high, and it locks itself on, just as the first gate did.

The second AND gate feeds the third AND gate, so when you press the 7 button, the third AND gate changes its output from low to high. This passes through an inverter, so the output from the inverter goes from high to low. This in turn goes to the trigger of a 555 timer wired in monostable mode.

When the trigger of a 555 timer goes from high to low, the timer emits a positive pulse through its output, pin 3. This runs down to the upper coil of the latching relay, and also flashes an LED to confirm that the code has been accepted and the relay has been activated.

Two of the contacts in the relay are wired into the power-up button of your computer. A little later in this description I'll explain why this should be safe with any modern computer.

Because we're using a latching relay, it flips into its "on" state and remains there, even when the power pulse from the timer ends. So now you can let go of the asterisk button to disconnect the battery power to your combination lock, and press the power-up button that switches on your computer.

At the end of your work session, you shut down your computer as usual, then press the pound button on your keypad, which flips the relay into its other position, reactivating the combination lock.

Incorrect Inputs

What happens if you enter the wrong code? If you press any button other than 1, 4, or 7, it sends positive voltage to the inverter near the top of the schematic. The positive voltage overwhelms the negative voltage being applied to the inverter through a pull-down resistor, and causes the inverter to output a negative voltage, which it applies to one of the logical inputs of the first AND gate. If the AND gate was locked on, the negative input will switch it off. If it was supplying the second AND gate, it'll switch that one off too.

Thus, any error when entering the first, second, or third digit of the secret code will reset the AND gates, forcing you to begin the sequence all over again.

What if you enter 1, 4, and 7 out of their correct sequence? The circuit won't respond. The third AND gate needs a high input supplied by the second AND gate, and the second AND gate needs a high input supplied by the first AND gate. So you have to activate the AND gates in the correct sequence.

Questions

Why did I use a 555 timer to deliver the pulse to the relay? Because the logical output from an AND gate cannot deliver sufficient power. I could have passed it through a transistor, but I liked the idea of a pulse of a fixed length to flip the relay and illuminate an LED for about 1 second, regardless of how briefly the user presses the 7 button.

Why do I need three LEDs? Because when you're punching buttons to unlock your computer, you need to know what's going on. The Power On LED reassures you that your battery isn't dead. The Relay Active LED tells you that the system is now unlocked, in case you are unable to hear the relay click. The System Relocked LED reassures you that you have secured your computer.

Because all the LEDs are driven either directly from the 5-volt supply or from the output of the 555 timer, they don't have to be low-current LEDs and can be used with 330Ω series resistors, so they'll be nice and bright.

How do you connect the keypad with the circuit? That's where your ribbon cable comes in. You carefully strip insulation from each of the conductors, and solder them to the contact strip or edge connector on your keypad. Push the conductors on the other end of the cable into your breadboard (when you're test-building the circuit) or solder them into perforated board (when you're building it permanently). Find a convenient spot inside your computer case where you can attach the perforated board, with double-sided adhesive or small bolts or whatever is convenient. Include a 9-volt battery carrier, and don't forget your power regulator to step the voltage down to 5 volts.

Breadboarding

No doubt you have realized by now that breadboards are very convenient as a quick way to push in some components and create connections, but the layout of their conductors forces you to put components in unintuitive configurations. Still, if you carefully compare the breadboard schematic in Figure 4-83 with the simplified schematic in Figure 4-84, you'll find that the connections are the same.

To help it make sense, I've shown the logic gates that exist inside the chips. I've also colored the power supply wires, as before, to reduce the risk of confusion. The positive side of the supply goes only to the common terminal on your keypad, and you have to press the asterisk key to send the power back down the ribbon cable, to supply the chips.

If you build the circuit and you can't understand why everything's dead, it's most likely because you forgot to hold down the asterisk button.

Note that the "wrong" numbers on the keypad are all shorted together. This will create some inconvenience if you want to change the combination in the future. I'll suggest a different option in the "enhancements" section that follows. For now, ideally, you should run a wire from every contact on your keypad, down to your circuit on its breadboard, and short the "wrong" keypad numbers together with jumper wires on the breadboard.

Also note that if you use a meter to test the inputs to the AND gates, and you touch your finger against the meter probe while doing so, this can be sufficient to trigger the sensitive CMOS inputs and give a false positive.

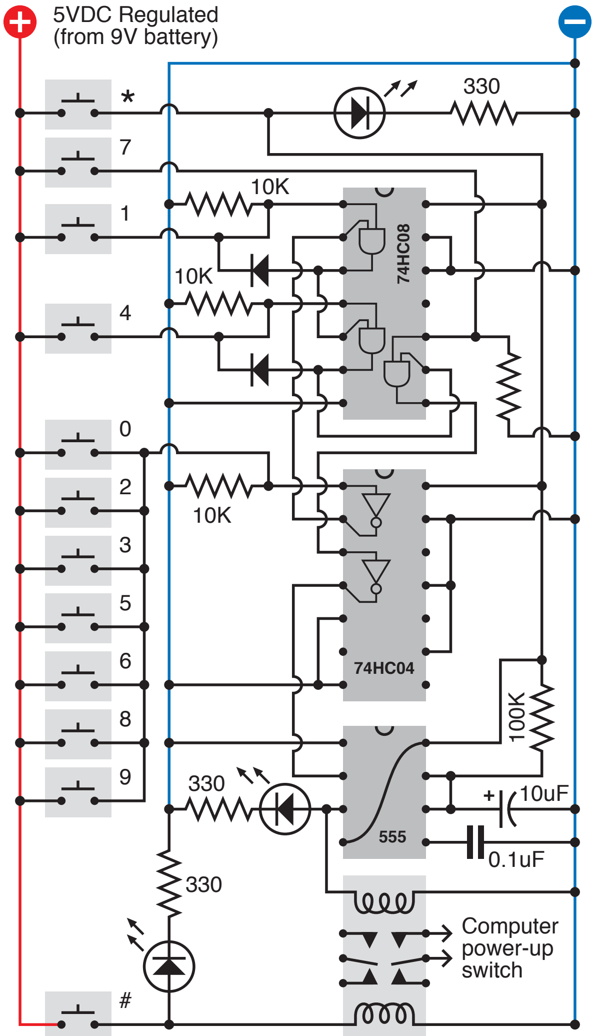

Figure 4-84. *The combination lock schematic redrawn to show how the components can be laid out on a breadboard.*

One Little Detail: The Computer Interface

Old computers used to have a big switch at the back, attached to the heavy metal box inside the computer, that transformed house current to regulated voltages that the computer needs. Most modern computers are not designed this way; you leave the computer plugged in, and you touch a little button on the box (if it's a Windows machine) or the keyboard (if it's a Mac), which sends a low-voltage pulse to the motherboard.

This is ideal from our point of view, because we don't have to mess with high voltages. Don't even think of opening that metal box with the fan mounted in it, containing the computer power supply. Just look for the wire (usually containing two conductors, on a Windows machine) that runs from the "power up" button to the motherboard.

To check that you found the right one, *make sure that your computer is unplugged*, ground yourself (because computers contain CMOS chips that are sensitive to static electricity) and very carefully snip just one of the two conductors in the wire. Now plug in your computer and try to use the "power up" button. If nothing happens, you've probably cut the right wire. Even if you cut the wrong wire, it still prevented your computer from booting, which is what you want, so you can use it anyway. Remember, we are not going to introduce any voltage to this wire. We're just going to use the relay as a switch to reconnect the conductor that you cut. You should have no problem if you maintain a cool and calm demeanor, and look for that single wire that starts everything. Check online for the maintenance manual for your computer if you're really concerned about making an error.

After you find the wire and cut just one of its conductors, unplug your computer again, and keep it unplugged during the next steps.

Find where the wire attaches to the motherboard. Usually there's a small unpluggable connector. First, mark it so that you know how to plug it back in the right way around, and then disconnect it while you follow the next couple of steps.

Strip insulation from the two ends of the wire that you cut, and solder an additional piece of two-conductor wire, as shown in Figure 4-85, with heat-shrink tube to protect the solder joints. (This is very important!)

Run your new piece of wire to the latching relay, making sure you attach it to the pair of contacts which close, inside the relay, when it is energized by the unlocking operation. You don't want to make the mistake of unlocking your computer when you think you're locking it, and vice versa.

Reconnect the connector that you disconnected from your motherboard, plug in your computer, and try to power it up. If nothing happens, this is probably good! Now enter the secret combination on your keypad (while holding down the asterisk button to provide battery power) and listen for the click as the relay latches. Now try the "power up" button again, and everything should work.

Figure 4-85. *The combination lock project can be interfaced with a typical desktop computer by cutting one conductor in the wire from the "power up" pushbutton, soldering an extension, and covering the joints with heat-shrink tube.*

Enhancements

At the end of any project, there's always more you can do.

To make this setup more secure, you could remove the usual screws that secure the case of the computer, and replace them with tamper-proof screws. Check any online source for "tamper-proof screws," such as *http://www.mcmaster.com*. Naturally, you will also need the special tool that fits the screws, so that you can install them (or remove them, if your security system malfunctions for any reason).

Another enhancement could be an additional 555 timer that is activated by the asterisk button, and delivers power to the other chips for, say, a limited period of 30 seconds, allowing you that much time to unlock the system. This would eliminate the need to hold down the asterisk button while you enter the unlocking code. A 555 timer can supply power to all the other chips, because they don't use very much. I omitted this feature for the sake of simplicity.

Yet another enhancement, if you are security-crazed, is to go for a four-button code. After all, the 74HC08 chip still has one unused AND gate. You could insert that into the chain of the existing AND gates and wire it to another keypad button of your choice.

Still another enhancement would be a way to change the code without unsoldering and resoldering wires. You can use the miniature sockets that I suggested in the heartbeat flasher project. These should enable you to swap around the ends of your wires from the keypad.

And for those who are absolutely, positively, totally paranoid, you could fix things so that entering a wrong code flips a second high-amperage relay which supplies a massive power overload, melting your CPU and sending a big pulse through a magnetic coil clamped to your hard drive, instantly turning the data to garbage (Figure 4-86). Really, if you want to protect information, messing up the hardware has major advantages compared with trying to erase data using software. It's faster, difficult to stop, and tends to be permanent. So, when the Record Industry Association of America comes to your home and asks to switch on your computer so that they can search for illegal file sharing, just accidentally give them an incorrect unlocking code, sit back, and wait for the pungent smell of melting insulation.

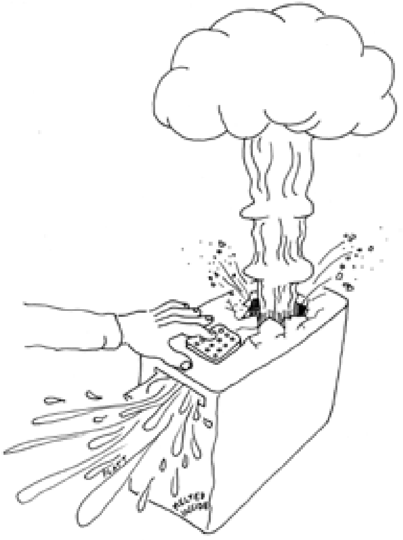

Figure 4-86. *For those who are absolutely, positively, totally paranoid: a meltdown/self-destruct system controlled by a secret key combination provides enhanced protection against data theft or intrusions by RIAA investigators asking annoying questions about file sharing.*

If you pursue this option, I *definitely* take no responsibility for the consequences.

On a more realistic level, no system is totally secure. The value of a hardware locking device is that if someone does defeat it (for instance, by figuring out how to unscrew your tamper-proof screws, or simply ripping your keypad out of the computer case with metal shears), at least you'll know that something happened—especially if you put little dabs of paint over the screws to reveal whether they've been messed with. By comparison, if you use password-protection software and someone defeats it, you may never know that your system has been compromised.

Experiment 21: Race to Place

The next project is going to get us deeper into the concept of feedback, where the output is piped back to affect the input—in this case, blocking it. It's a small project, but quite subtle, and the concepts will be useful to you in the future.

You will need:

- 74HC32 chip containing four OR gates. Quantity: 1.
- 555 timers. Quantity: 2.
- SPDT switch. Quantity: 1.
- SPST tactile switches. Quantity: 2.
- Various resistors.
- 5V supply using power regulator as before.

The Goal

On quiz shows such as *Jeopardy*, contestants race to answer each question. The first person who hits his answer button automatically locks out the other contestants, so that their buttons become inactive. How can we make a circuit that will do the same thing?

If you search online, you'll find several hobby sites where other people have suggested circuits to work this way, but they lack some features that I think are necessary. The approach I'm going to use here is both simpler and more elaborate. It's simpler because it has a very low chip count, but it's more elaborate in that it incorporates "quizmaster control" to make a more realistic game.

I'll suggest some initial ideas for a two-player version. After I develop that idea, I'll show how it could be expanded to four or even more players.

A Conceptual Experiment

I want to show how this kind of project grows from an idea to the finished version. By going through the steps of developing a circuit, I'm hoping I may inspire you to develop ideas of your own in the future, which is much more valuable than just replicating someone else's work. So join me in a conceptual experiment, thinking our way from a problem to a solution.

First consider the basic concept: two people have two buttons, and whoever goes first locks out the other person. I always find it helps me to visualize this kind of thing if I draw a sketch, so that's where I'll begin. In Figure 4-87, the signal from each button passes through a component that I'll call a "button blocker," activated by the other person's button. I'm not exactly sure what the button blocker will be or how it will work, yet.

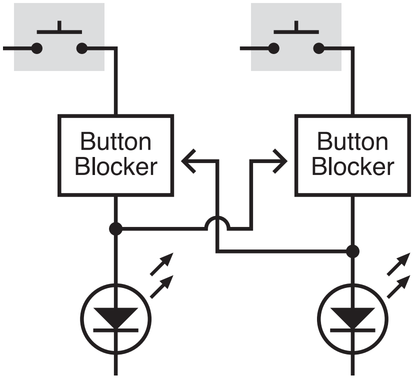

Figure 4-87. *The basic concept of the quiz project is that the output from one button should feed back to intercept the output of another button. At this point, the way in which the "button blocker" circuit works has not been figured out.*

Now that I'm looking at it, I see a problem here. If I want to expand this to three players, it will get complicated, because each player must activate the "button blockers" of *two* opponents. Figure 4-88 shows this. And if I have four players, it's going to get even more complicated.

Anytime I see this kind of complexity, I think there has to be a better way.

Also, there's another problem. After a player lets his finger off the button, the other players' buttons will be unblocked again. I need a latch to hold the signal from the first player's button and continue to block the other players.

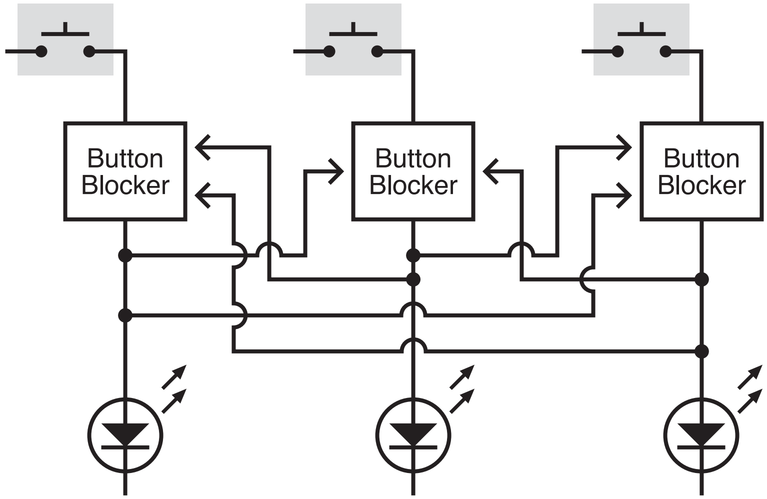

Figure 4-88. *The quiz concept becomes more complicated when an additional pushbutton is added. Now each button must block two other buttons. If a fourth button is added, the circuit will become unmanageably complex. There has to be a better way.*

This now sounds even more complicated. But wait a minute, if I have a latch which allows the winning player to take his finger off his button, I don't care if any of the buttons are being pressed anymore—including the button of the winning player. As soon as his signal is latched, *all* the buttons can be blocked. This makes things much simpler. I can summarize it as a sequence of events:

1. First player presses his button.
2. The signal is latched.
3. The latched signal feeds back and blocks all the buttons.

The new sketch in Figure 4-89 shows this. Now the configuration is modular, and can be expanded to almost any number of players, just by adding more modules.

There's something important missing, though: a reset switch, to put the system back to its starting mode after the players have had time to press their buttons and see who won. Also, I need a way to prevent players from pressing their buttons too soon, before the quizmaster has finished asking the question. Maybe I can combine this function in just one switch, which will be under the quizmaster's control. In its Reset position, the switch can reset the system and remove power to the buttons. In its Play position, the switch stops holding the system in reset mode, and provides power to the buttons. Figure 4-90 shows this. I've gone back to showing just two players, to minimize the clutter of lines and boxes, but the concept is still easily expandable.

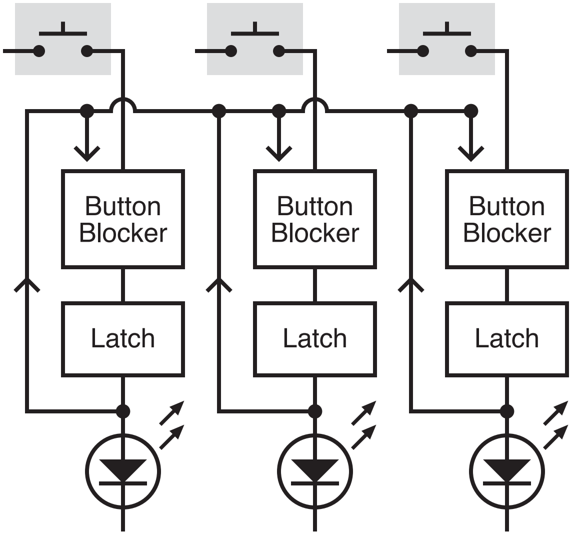

Figure 4-89. *If a latch is added below each button, it can retain one input and then block all inputs from all buttons. This simplifies the concept.*

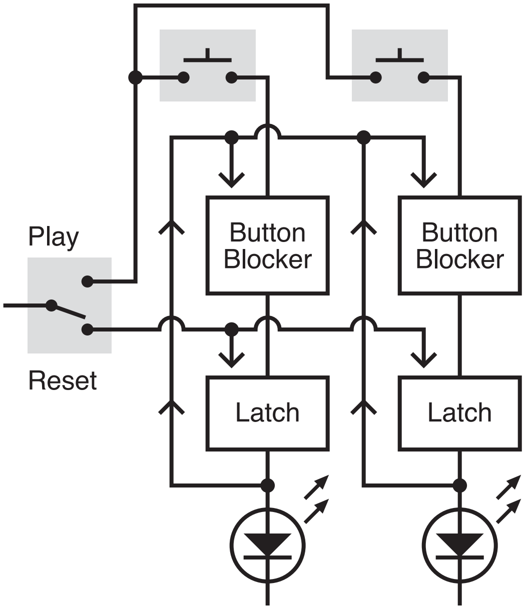

Figure 4-90. *A quizmaster switch will be needed to activate the buttons initially and then reset the circuit after a winning input has been recorded.*

Now I have to deal with a logic problem in the diagram. The way I've drawn it, after the output from the lefthand latch goes up to the "button blockers," it can also run down the wire to the other half of the circuit (against the direction to the arrows), because everything is joined together. In other words, if the lefthand LED lights up, the righthand LED will light up, too. How can I stop this from happening?

Well, I could put diodes in the "up" wires to block current from running down them. But I have a more elegant idea: I'll add an OR gate, because the inputs to an OR gate are separated from each other electrically. Figure 4-91 shows this.

Usually an OR gate has only two logical inputs. Will this prevent me from adding more players? No, because you can actually buy an OR that has eight inputs. If any one of them is high, the output is high. For fewer than eight players, I can short the unused inputs to ground, and ignore them.

Looking again at Figure 4-91, I'm getting a clearer idea of what the thing I've called a "button blocker" should actually be. I think it should be another logic gate. It should say, "If there's only one input, from a button, I'll let it through. But if there is a second input from the OR gate, I won't let it through."

That sounds like a NAND gate, but before I start choosing chips, I have to decide what the latch will be. I can buy an off-the-shelf flip-flop, which flips "on" if it gets one signal and "off" if it gets another, but the trouble is, chips containing flip-flops tend to have more features than I need for a simple circuit like this. Therefore I'm going to use 555 timers again, in flip-flop mode. They require very few connections, work very simply, and can deliver a good amount of current. The only problem with them is that they require a negative input at the trigger pin to create a positive output. But I think I can work with that.

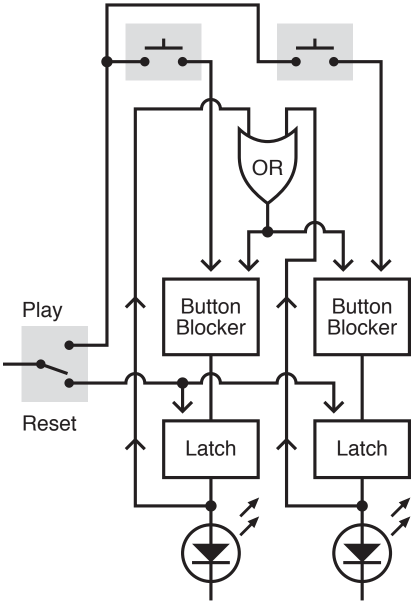

Figure 4-91. *To prevent the output from one latch feeding back around the circuit to the output from another latch, the outputs can be combined in an OR gate.*

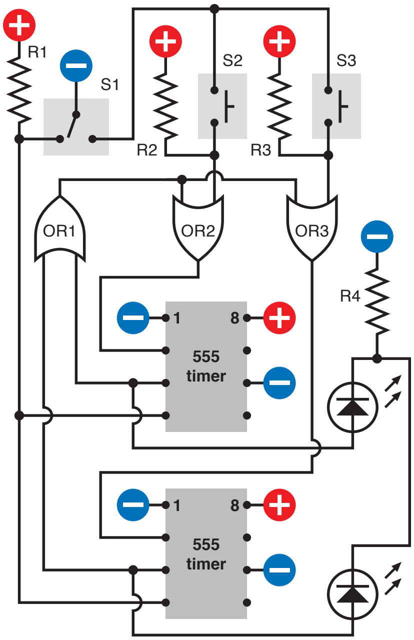

Figure 4-92. *Now that the basic concept of the quiz circuit has been roughed out, specific components can be inserted, with compatible inputs and outputs.*

So now, finally, here's a simplified schematic, in Figure 4-92. I like to show the pins of the 555 timers in their correct positions, so I had to move the components around a little to minimize wire crossovers, but you can see that logically, it's the same basic idea.

Before you try to build it, just run through the theory of it, because that's the final step, to make sure there are no mistakes. The important thing to bear in mind is that because the 555 needs a negative input on its trigger pin to create its output, when any of the players presses a button, the button has to create a negative "flow" through the circuit. This is a bit counterintuitive, so I'm including a three-step visualization in Figure 4-93, showing how it will work.

In Step 1, the quizmaster has asked a question and flipped his switch to the right, to supply (negative) power to the players' buttons. So long as no one presses a button, the pull-up resistors supply positive voltage to OR2 and OR3. An OR gate has a positive output if it has any positive input, so OR2 and OR3 keep the trigger inputs of the 555 timers positive. Their outputs remain low, and nothing is happening yet.

In Step 2, the lefthand player has pressed his button. Now OR2 has two negative inputs, so its output has gone low. But IC1 hasn't reacted yet.

In Step 3, just a microsecond later, IC1 has sensed the low voltage on its trigger, so its output from pin 3 has gone high, lighting the LED. Remember, this 555 timer is in flip-flop mode, so it locks itself into this state immediately. Meanwhile its high output also feeds back to OR1. Because OR1 is an OR gate, just one high input is enough to make a high output, so it feeds this back to OR2 and OR3. And now that they have high inputs, their outputs also go high, and will stay high, regardless of any future button-presses.

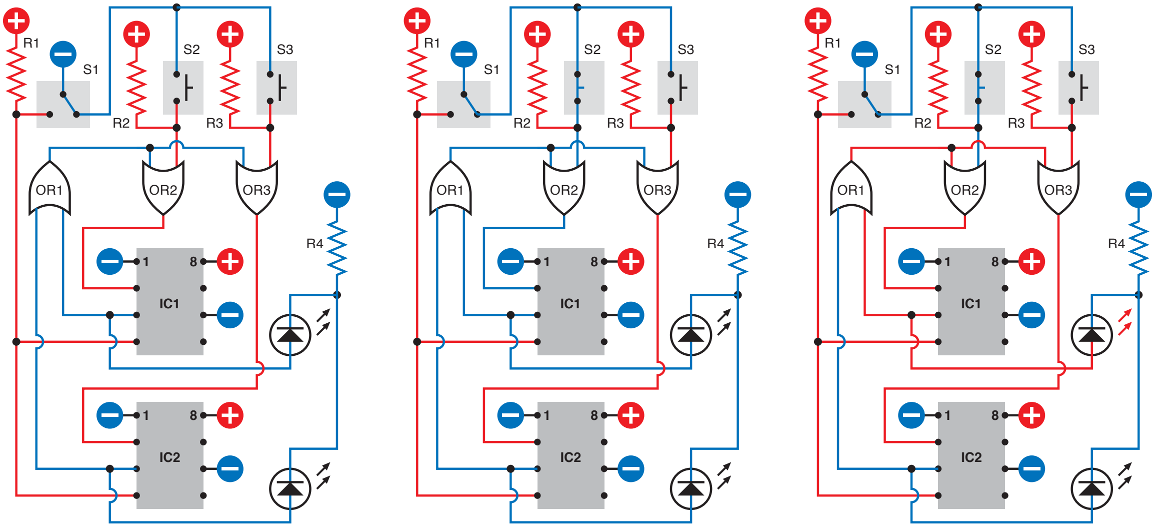

Figure 4-93. *These three schematics show the prevalence of higher and lower voltages (red and blue lines) through the quiz circuit when a pushbutton is pressed.*

Because OR2 and OR3 now have high inputs and outputs, IC1 and IC2 cannot be triggered. But IC1 is still locked into its "on" state, keeping the LED illuminated.

The only way to change IC1 is if the quizmaster flips his switch back to the left. That applies negative power to the reset pins of both the timers. Consequently their outputs go low, the LED goes out, and the circuit goes back into the same state as where it started. Having reset it, the quizmaster can ask another question, but the players' buttons are not activated until the quizmaster flips the switch back to the right again.

There's only one situation that I haven't addressed: what if both players press their buttons absolutely simultaneously? In the world of digital electronics, this is highly unlikely. Even a difference of a microsecond should be enough time for the circuit to react and block the second button. But if somehow both buttons are pressed at the same instant, both of the timers should react, and both of the LEDs will light up, showing that there has been a tie.

In case you feel a little uncertain about the way in which a two-player circuit can be upgraded to handle extra players, I've included a simplified three-player schematic in Figure 4-94.

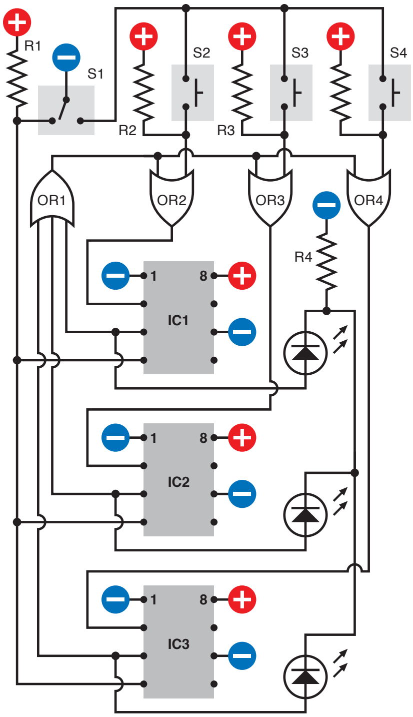

Figure 4-94. *The two-player schematic in can be easily upgraded to a three-player version, as shown here, provided the first OR gate can handle three inputs.*

Breadboarding It

Now it's time to create a schematic that's as close to the breadboard layout as possible, so that you can build this thing easily. The schematic is shown in Figure 4-95 and the actual components on a breadboard are in Figure 4-96. Because the only logic gates that I've used are OR gates, and there are only three of them, I just need one logic chip: the 74HC32, which contains four 2-input OR gates. (I've grounded the inputs to the fourth). The two OR gates on the left side of the chip have the same functions as OR2 and OR3 in my simplified schematic, and the OR gate at the bottom-right side of the chip works as OR1, receiving input from pin 3 of each 555 timer. If you have all the components, you should be able to put this together and test it quite quickly.

You may notice that I've made one modification of the previous schematic. A 0.01 µF capacitor has been added between pin 2 of each 555 timer (the Input) and negative ground. Why? Because when I tested the circuit without the capacitors, sometimes I found that one or both of the 555 timers would be triggered simply by flipping S1, the quizmaster switch, without anyone pressing a button.

At first this puzzled me. How were the timers getting triggered, without anyone doing anything? Maybe they were responding to "bounce" in the quizmaster switch. Sure enough, the small capacitors solved the problem. They may also slow the response of the 555 timers fractionally, but not enough to interfere with slow human reflexes.

As for the buttons, it doesn't matter if they "bounce," because each timer locks itself on at the very first impulse and ignores any hesitations that follow.

You can experiment building the circuit, disconnecting the 0.01 µF capacitors, and flipping S1 to and fro a dozen times. If you have a high-quality switch, you may not experience any problem. If you have a lower-quality switch, you may see a number of "false positives." I'm going to explain more about "bounce," and how to get rid of it, in the next experiment.

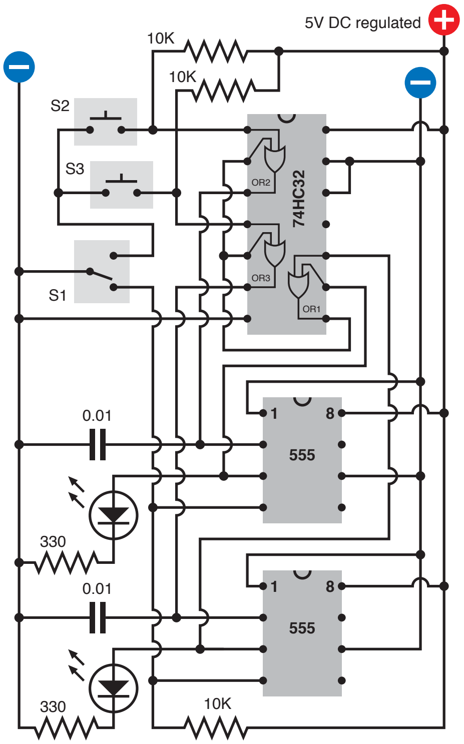

Figure 4-95. *Applying the simplified schematic to a breadboard inevitably entails a wiring layout that is less intuitively obvious and appears more complex. The connections are the same, though.*

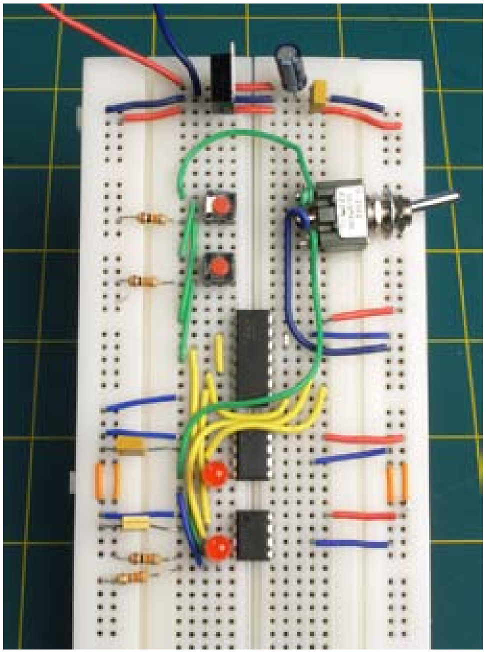

Figure 4-96. *The quiz schematic applied to a breadboard, to test the concept prior to full-scale implementation.*

Enhancements

After you breadboard the circuit, if you proceed to build a permanent version, I suggest that you expand it so that at least four players can participate. This will require an OR gate capable of receiving four inputs. The 74HC4078 is the obvious choice, as it allows up to eight. Just connect any unused inputs to negative ground.

Alternatively, if you already have a couple of 74HC32 chips and you don't want to bother ordering a 74HC4078, you can gang together three of the gates inside a single 74HC32 so that they function like a four-input OR. Look at the simple logic diagram in Figure 4-97 showing three ORs, and remember that the output from each OR will go high if at least one input is high.

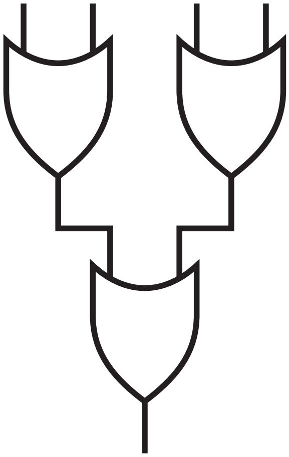

Figure 4-97. *Although a four-input OR gate is not manufactured, its functionality can be achieved easily by linking three 2-input OR gates together.*

And while you're thinking about this, see if you can figure out the inputs and output of three ANDs in the same configuration.

For a four-player game, you'll also need two additional 555 timers, of course, and two more LEDs, and two more pushbuttons.

As for creating a schematic for the four-player game—I'm going to leave that to you. Begin by sketching a simplified version, just showing the logic symbols. Then convert that to a breadboard layout. And here's a suggestion: pencil, paper, and an eraser can still be quicker, initially, than circuit-design software or graphic-design software, in my opinion.

Experiment 22: Flipping and Bouncing

I mentioned in the previous experiment that "bounce" from the buttons in the circuit wouldn't be a problem, because the buttons were activating 555 timers that were wired in bistable, flip-flop mode. As soon as the timer receives the very first pulse, it flips into its new state and flops there, ignoring any additional noise in the circuit. So can we debounce a switch or a button using a flip-flop? And as some 74HCxx chips are available containing flip-flops, can we use them?

The answers are yes, and yes, although it's not quite as simple as it sounds.

You will need:

- 74HC02 logic chip containing 4 NOR gates. 74HC00 logic chip containing 4 NAND gates. Quantity: 1 of each.
- SPDT switch. Quantity: 1.
- LEDs, low-current. Quantity: 2.
- 10K resistors and 1K resistors. Quantity: 2 of each.

Assemble the components on your breadboard, following the schematic shown in Figure 4-98. When you apply power (through your regulated 5-volt supply), one of the LEDs should be lit.

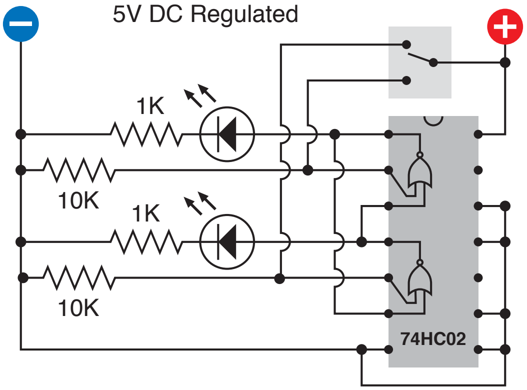

Figure 4-98. *A simple circuit to test the behavior of two NOR gates wired as a simple flip-flop that retains its state after an input pulse ceases.*

Now I want you to do something odd. Please disconnect the SPDT switch by taking hold of the wire that connects the positive power supply to the pole of the switch, and pulling the end of the wire out of the breadboard. When you do this, you may be surprised to find that the LED remains lit.

Push the wire back into the breadboard, flip the switch, and the first LED should go out, while the other LED should become lit. Once again, pull out the wire, and once again, the LED should remain lit.

Here's the take-home message:

- A flip-flop requires only an initial pulse.
- After that, it ignores its input.

How It Works

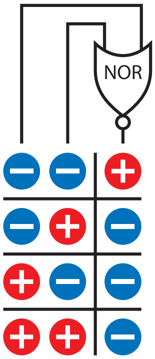
Two NOR gates or two NAND gates can function as a flip-flop:

- Use NOR gates when you have a positive input from a double-throw switch.
- Use NAND gates when you have a negative input from a double-throw switch.

Either way, you have to use a double-throw switch.

I've mentioned the double-throw switch three times (actually, four times if you count this sentence!) because for some strange reason, most introductory books fail to emphasize this point. When I first started learning electronics, I went crazy trying to understand how two NORs or two NANDs could debounce a simple SPST pushbutton—until finally I realized that they can't. The reason is that when you power up the circuit, the NOR gates (or NAND gates) need to be told in which state they should begin. They need an initial orientation, which comes from the switch being in one state or the other. So it has to be a double-throw switch. (Now I've mentioned it five times.)

I'm using another simplified multiple-step schematic, Figure 4-99, to show the changes that occur as the switch flips to and fro with two NOR gates. To refresh your memory, I've also included a truth table showing the logical outputs from NOR gates for each combination of inputs.



−	−	+
−	+	−
+	−	−
+	+	−

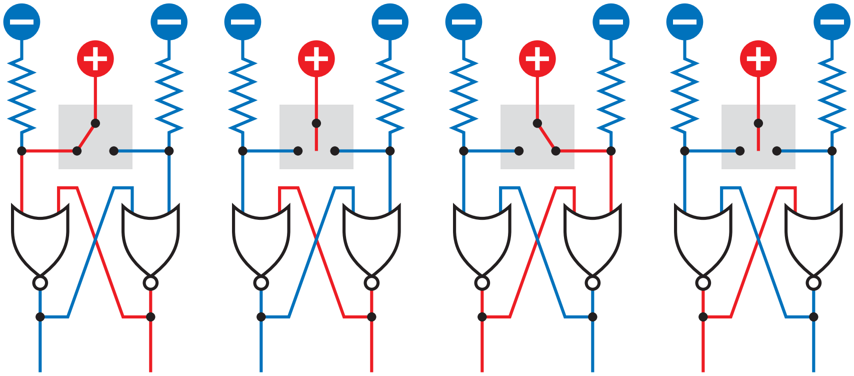


Figure 4-99. *Using two NOR gates in conjunction with a positive input through a SPDT switch, this sequence of four diagrams shows how a flip-flop circuit responds.*

Suppose that the switch is turned to the left. It sends positive current to the lefthand side of the circuit, overwhelming the negative supply from the pull-down resistor, so we can be sure that the NOR gate on the left has one positive logical input. Because any positive logical input will make the NOR give a negative output (as shown in the truth table), the negative output crosses over to the righthand NOR, so that it now has two negative inputs, which make it give a positive output. This crosses back to the lefthand NOR gate. So, in this configuration everything is stable.

Now comes the clever part. Suppose that you move the switch so that it doesn't touch either of its contacts. (Or suppose that the switch contacts are bouncing, and failing to make a good contact. Or suppose you disconnect the switch entirely.) Without a positive supply from the switch, the lefthand input of the left NOR gate goes from positive to negative, as a result of the pull-down resistor. But the righthand input of this gate is still positive, and one positive is all it takes to make the NOR maintain its negative output, so nothing changes. In other words, the circuit has "flopped" in this state.

Now if the switch turns fully to the right and supplies positive power to the righthand pin of the right NOR gate, quick as a flash, that NOR recognizes that it now has a positive logical input, so it changes its logical output to negative. That goes across to the other NOR gate, which now has two negative inputs, so its output goes positive, and runs back to the right NOR.

In this way, the output states of the two NOR gates change places. They flip, and then flop there, even if the switch breaks contact or is disconnected again. The second set of drawings in Figure 4-100 shows exactly the same logic, using a negatively powered switch and two NAND gates. You can use your 74HC00 chip, specified in the parts list for this experiment, to test this yourself.

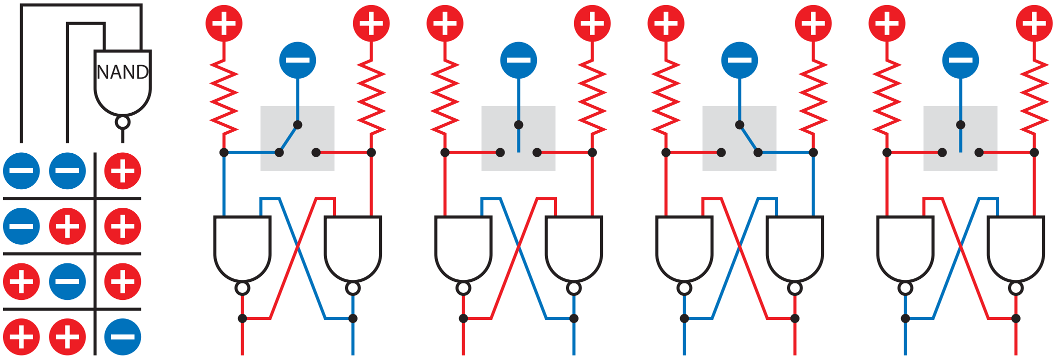

Figure 4-100. *The schematic from Figure 4-99 can be rewired with NAND gates and a negative switched input.*

Both of these configurations are examples of a jam-type flip-flop, so called because the switch forces it to respond immediately, and jams it into that state. You can use this circuit anytime you need to debounce a switch (as long as it's a double-throw switch).

A more sophisticated version is a clocked flip-flop, which requires you to set the state of each input first and then supply a clock pulse to make the flip-flop respond. The pulse has to be clean and precise, which means that if you supply it from a switch, the switch must be debounced—probably by using another jam-type flip-flop! Considerations of this type have made me reluctant to use clocked flip-flops in this book. They add a layer of complexity, which I prefer to avoid in an introductory text.

What if you want to debounce a single-throw button or switch? Well, you have a problem! One solution is to buy a special-purpose chip such as the 4490 "bounce eliminator," which contains digital delay circuitry. A specific part number is the MC14490PG from On Semiconductor. This contains six circuits for six separate inputs, each with an internal pull-up resistor. It's relatively expensive, however—more than 10 times the price of a 74HC02 containing NOR gates. Really, it may be simpler to use double-throw switches that are easily debounced as described previously.

Experiment 23: Nice Dice

This is the one experiment where I want you to use the 74LSxx generation of the TTL logic family, instead of the 74HCxx family of CMOS. Two reasons: first, I need to use the 7492 counter, which is unavailable in the HC family. And second, you should know the basic facts about the LS series of TTL chips, as they still crop up in circuits that you'll find in electronics books and online.

In addition, you'll learn about "open collector" TTL chips such as the 74LS06 inverter, which can be a convenient substitute for transistors when you want to deliver as much as 40mA of current.

The idea of this circuit is simple enough: run a 555 timer sending very fast pulses to a counter that counts in sixes, driving LEDs that are placed to imitate the spots on a die. (Note that the word "die" is the singular of "dice.") The counter runs so fast, the die-spots become a blur. When the user presses a button, the counter stops arbitrarily, displaying an unpredictable spot pattern.

Dice simulations have been around for many, many years, and you can even buy kits online. But this one will do something more: it will also demonstrate the principles of binary code.

So, if you're ready for the triple threat of TTL chips, open collectors, and binary, let's begin.

You will need:

- 74LS92 counter such as SN74LS92N by Texas Instruments. Quantity: 1 if you want to create one die, 2 to make two dice.
- 74LS27 three-input NOR gate such as SN74LS27N by Texas Instruments. Quantity: 1.
- 555 timers. Quantity: 1 if you want to make one die, 2 to make two dice.
- Signal diodes, 1N4148 or similar. Quantity: 4, or 8 to make two dice.

Seeing Binary

The counter that we dealt with before was unusual, in that its outputs were designed to drive seven-segment numerals. A more common type has outputs that count in binary code.

The 74LS92 pinouts are shown in Figure 4-101. Plug the chip into your breadboard and make connections as shown in Figure 4-102. Initially, the 555 timer will drive the counter in slow-motion, at around 1 step per second. Figure 4-103 shows the actual components on a breadboard.

Note that the counter has unusual power inputs, on pins 5 and 10 instead of at the corners. Also four of its pins are completely unused, and do not connect with anything inside the chip. Therefore, you don't need to attach any wire to them on the outside.

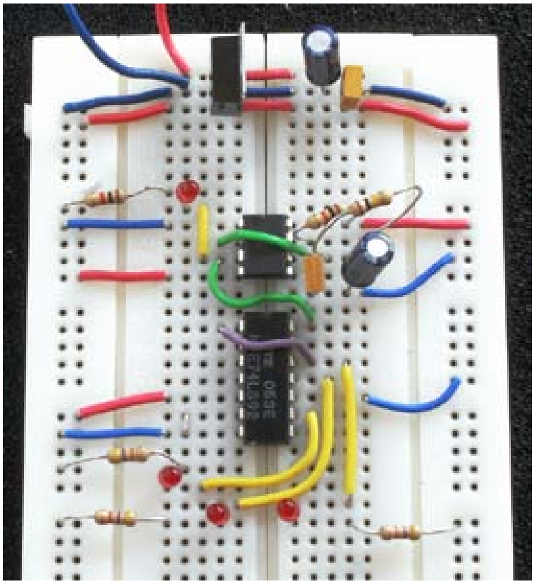

Figure 4-103. *The breadboard version of the schematic in Figure 4-102 to display the outputs from a 74LS92 counter.*

Now we come to the first new and difficult fact about the 74LSxx generation of TTL chips that makes them less desirable, for our purposes, than the 74HCxx generation of CMOS chips that I have recommended in previous projects. The modern and civilized HC chips will source 4mA or sink 4mA at each logical output, but the older LS generation is fussier. It will sink around 8mA into each output pin from a positive source, but when its output is high, it hardly gives you anything at all. This is a very basic principle:

- Outputs from TTL logic chips are designed to sink current.
- They are not designed to source significant current.

In fact, the 74LS92 is rated to deliver less than half a milliamp. This is quite acceptable when you're just connecting it with another logic chip, but if you want to drive an external device, it doesn't provide much to work with.

The proper solution is to say to the chip, "All right, we'll do it your way," and set things up with a positive source that flows through a load resistor to the LED that you want to use, and from there into the output from the chip. This is the "better" option shown in Figure 4-104.

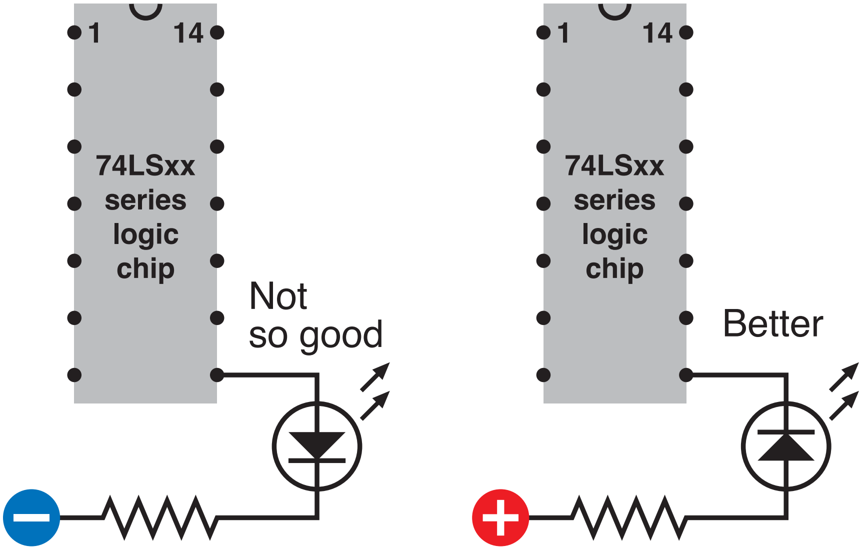

Figure 4-104. *Most TTL chips, including those in the LS generation, are unable to source much current from their logical output pins (left) and should usually be wired to sink current from a positive source (right).*

The only problem is that now the LED lights up when the counter's output is low. But the counter is designed to display its output in high pulses. So your LED is now off when it should be on, and on when it should be off.

You can fix this by passing the signal through an inverter, but already I'm getting impatient with this inconvenience. My way around the problem, at least for demo purposes, is to use the "Not so good" option in Figure 4-104 and make it work by connecting a very-low-current LED with a large 4K7 load resistor. This will enable us to "see" the output from the counter without asking it to give more than its rated limit, and if you want to create a more visibly powerful display for a finished version of the dice circuit, I'll deal with that later. According to my meter, the 4K7 resistor holds the current between 0.3mA and 0.4mA, which is the counter's rated maximum.

Set up your initial version of the circuit as shown in Figures 4-102 and 4-103. Be careful when you wire the positive and negative power supply to the counter chip, with its nonstandard pin assignments.

The 555 will run in astable mode, at about 1 pulse per second. This becomes the clock signal for the counter. The first three binary outputs from the counter then drive the three LEDs.

The counter advances when the input signal goes from *high* to *low*. So when the LED beside the 555 timer goes out, that's when the counter advances.

If you stare at the pattern generated by the outputs for long enough, you may be able to see the logic to it, bearing in mind that its zero state is when they are all off, and it counts up through five more steps before it repeats. The diagram in Figure 4-105 shows this sequence. If you want to know why the pattern works this way, check the following section, "Theory: Binary arithmetic."

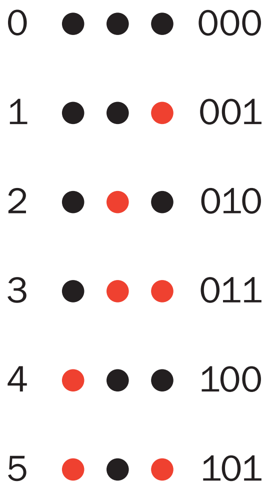

Figure 4-105. *The three output pins of the 74LS92 counter have high states shown by the red circles as the counter steps from 000 to 101 in binary notation.*

THEORY

Binary arithmetic

The rule for binary counting is just a variation of the rule that we normally use for everyday counting, probably without thinking much about it. In a 10-based system, we count from 0 to 9, then carry 1 over to the next position on the left, and go from 0 to 9 again in the right-most position. We repeat this procedure until we get to 99, then carry a 1 over to a new position to make 100, and continue counting.

In binary we do the same thing, except that we restrict ourselves to digits 0 and 1 only. So begin with 0 in the rightmost position, and count up to 1. As 1 is our limit, to continue counting we carry 1 over to the next place on the left, and start again from 0 in the right-most position. Count up to 1, then add 1 to the next place on the left—but, it already has a 1 in it, so it can't count any higher. So, carry 1 from there one space further, to the next place beside that—and so on.

If a glowing LED represents a 1, and a dark LED represents a 0, the diagram in Figure 4-105 shows how the 74LS92 counts up from 0 to (decimal) 6 or (binary) 101 in its inimitable fashion. I've also included a diagram in Figure 4-106 showing how a counter with four binary outputs would display decimal numbers from 0 through 15, again using the LEDs to represent 1s and 0s.

Here's a question for you: how many LEDs would you need to represent the decimal number 1024 in binary? And how many for 1023?

Obviously binary code is ideally suited to a machine full of logic components that either have a high or a low state. So it is that all digital computers use binary arithmetic (which they convert to decimal, just to please us).

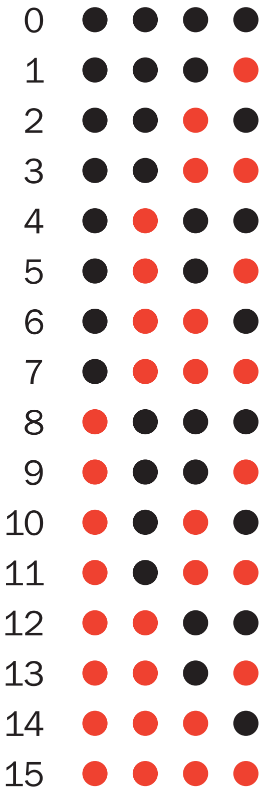

Figure 4-106. *A hexadecimal (16-based) binary counter would generate this succession of high states from its four output pins as it counts from 0 through 15 in decimal notation.*

Getting back to our project: I want to take the three binary outputs and make them create patterns like the spots on a die. How can I do this? Quite easily, as it turns out.

I'm assuming that I'll use seven LEDs to simulate the patterns of spots on a die. These patterns can be broken down into groups, which I have assigned to the three outputs from the counter in Figure 4-108. The first output (farthest to the right) can drive an LED representing the dot at the center of the die face. The second (middle) output can drive two more diagonal LEDs. The third output must switch on all four corner LEDs.

This will work for patterns 1 through 5, but won't display the die pattern for a 6. Suppose I tap into all three outputs from the counter with a three-input NOR gate. It has an output that goes high only when all three of its inputs are low, so it will only give a high output when the counter is beginning with all-low outputs. I can take advantage of this to make a 6 pattern.

Note that it's bad practice to mix the LS generation of TTL chips with the HC generation of CMOS chips, as their input and output ranges are different; so, the NOR chip has to be a 74LS27, not a 74HC27.

We're ready now for a simple schematic. In Figure 4-107 I've colored some of the wires just to make it easier for you to distinguish them. The colors have no other significance.

Figure 4-108. *Binary outputs from the 74LS92 counter can be used to power LEDs arrayed in groups to simulate the pattern of spots on a die.*

Each of the LEDs is grounded through a separate 4K7 load resistor. Unfortunately, this means that when they are displaying the pattern for a 6, all of them are running in parallel from the output of the NOR gate, which overloads it. As long as you don't leave the display in this mode for very long periods, it shouldn't cause a problem. You could compensate by increasing the load resistors, or by running pairs of the LEDs through one resistor, but this will make them so dim that they'll be difficult to see, as they're so close to their lower limit for current already.

Notice how I have added four signal diodes, D1 through D4. When Output C goes high, it has to illuminate all four corner LEDs, and so its power goes into the brown wire as well as the gray wire. But we must never allow one output to feed back into another, so D4 is needed to protect Output B when Output C is high.

Because there is now a connection between B and C, we need D2 to protect Output C when Output B is high. And because Output B must only feed two of the corner LEDs, we also need D3 to stop it from illuminating the other two. And, we have to protect the output from the NOR gate when either Output C or Output B is high. This requires D1.

Figure 4-109 shows everything that I've described so far assembled in breadboard format, while Figure 4-110 shows the test version that I built. Note that the unused logical inputs on the 74LS27 chip are shorted together and connected to the *positive* side of the power supply. Here's the rule:

- When using CMOS chips (such as the HC series), connect unused logical inputs to the negative side of the power supply.
- When using TTL chips (such as the LS series), connect unused logical inputs to the positive side of the power supply.

I assume that you have had enough fun watching the LEDs count slowly, so I've changed the capacitor and resistor values for the 555 to increase its speed from approximately 1 pulse per second to about 50,000 pulses per second. The counter could run much faster than this, but I just want it to cycle fast enough so that when the user presses and releases a button, the count will stop at an unforeseeable number.

The button starts and stops the 555 timer by applying and releasing power to the timing circuit only. This is the equivalent of shaking and then throwing the die.

While the counter is running fast, the LEDs are flashing so fast that all of them will seem to be on at once. At the same time, the circuit charges a new 68 µF capacitor, which I have added between the pushbutton and ground. When you release the button, this capacitor discharges itself through the 1K timing resistor. As the charge dissipates, the timing capacitor will take longer and longer to charge, and discharge, and the frequency of the 555 will gradually diminish. Consequently the LED display will also flash slower, like the reel on a Las Vegas slot machine gradually coming to a stop. This increases the tension as players can see the die display counting to the number that they're hoping for—and maybe going one step beyond it.

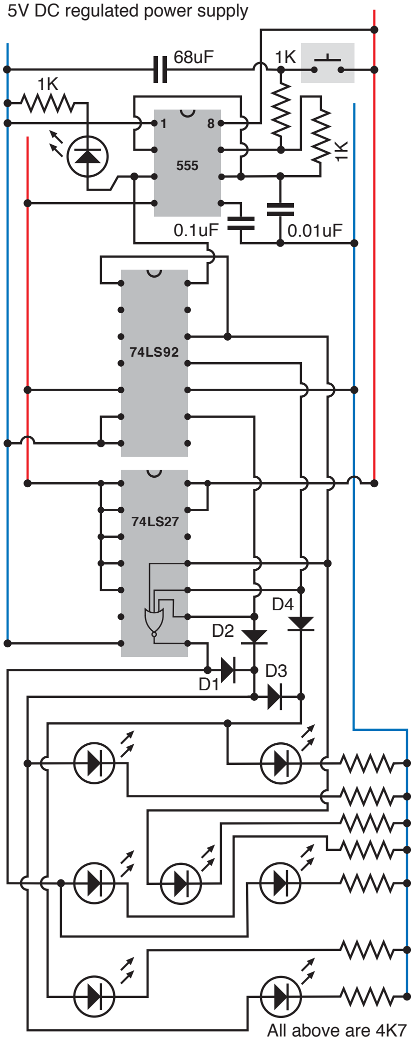

Figure 4-109. *With some extra components, the schematics from Figures 4-102 and 4-107 can be combined to make the working dice simulation.*

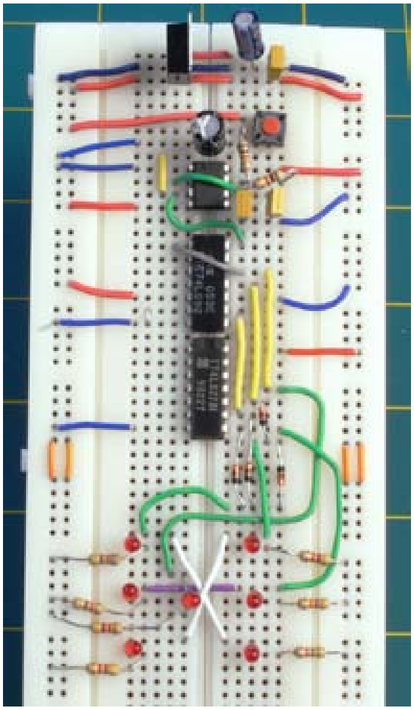

Figure 4-110. *The electronic dice schematic applied to a breadboard, with a pushbutton at the top to start and stop the counter, and 7 LEDs at the bottom to display the output.*

Note that to maximize this effect, the button has to be held down for a full second or more, so that the 68 μF capacitor becomes fully charged before the button is released.

So, this circuit now fulfills the original goal. But can it be better? Of course it can.

Enhancements

The main thing I want to improve is the brightness of the LEDs. I could add a transistor to amplify the current to each one, but there's a simpler alternative: a TTL "open collector" inverter.

I want to use an inverter because in the world of TTL, as I mentioned earlier, we can sink much more power into the output pin of a chip than we can source from it. So, I'm going to turn each LED the other way around and connect their load resistors to the positive side of the power supply. This way, they'll sink their power into the outputs of the inverter.

And the great advantage of an "open collector" version of the inverter chip is that it is designed to sink much more current than a normal TTL logic chip. It is rated for 40mA per pin. The only disadvantage is that it cannot source any current at all; instead of its output going high, it just behaves like an open switch. But that's OK for this circuit.

So the next and final schematic, in Figure 4-111, includes the 74LS06 inverter, which has also been added to the breadboarded version shown in Figure 4-112. I suggest that you put aside the little low-current LEDs and substitute some normal-size ones. Using Kingbright "standard" WP15031D 5mm LEDs, I find that each draws almost exactly 20mA with a voltage drop of about 2V with a 120 ohm series resistor. Because each output pin from the 74LS06 inverter powers no more than two LEDs at a time, this is exactly within its specification. I suggest that if you build this circuit, you check the consumption of your particular choice of LEDs and adjust the resistors if necessary.

Remember: to measure the voltage drop across an LED, simply touch the probes of your meter across it while it is illuminated. To measure the current, disconnect one side of the LED and insert the meter, in milliamp mode, between the leg of the LED and the contact that it normally makes in the circuit.

For a really dramatic display, you can get some 1 cm diameter LEDs (Figure 4-113). Check the specification, and you should find that many of these don't use more power than the usual 5 mm type. But whatever kind you use, don't forget to turn them around so that their negative sides face toward the inverter, and their positive sides face the resistors, which are connected to the positive side of the power supply.

One last detail: I had to add two 10K resistors to this version of the circuit. Can you see why? Diodes D1 through D4 are designed to transmit positive voltage through to the inverter when appropriate, but they prevent the inputs of the inverter from "seeing" the negative side of the power supply when the counter outputs are low. These inverter inputs require pull-down resistors to prevent them from "floating" and producing erroneous results.

Figure 4-111. *If open-collector inverters are added to the dice schematic, it can drive full-size LEDs with up to 40mA, as long as the LEDs are turned around to sink current into the TTL output stage instead of trying to source current from it.*

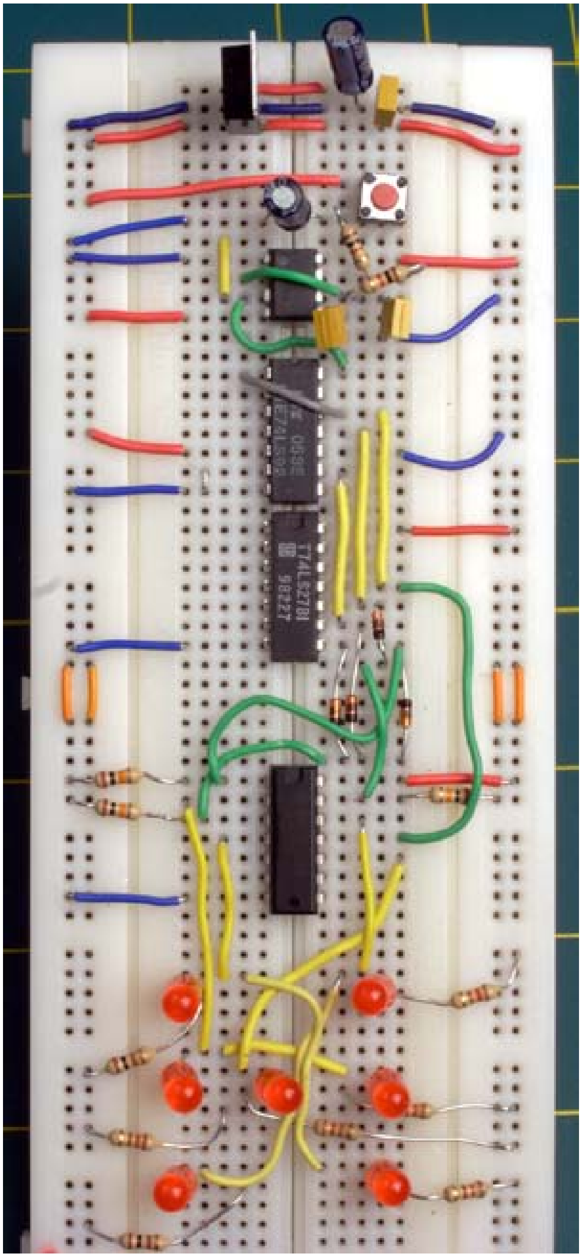

Figure 4-112. *The completed circuit using an open-collector inverter to drive full-size LEDs.*

The final enhancements are up to you. Most obviously, you can add a second die, as many games require two dice. The 74LS27 chip still has a couple of spare NOR gates in it, one of which you can make use of, but you will need an additional 555 timer, running at a significantly different speed to ensure randomness, and it will have to drive a second counter.

After you get your dice up and running, you may want to test them for randomness. Because the pulses from a 555 timer are of equal length, every number has an equal chance of coming up; but the longer you hold down the Start button, the better your odds are of interrupting the counting process at a truly random moment. Anyone using your electronic dice should be told that "shaking" them for a full second is mandatory.

Of course, I could have simulated dice more easily by writing a few lines of software to generate random numbers on a screen, but even a fancy screen image cannot have the same appeal as a well-made piece of hardware. Figure 4-113 shows white 1 cm LEDs mounted in a sanded polycarbonate enclosure for dramatic effect.

Most of all, I derived satisfaction from using simple, dedicated chips that demonstrate the binary arithmetic that is fundamental in every computer.

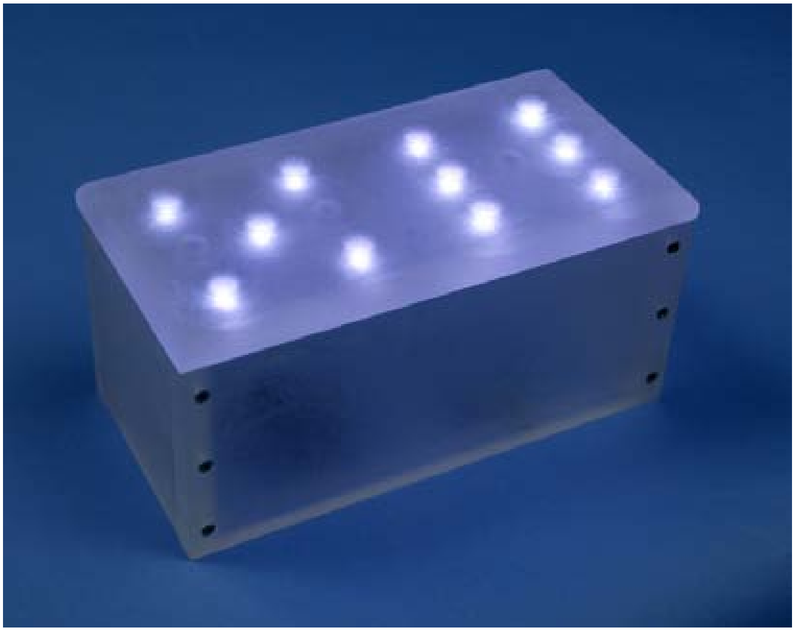

Figure 4-113. *The open-collector inverter chip in the dice circuit is sufficiently powerful to drive 1-cm white LEDs that draw about 20mA each, using a potential of 2V. In this finished version, the LEDs were embedded in cavities drilled from the underside of half-inch polycarbonate, which has been treated with an orbital sander to create a translucent finish.*

Experiment 24: Intrusion Alarm Completed

Now let me suggest how you can apply the knowledge from this chapter of the book to upgrade the burglar alarm project that was last modified in Experiment 15. You'll probably need to check Chapters 2 and 3 to refamiliarize yourself with some features of the alarm.

Upgrade 1: Delayed Activation

The biggest flaw in the alarm was that as soon as it was activated, it would immediately respond to any signal from the door and window sensors. It needed a feature to delay activation to give you a chance to exit from the building before the alarm armed itself. A 555 timer can provide this functionality, probably in conjunction with a relay. The power to the alarm should pass through the contacts of the relay, which are normally closed. When you press a button on the timer, it sends a positive pulse to the relay lasting for around 30 seconds, holding the relay open for that period. You could mount the timer in its own little box with a button on it, which you press when you're ready to leave the building. The 12-volt power supply to the burglar alarm passes through the box containing the delay circuit. For 30 seconds, the 555 interrupts power to the alarm, and then restores it, ready for action.

Upgrade 2: Keypad Deactivation

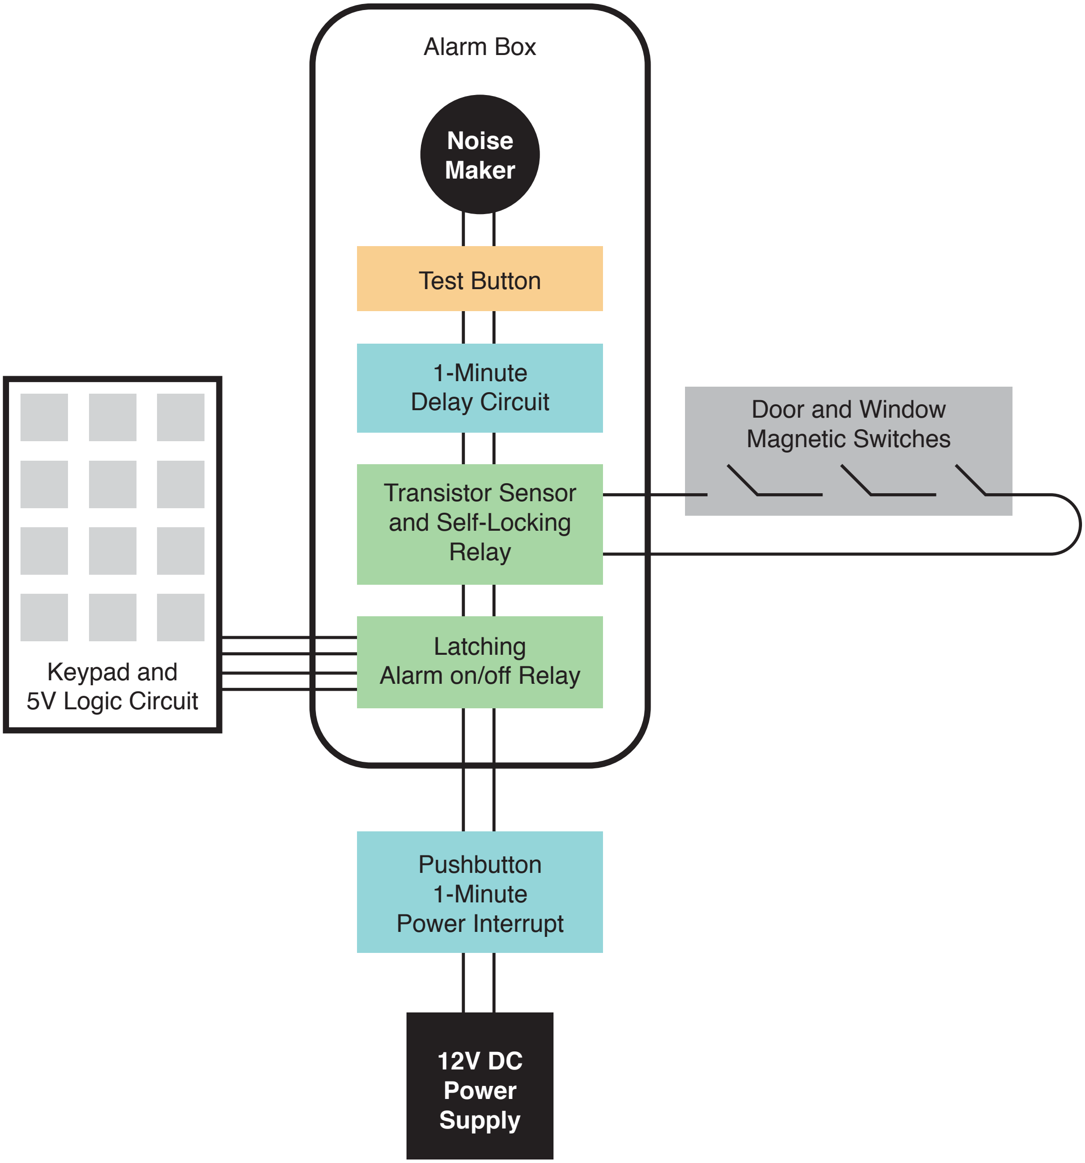
This is now really simple. You can substitute a latching relay instead of the switch, S1, on the alarm box (shown in Figure 3-110), and use a keypad to set and reset the relay in exactly the same way as in the combination lock in Experiment 20. You'll have to run an additional three wires from the relay, out of the alarm box, to the keypad (one supplying power to the "on" relay coil, another supplying power to the "off" coil, the third being a common ground). You can either use a 9-volt battery to power the electronics in association with the keypad, or run an additional fourth wire from the alarm box, to carry positive power to the logic chips, bearing in mind that you have to insert a voltage regulator at some point, to drop the 12 volts that the alarm uses to the 5 volts that the logic gates require. As the gates consume so little power, the 12-to-5 drop should be OK for the voltage regulator; it won't have to dissipate too much heat.

With this additional feature, you can use the alarm like this:

- Press the pound key on the keypad to flip the latching relay into its "on" mode, so that it passes power to the alarm box, which is now armed.
- If you want to leave the house, push the button on the delay unit to give you 30 seconds in which to do so.
- If the alarm is triggered, enter your secret code on the keypad to deactivate it by flipping the latching relay to its "off" position and cutting power to the alarm box.

These modifications are so simple that I think the block diagram in Figure 4-114 should be all you need. I don't think I need to give you any schematics. The only change you have to make to the existing alarm is to substitute the latching relay for the on/off switch.

But, there is still one obvious necessary enhancement needed: how can you get back into the house without instantly triggering the alarm?



Alarm Box
Noise Maker
Test Button
1-Minute Delay Circuit
Door and Window Magnetic Switches
Transistor Sensor and Self-Locking Relay
Keypad and 5V Logic Circuit
Latching Alarm on/off Relay
Pushbutton 1-Minute Power Interrupt
12V DC Power Supply

Figure 4-114. *This block diagram shows the relative placement of the old and new components. The pushbutton power interrupt (which allows you to leave the house before the alarm switches itself back on) goes between the power supply and everything else. The latching relay substitutes for the DPDT switch on the previous version of the alarm. The transistor and self-locking relay, connected with the door and window magnetic switches, remain unchanged. The new delay circuit is inserted between the self-locking relay and the noisemaker. The test button is wired with the latching relay in the same way that it was wired previously with the DPDT switch.*

Upgrade 3: Delay Before Deactivation

Typically, alarms include another delay feature. When you open a door on your way into the building and it triggers the alarm, you have 30 seconds to deactivate it, before it starts making a noise.

How can we implement this delay feature? If I try to use another 555 timer to generate a pulse to inhibit the noise, that won't work, because the output from either the transistor or the relay can continue indefinitely. The relay locks itself on, and the transistor can continue passing voltage for as long as someone leaves a door open. If either of these signals activates a timer in monostable mode, the pulse from the timer will never end, and it will suppress the alarm indefinitely.

I think what I have to do is use a resistor and a capacitor to create a delay. I'll power them through the existing relay, so that I can be sure that they'll receive the full voltage of the power supply, after beginning from zero. Gradually the capacitor will acquire voltage—but I can't connect this directly to the noisemaker, because the noisemaker will gradually get louder as the voltage increases.

I have to insert a device that will be triggered to give full voltage when the input rises past a certain point. To do this, I'll use a 555 timer that's wired in bistable mode. This kind of modification is generally known as a "kludge," because it's not elegant, uses too many components, and does not use them appropriately. What I really need is a comparator, but I don't have space to get into that topic. So, using the knowledge that you have so far, the schematic in Figure 4-115 shows how a delay can be added to the alarm—not elegantly, but reliably.

The only problem is that if you power up a 555 timer in bistable mode, there's a 50-50 chance that the timer starts itself with its output high or low. So I need to pull the voltage low on the reset pin (to start the timer with its output inhibited) and gradually let it become positive (to permit the output). At the same time, I want to start with the voltage high on the trigger pin and gradually lower it, until it falls below 1/3 of the power supply and triggers the output.

So there are two timing circuits. The one for the reset pin works faster than the one on the trigger pin, so that at the point when the timer is triggered, the reset won't stop it.

The schematic shows component values that will do this. The 10 µF capacitor starts low but is charged through the 10K resistor in a couple of seconds. The timer is now ready to be triggered. But the 68 µF capacitor starts high (being connected with the positive side of the power supply) and takes a full minute to be pulled down to 1/3 of supply voltage through the 1M resistor. At that point, its voltage is low enough to trigger the 555. The timer output goes high and supplies the noisemaker.

You should be able to insert this little delay module in your alarm box, between the output from the relay and the input to the noisemaker without too much trouble. And if you want to adjust the delay, just use a higher or lower value resistor than 1M.

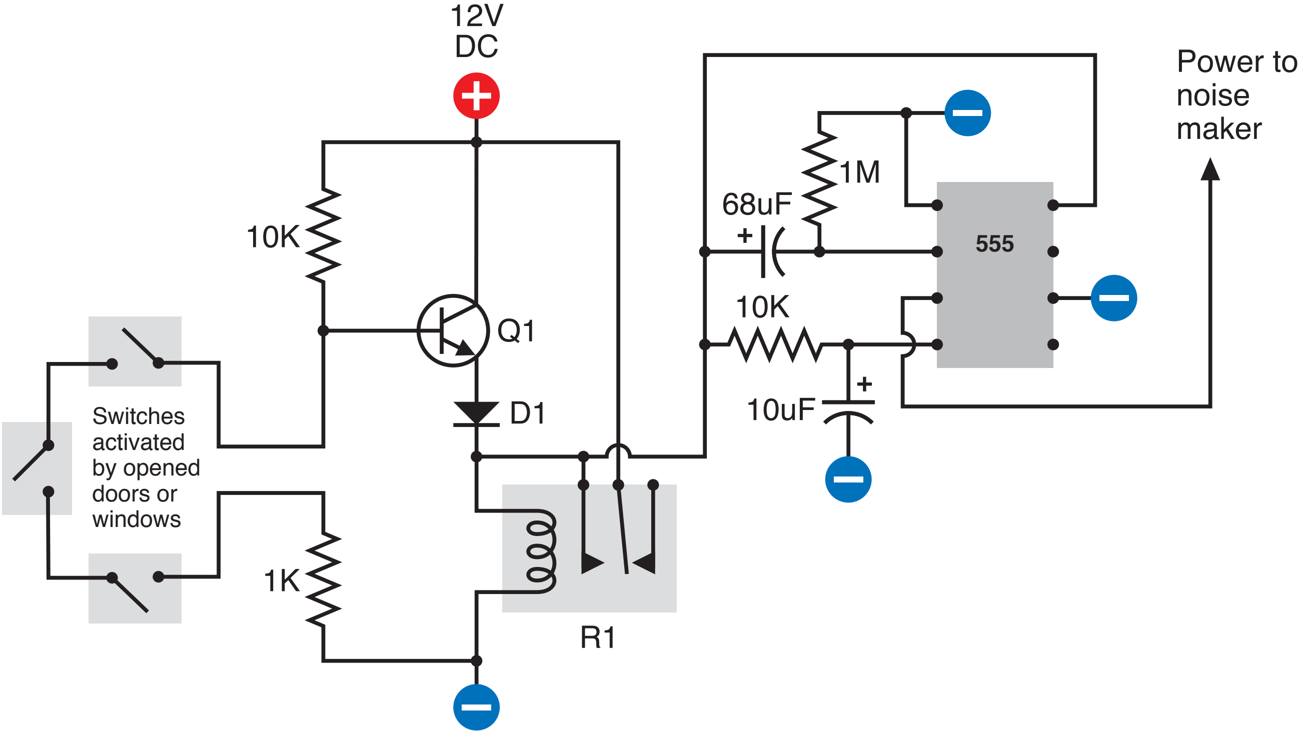


Figure 4-115. *This addition to the original alarm circuit imposes a one-minute delay before the alarm sounds. The 555 timer (wired in bistable mode) receives power through relay R1. The lower timing circuit initially applies negative voltage to the reset, ensuring that the 555 powers up with its output suppressed. This voltage quickly rises. Meanwhile the upper timing circuit applies a voltage to the trigger that gradually diminishes as the 68 μF capacitor equalizes its charge through the 1M resistor. When the voltage diminishes to 1/3 of the supply, the timer's output goes high and starts the noisemaker. If the power to the circuit is interrupted at any time before this, the relay relaxes, the capacitors gradually discharge, and the alarm does not sound.*

The Wrap-Up

If you add these three enhancements, your alarm will have all the features on my original wish list. Of course, if I were designing it from scratch, with all the information that has been added in this chapter of the book, it could be more elegant. But the modifications have not entailed making destructive changes to our original project, and all the design goals have been met.

What Next?

5

At this point, we can branch out in numerous directions. Here are some possibilities:

Audio electronics
This is a field in itself, including hobby projects, such as simple amplifiers and "stomp boxes," to modify guitar sound.

Radio-frequency devices
Anything that receives or transmits radio waves, from an ultra-simple AM radio to remote controllers.

Motors
The field of robotics has encouraged the growth of many online sites selling stepper motors, gear motors, synchronous motors, servo motors, and more.

Programmable microcontrollers
These are tiny computers on a single chip. You write a little program on your desktop computer, which will tell the chip to follow a series of procedures, such as receiving input from a sensor, waiting for a fixed period, and sending output to a motor. Then you download your program onto the chip, which stores it in nonvolatile memory. Popular controllers include the PICAXE, BASIC Stamp, Arduino, and many more. The cheapest ones retail for a mere $5 each.

Obviously, I don't have space to develop all of these topics fully, so what I'm going to do is introduce you to them by describing just one or two projects in each category. You can decide which interests you the most, and then proceed beyond this book by reading other guides that specialize in that interest.

I'm also going to make some suggestions about setting up a productive work area, reading relevant books, catalogs, and other printed sources, and generally proceeding further into hobby electronics.

Tools

You won't need any new tools for this section of the book.

Supplies and Components

As we have progressed to the point where you may want to pick and choose which projects you attempt, I will list the supplies and components at the beginning of each experiment.

Customizing Your Work Area

At this point, if you're getting hooked on the fun of creating hardware but haven't allocated a permanent corner to your new hobby, I have some suggestions. Having tried many different options over the years, my main piece of advice is this: don't build a workbench!

Many hobby electronics books want you to go shopping for 2×4s and plywood, as if a workbench has to be custom-fabricated to satisfy strict criteria about size and shape. I find this puzzling. To me, the exact size and shape of a bench is not very important. I think the most important issue is storage.

I want tools and parts to be easily accessible, whether they're tiny transistors or big spools of wire. I certainly don't want to go digging around on shelves that require me to get up and walk across the room.

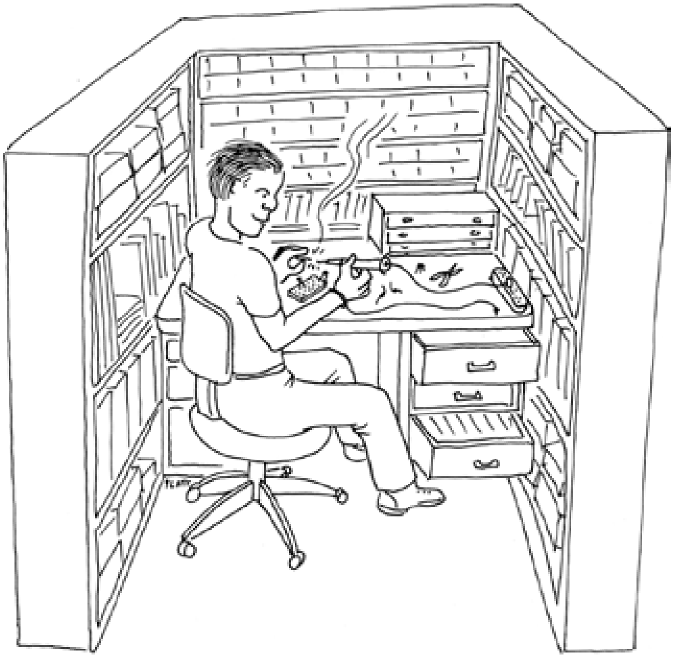

Figure 5-1. *The ideal work area: surrounded by storage. Never again will you need to get out of your chair!*

This leads me to two conclusions:

1. You need storage above the workbench.
2. You need storage below the workbench.

Many DIY workbench projects allow little or no storage underneath. Or, they suggest open shelves, which will be vulnerable to dust. My minimum configuration would be a pair of two-drawer file cabinets with a slab of 3/4-inch plywood or a Formica-clad kitchen countertop placed across them. File cabinets are ideal for storing all kinds of objects, not just files.

Of all the workbenches I've used, the one I liked best was an old-fashioned steel office desk—the kind of monster that dates back to the 1950s. They're difficult to move (because of their weight) and don't look beautiful, but you can buy them cheaply from used office furniture dealers, they're generous in size, they withstand abuse, and they last forever. The drawers are deep and usually slide in and out smoothly, like good file-cabinet drawers. Best of all, the desk has so much steel in it that you can use it to ground yourself before touching components that are sensitive to static electricity. If you use an anti-static wrist strap, you can simply attach it to a sheet-metal screw that you drive into one corner of the desk.

What will you put in the deep drawers of your desk or file cabinets? Some paperwork may be useful, perhaps including the following documents:

- Product data sheets
- Parts catalogs
- Sketches and plans that you draw yourself

The remaining capacity of each drawer can be filled with plastic storage boxes. The boxes can contain tools that you don't use so often (such as a heat gun or a high-capacity soldering iron), and larger-sized components (such as loudspeakers, AC adapters, project boxes, and circuit boards). You should look for storage boxes that measure around 11 inches long, 8 inches wide, and 5 inches deep, with straight sides. Boxes that you can buy at Wal-Mart will be cheaper, but they often have tapering sides (which are not space-efficient).

The boxes that I like best are Akro-Grids, made by Akro-Mils (see Figures 5-2 and 5-3). These are very rugged, straight-sided, with optional transparent snap-on lids. You can download the full Akro-Mills catalog from *http://www.akro-mils.com* and then search online for retail suppliers. You'll find that Akro-Mils also sells an incredible variety of parts bins, but I don't like open bins because their contents are vulnerable to dust and dirt.

For medium-size components, such as potentiometers, power connectors, control knobs, and toggle switches, I like storage containers measuring about 11 inches long, 8 inches wide, and 2 inches deep , divided into four to six sections. You can buy these from Michaels (the craft store), but I prefer to shop online for the Plano brand, as they seem more durably constructed. The Plano products that are most suitable for medium-size electronic parts are classified as fishing-tackle boxes, and you'll see them at *http://www.planomolding.com/tackle/products.asp*.

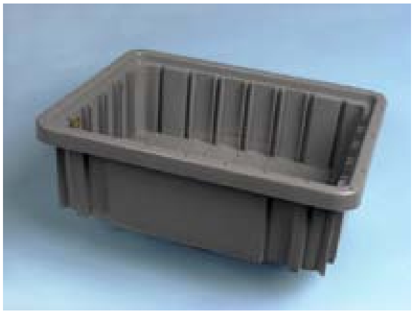

Figure 5-2. *Akro-Grid boxes contain grooves allowing them to be partitioned into numerous compartments for convenient parts storage.*

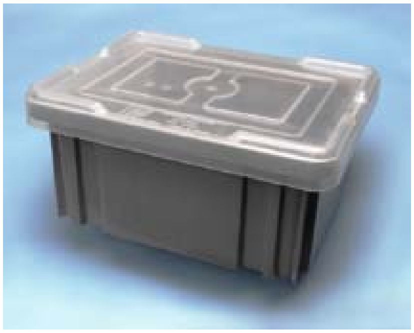

Figure 5-3. *Lids are sold separately for Akro-Grid boxes to keep the contents dust-free. The height of the box in Figure 5-2 allows three to be stacked in a typical file-cabinet drawer. The box shown here allows two to be stacked.*

For undivided, flat-format storage boxes, the Prolatch 23600-00 is ideally sized to fit a file-cabinet drawer, and the latches are sufficiently secure that you could stack a series of them on their long edges. See Figure 5-4.

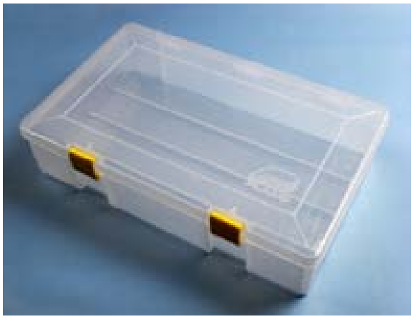

Figure 5-4. *This Plano brand box is undivided, making it useful for storing spools of wire or medium-size tools. When stacked upright on its long edge, three will fit precisely in a file-cabinet drawer.*

Plano also sells some really nicely designed toolboxes, one of which you can place on your desktop. It will have small drawers for easy access to screwdrivers, pliers, and other basics. Because you need a work area that's only about three feet square for most electronics projects, surrendering some desk space to a toolbox is not a big sacrifice.

If you have a steel desk with relatively shallow drawers, one of them can be allocated for printed catalogs. Don't underrate the usefulness of hard copy, just because you can buy everything online. The Mouser catalog, for instance, has an index, which is better in some ways than their online search feature, and the catalog is divided into helpful categories. Many times I've found useful parts that I never knew existed, just by browsing, which is much quicker than flipping through PDF pages online, even with a broadband connection. Currently, Mouser is still quite generous about sending out their catalogs, which contain over 2,000 pages. McMaster-Carr will also send you a catalog, but only after you've ordered from them, and only once a year.

Now, the big question: how to store all those dinky little parts, such as resistors, capacitors, and chips? I've tried various solutions to this problem. The most obvious is to buy a case of small drawers, each of which is removable, so you can place it on your desk while you access its contents. But I don't like this system, for two reasons. First, for very small components, you need to subdivide the drawers, and the dividers are never secure. And second, the removability of the drawers creates the risk of accidentally emptying the contents on the floor. Maybe you're too careful to allow this to happen, but I'm not!

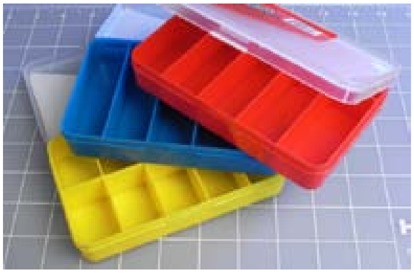

Figure 5-5. *Darice Mini-Storage boxes are ideal for components such as resistors, capacitors, and semiconductors. The boxes can be stacked stably or stored on shelves, with their ends labeled. The brand sticker is easily removed after being warmed with a heat gun.*

My personal preference is to use Darice Mini-Storage boxes, shown in Figure 5-5. You can find these at Michaels in small quantities, or buy them more economically in bulk online from suppliers such as *http://www.craftamerica.com*. The blue boxes are subdivided into five compartments that are exactly the right size and shape for resistors. The yellow boxes are subdivided into ten compartments, which are ideal for semiconductors. The purple boxes aren't divided at all, and the red boxes have a mix of divisions.

The dividers are molded into the boxes, so you don't have the annoyance associated with removable dividers that slip out of position, allowing components to mix together. The box lids fit tightly, so that even if you drop one of the boxes, it probably won't open. The lids have metal hinges, and a ridge around the edge that makes the boxes securely stackable.

I keep my little storage boxes on a set of shelves above the desk, with a gap of 3 inches between one shelf and the next, allowing two boxes to be stacked on each shelf. If I want to work with a particular subset of boxes, I shift them onto the desktop and stack them there.

Labeling

No matter which way you choose to store your parts, labeling them is essential. Any ink-jet printer will produce neat-looking labels, and if you use peelable (nonpermanent) labels, you'll be able to reorganize your parts in the future, as always seems to become necessary. I use color-coded labels for my collection of resistors, so that I can compare the stripes on a resistor with the code on the label, and see immediately if the resistor has been put in the wrong place. See Figure 5-6.

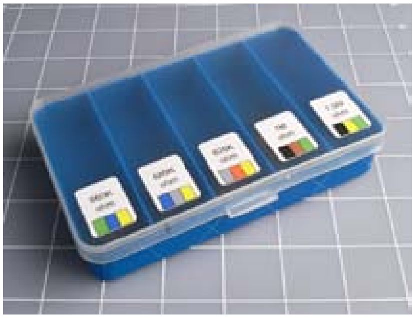

Figure 5-6. *To check that resistors are not placed in the wrong compartments, print the color code on each label.*

Even more important: you need to place a second (non-adhesive) label inside each compartment with the components. This label tells you the manufacturer's part number and the source, so that reordering is easy. I buy a lot of items from Mouser, and whenever I open their little plastic bags of parts, I snip out the section of the bag that has the identifying label on it, and slide it into the compartment of my parts box before I put the parts on top of it. This saves frustration later.

If I were *really* well organized, I would also keep a database on my computer listing everything that I buy, including the date, the source, the type of component, and the quantity. But I'm not that well organized.

On the Bench

Some items are so essential that they should sit on the bench or desktop on a permanent basis. These include your soldering iron(s), helping hands with magnifier, desk lamp, breadboard, power strip, and power supply. For a desk lamp, I prefer the type that has a daylight-spectrum fluorescent bulb, because it spreads a uniform light and helps me to distinguish colors of adjacent stripes on resistors.

The power supply is a matter of personal preference. If you're serious about electronics, you can buy a unit that delivers properly smoothed current at a variety of properly regulated and calibrated voltages. Your little wall-plug unit from RadioShack cannot do any of these things, and its output may vary depending on how heavily you load it. Still, as you've seen, it is sufficient for basic experiments, and when you're working with logic chips, you need to mount a 5-volt regulator on your breadboard anyway. Overall, I consider a good power supply optional.

Another optional item is an oscilloscope. This will show you, graphically, the electrical fluctuations inside your wires and components, and by applying probes at different points, you can track down errors in your circuit. It's a neat gadget to own, but it will cost a few hundred dollars, and for our tasks so far, it has not been necessary. If you plan to get seriously into audio circuits, an oscilloscope becomes far more important, because you'll want to see the shapes of the waveforms that you generate.

You can try to economize on an oscilloscope by buying a unit that plugs into the USB port of your computer and uses your computer monitor to display the signal. I have tried one of these, and was not entirely happy with the results. It worked, but did not seem accurate or reliable for low-frequency signals. Maybe I was unlucky; I decided not to try any other brands.

The surface of your desk or workbench will undoubtedly become scarred by random scuffs, cut marks, and drops of molten solder. I use a piece of half-inch plywood, two feet square, to protect my primary work area, and I clamp a miniature vise to its edge. To reduce the risk of static electricity when working with sensitive components, I cover the plywood with a square of conductive foam. This is not cheap, but offers advantages in addition to protecting chips from being zapped. Instead of scattering stray components, I can stick them into the foam, like plants growing in a garden. And like a garden, I can divide it into sections, with resistors on one side, capacitors on the other, and chips straight ahead.

Inevitably, during your work you'll create a mess. Little pieces of bent wire, stray screws, fasteners, and fragments of stripped insulation tend to accumulate, and can be a liability. If metal parts or fragments get into a project that you're building, they can cause short circuits. So you need a trash container. But it has to be easy to use. I use a full-size garbage pail, because it's so big that I can't miss it when I throw something toward it, and I can never forget that it's there.

Last, but most essential: a computer. Now that all data sheets are available online, and all components can be ordered online, and many sample circuits are placed online by hobbyists and educators, I don't think anyone can work efficiently without quick Internet access. To avoid wasting space, I suggest you use a small, cheap laptop that has a minimal footprint. A possible workbench configuration, using a steel desk, is shown in Figure 5-7.

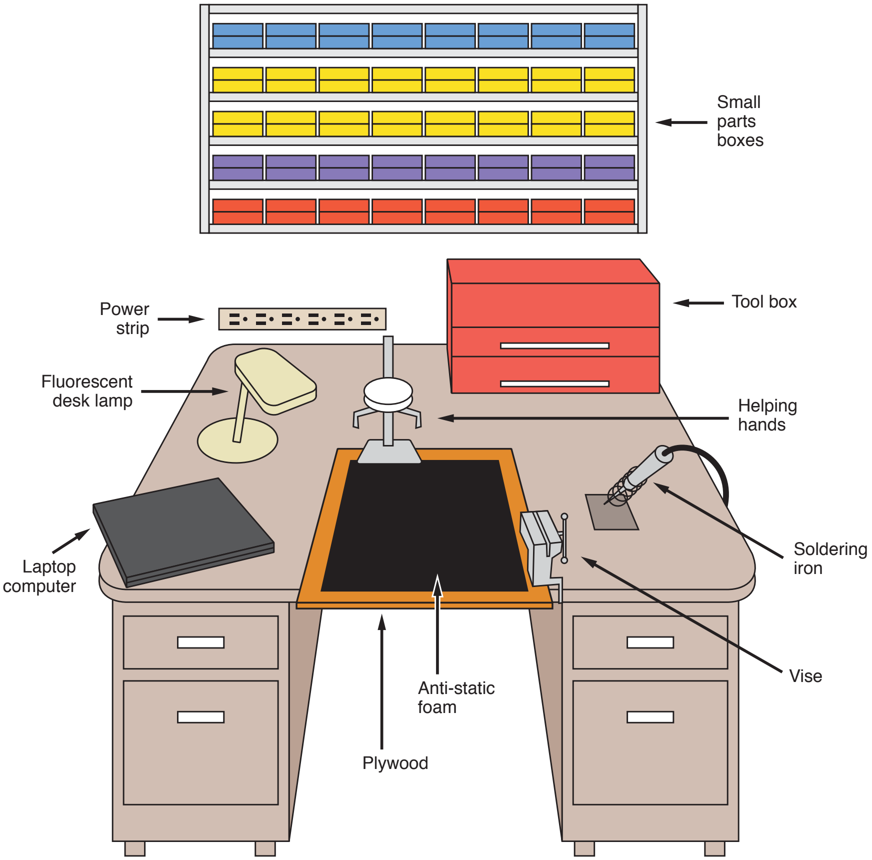

Figure 5-7. *An old steel office desk can be as good as, if not better than, a conventional workbench when building small electronics projects. It provides a large work area and ample storage, and has sufficient mass for you to ground yourself when dealing with components that are sensitive to static electricity.*

Reference Sources

Online

My favorite educational and reference site is Doctronics (*http://www.doctronics.co.uk)*. I like the way they draw their schematics, and I like the way they include many illustrations of circuits on breadboards (which most sites don't bother to do). They also sell kits, if you're willing to pay and wait for shipping from the UK. Part of a page from the doctronics website is reproduced in Figure 5-8.

use the oscilloscope to monitor the outputs of the 4060
add an LED with a current-limiting resistor to monitor the slow pulsing outputs

Figure 5-8. *A sample page from http://www.doctronics.co.uk shows their detailed instructional approach. This is a valuable free online resource.*

My next favorite hobby site is also British-based: the Electronics Club (*http://www.kpsec.freeuk.com)*. It's not as comprehensive as Doctronics, but very friendly and easy to understand.

For a more theory-based approach, try *http://www.electronics-tutorials.ws*. This will go a little farther than the theory sections I've included here.

For an idiosyncratic selection of electronics topics, try Don Lancaster's Guru's Lair (*http://www.tinaja.com*). Lancaster wrote *The TTL Cookbook* more than 30 years ago, which opened up electronics to at least two generations of hobbyists and experimenters. He knows what he's talking about, and isn't afraid of getting into some fairly ambitious areas such as writing his own PostScript drivers and creating his own serial-port connections. You'll find a lot of ideas there.

Books

Yes, you do need books. As you're already reading this one, I won't recommend other beginners' guides. Instead, in keeping with the orientation of this chapter, I'll suggest some titles that will take you farther in various directions, and can be used for reference. I own all of these myself, and find them valuable:

Practical Electronics for Inventors, by Paul Scherz (McGraw-Hill, Second Edition, 2007)

This is a massive, comprehensive book, well worth the $40 cover price. Despite its title, you won't need to invent anything to find it useful. It's my primary reference source, covering a wide range of concepts, from the basic properties of resistors and capacitors all the way to some fairly high-end math. If you buy only one book (in addition to this one, of course!), this would be my recommendation.

Getting Started with Arduino, by Massimo Banzi (Make: Books, 2009)

If you enjoy the simplicity and convenience of the PICAXE programmable microcontroller that I describe later in this chapter, you'll find that the Arduino can do a lot more. *Getting Started* is the simplest introduction around, and will help to familiarize you with the Processing language used in Arduino (similar to the C language, not much like the version of BASIC used by the PICAXE).

Making Things Talk, by Tom Igoe (Make: Books, 2007)

This ambitious and comprehensive volume shows how to make the most of the Arduino's ability to communicate with its environment, even getting it to access sites on the Internet.

TTL Cookbook, by Don Lancaster (Howard W. Sams & Co, 1974)

The 1974 copyright date is not a misprint! You may be able to find some later editions, but whichever one you buy, it will be secondhand and possibly expensive, as this title now has collectible value. Lancaster wrote his guide before the 7400 series of chips was emulated on a pin-for-pin basis by CMOS versions, but it's still a good reference, because the concepts and part numbers haven't changed, and his writing is so accurate and concise.

CMOS Sourcebook, by Newton C. Braga (Sams Technical Publishing, 2001)

This book is entirely devoted to the 4000 series of CMOS chips, not the 74HC00 series that I've dealt with primarily here. The 4000 series is older and must be handled more carefully, because it's more vulnerable to static electricity than the generations that came later. Still, the chips remain widely available, and their great advantage is their willingness to tolerate a wide voltage range, typically from 5 to 15 volts. This means you can set up a 12-volt circuit that drives a 555 timer, and use output from the timer to go straight into CMOS chips (for example). The book is well organized in three sections: CMOS basics, functional diagrams (showing pinouts for all the main chips), and simple circuits showing how to make the chips perform basic functions.

The Encyclopedia of Electronic Circuits, by Rudolf F. Graf (Tab Books, 1985)

A totally miscellaneous collection of schematics, with minimal explanations. This is a useful book to have around if you have an idea and want to see how someone else approached the problem. Examples are often more valuable than general explanations, and this book is a massive compendium of examples. Many additional volumes in the series have been published, but start with this one, and you may find it has everything you need.

The Circuit Designer's Companion, by Tim Williams (Newnes, Second Edition, 2005)

Much useful information about making things work in practical applications, but the style is dry and fairly technical. May be useful if you're interested in moving your electronics projects into the real world.

The Art of Electronics, by Paul Horowitz and Winfield Hill (Cambridge University Press, Second Edition, 1989)

The fact that this book has been through 20 printings tells you two things: (1) Many people regard it as a fundamental resource; (2) Secondhand copies should be widely available, which is an important consideration, as the list price is over $100. It's written by two academics, and has a more technical approach than *Practical Electronics for Inventors*, but I find it useful when I'm looking for backup information.

Getting Started in Electronics, by Forrest M. Mims III (Master Publishing, Fourth Edition, 2007)

Although the original dates back to 1983, this is still a fun book to have. I think I have covered many of its topics here, but you may benefit by reading explanations and advice from a completely different source, and it goes a little farther than I have into some electrical theory, on an easy-to-understand basis, with cute drawings. Be warned that it's a brief book with eclectic coverage. Don't expect it to have all the answers.

Experiment 25: Magnetism

This experiment should be a part of any school science class, but even if you remember doing it, I suggest that you do it again, because setting it up takes only a matter of moments, and it's going to be our entry point to a whole new topic: the relationship between electricity and magnetism. Quickly this will lead us into audio reproduction and radio, and I'll describe the fundamentals of self-inductance, which is the third and final basic property of passive components (resistance and capacitance being the other two). I left self-inductance until last because it's not very relevant to the experiments that you've done so far. But as soon as we start dealing with analog signals that fluctuate, it becomes essential.

You will need:

- Large screwdriver.
- 22-gauge wire (or thinner). Quantity: 6 feet.
- AA battery.

Procedure

This couldn't be simpler. Wind the wire around the shaft of the screwdriver, near its tip. The turns should be neat and tight and closely spaced, and you'll need to make 100 of them, within a distance of no more than 2 inches. To fit them into this space, you'll have to make turns on top of previous turns. If the final turn tends to unwind itself (which will happen if you're using stranded wire), secure it with a piece of tape. See Figure 5-11.

Now apply a battery, as shown in Figure 5-12. At first sight, this looks like a very bad idea, because you're going to short out your battery just as you did in Experiment 2. But by passing the current through a wire that's coiled instead of straight, we'll get some work out of it before the battery expires.

Put a small paper clip near the screwdriver blade, on a soft, smooth surface that will not present much friction. A tissue works well. Because many screwdrivers are already magnetic, you may find that the paper clip is naturally attracted to the tip of the blade. If this happens, move the clip just outside the range of attraction. Now apply the 1.5 volts to the circuit, and the clip should jump to the tip of the screwdriver. Congratulations: you just made an electromagnet.

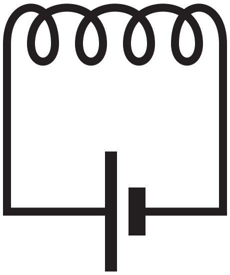

Figure 5-12. *A schematic can't get much simpler than this.*

FUNDAMENTALS

A two-way relationship

Every electric motor that was ever made uses some aspect of the relationship between electricity and magnetism. It's absolutely fundamental in the world around us. Remember that electricity can create magnetism:

When electricity flows through a wire, it creates a magnetic force around the wire.

The principle works in reverse: magnetism can create electricity.

When a wire moves through a magnetic field, it creates a flow of electricity in the wire.

This second principle is used in power generation. A diesel engine, or a water-powered turbine, or a windmill, or some other source of energy either turns coils of wire through a powerful magnetic field, or turns magnets amid some massive coils of wire. Electricity is induced in the coils. In the next experiment, you'll see a dramatic mini-demo of this effect.

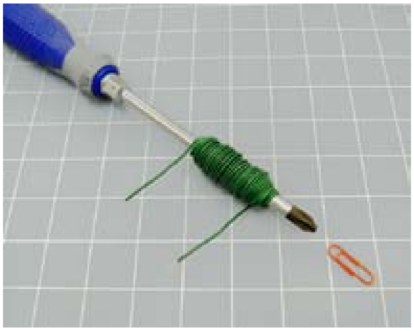

Figure 5-11. *Anyone who somehow missed this most basic childhood demo of electromagnetism should try it just for the fun of proving that a single AA battery can move a paper clip.*

THEORY

Inductance

When electricity flows through a wire, it creates a magnetic field around the wire. Because the electricity "induces" this effect, it is known as *inductance*. The effect is illustrated in Figure 5-13.

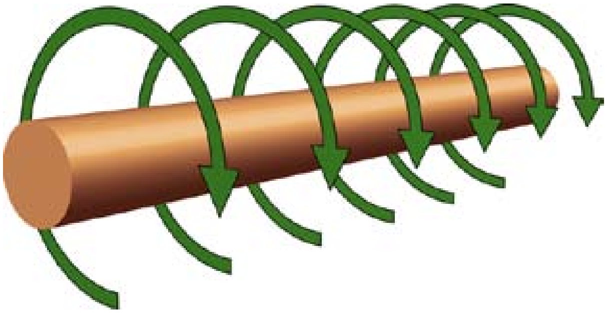

Figure 5-13. *When the flow of electricity is from left to right along this conductor, it induces a magnetic force shown by the green arrows.*

The field around a straight wire is very weak, but if we bend the wire into a circle, the magnetic force starts to accumulate, pointing through the center of the circle, as shown in Figure 5-14. If we add more circles, to form a coil, the force accumulates even more. And if we put a magnetic object (such as a screwdriver) in the center of the coil, the effectiveness increases further.

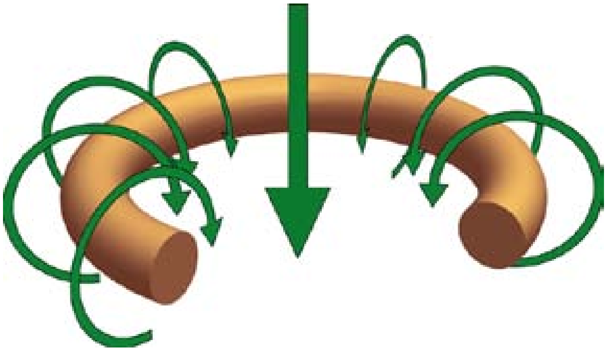

Figure 5-14. *When the conductor is bent to form a circle, the cumulative magnetic force acts through the center of the circle, as shown by the large arrow.*

Here's an approximated formula showing the relationship between the diameter of the coil, the width of the coil from end to end, the number of turns, and its inductance. The letter L is the symbol for inductance, even though the unit is the Henry, named after an American electrical pioneer named Joseph Henry:

L (in microHenrys) =
[(D × D) × (N x N)] / [(18 × D) + (40 × W)]
(Approximately)

In this formula, D is the diameter of the coil, N is the number of turns, and W is the width of the coil from end to end. See Figure 5-15. Here are three simple conclusions from this formula:

- Inductance increases with the diameter of the coil.
- Inductance increases with the square of the number of turns. (In other words, three times as many turns create nine times the inductance.)
- If the number of turns remains the same, inductance is lower if you wind the coil so that it's slender and long, but is higher if you wind it so that it's fat and short.

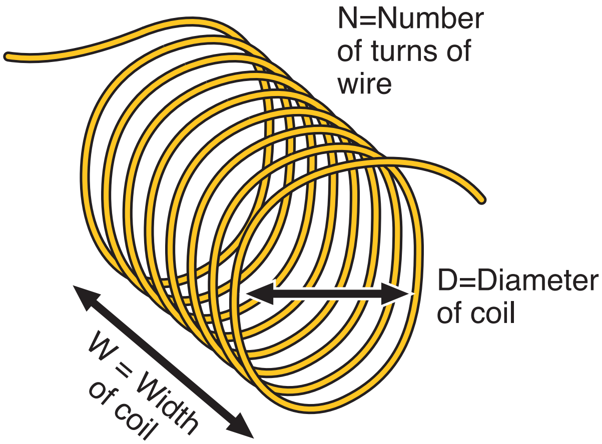

Figure 5-15. *The inductance of a coil increases with its diameter and with the square of its number of turns. If all other parameters remain the same, reducing the width (the distance from end to end) by packing the turns more tightly will increase the inductance.*

FUNDAMENTALS

Coil schematics and basics

Check the schematic symbols for coils in Figure 5-16. Note that if a coil has an iron core, this is shown with an extra couple of lines (sometimes only one line). If it has a ferrite core, the line is sometimes shown with dashes.

An iron core will add to the inductance of a coil, because it increases the magnetic effect.

A coil in isolation does not generally have any polarity. You can connect it either way around, but the magnetic force will be reversed accordingly (coils that interact with stuff—such as in transformers and solenoids—do have polarity).

Perhaps the most widespread application of coils is in transformers, where alternating current in one coil induces alternating current in another, often sharing the same iron core. If the primary (input) coil has half as many turns as the secondary (output) coil, the voltage will be doubled, at half the current—assuming hypothetically that the transformer is 100% efficient.

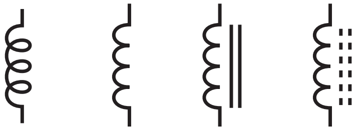

Figure 5-16. *Schematic diagrams represent coils. At far right is the older style. The third and fourth symbols indicate that the coil is wound around a solid or powdered magnetic core, respectively.*

BACKGROUND

Joseph Henry

Born in 1797, Joseph Henry was the first to develop and demonstrate powerful electromagnets. He also originated the concept of "self-inductance," meaning the "electrical inertia" that is a property of a coil of wire.

Henry started out as the son of a day laborer in Albany, New York. He worked in a general store before being apprenticed to a watchmaker, and was interested in becoming an actor. Friends persuaded him to enroll at the Albany Academy, where he turned out to have an aptitude for science. In 1826, he was appointed Professor of Mathematics and Natural Philosophy at the Academy, even though he was not a college graduate and described himself as being "principally self-educated." Michael Faraday was doing similar work in England, but Henry was unaware of it.

Henry was appointed to Princeton in 1832, where he received $1,000 per year and a free house. When Morse attempted to patent the telegraph, Henry testified that he was already aware of its concept, and indeed had rigged a system on similar principles to signal his wife, at home, when he was working in his laboratory at the Philosophical Hall.

Henry taught chemistry, astronomy, and architecture, in addition to physical science, and because science was not divided into strict specialties as it is now, he investigated phenomena such as phosphorescence, sound, capillary action, and ballistics. In 1846, he headed the newly founded Smithsonian Institution as its secretary.

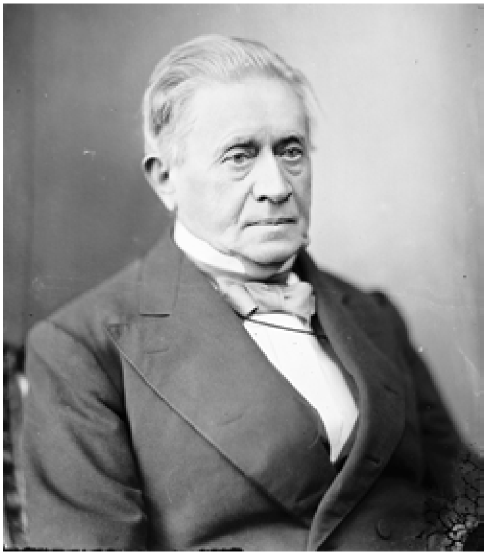

Figure 5-17. *Joseph Henry was an American experimenter who pioneered the investigation of electromagnetism. This photograph is archived in Wikimedia Commons.*

Experiment 26: Tabletop Power Generation

If you have just three components, you can see magnetism generating electricity right in front of you, right now.

You will need:

- Cylindrical neodymium magnet, 3/4-inch diameter, axially magnetized. Quantity: 1. (Obtainable online at sites such as *http://www.kjmagnetics.com*.)
- Spool of hookup wire, 26-gauge, 100 feet. Quantity: 1.
- Spool of magnet wire, quarter-pound, 26-gauge, about 350 feet. Quantity: 1. (Search online for sources for "magnet wire.")
- Generic LED. Quantity: 1.
- 100 µF electrolytic capacitor. Quantity: 1.
- Signal diode, 2N4001 or similar. Quantity: 1.
- Jumper wires with alligator clips on the ends. Quantity: 2.

Procedure

You may be able to make this experiment work with the spool of hookup wire, depending on the size of the spool relative to the size of your magnet, but as the results are more likely to be better with the magnet wire, I'll assume that you're using that—initially, at least. The advantage of the magnet wire is that its very thin insulation allows the coils to be closely packed, increasing their inductance.

First peek into the hollow center of the spool to see if the inner end of the wire has been left accessible, as is visible in Figures 5-18 and 5-19. If it hasn't, you have to unwind the wire onto any large-diameter cylindrical object, then rewind it back onto the spool, this time taking care to leave the inner end sticking out.

Scrape the transparent insulation off each end of the magnet wire with a utility knife or sandpaper, until bare copper is revealed. To check, attach your meter, set to measure ohms, to the free ends of the wire. If you make a good contact, you should measure a resistance of 30 ohms or less.

Place the spool on a nonmagnetic, nonconductive surface such as a wooden, plastic, or glass-topped table. Attach the LED between the ends of the wire using jumper wires. The polarity is not important. Now take a cylindrical neodymium magnet of the type shown in Figure 5-20 and push it quickly down into the hollow core, then pull it quickly back out. See Figure 5-21. You should see the LED blink, either on the down stroke or the up stroke.

The same thing may or may not happen if you use 100 feet of 26-gauge hookup wire. Ideally, your cylindrical magnet should fit fairly closely in the hollow center of the spool. If there's a big air gap, this will greatly reduce the effect of the magnet. Note that if you use a weaker, old-fashioned iron magnet instead of a neodymium magnet, you may get no result at all.

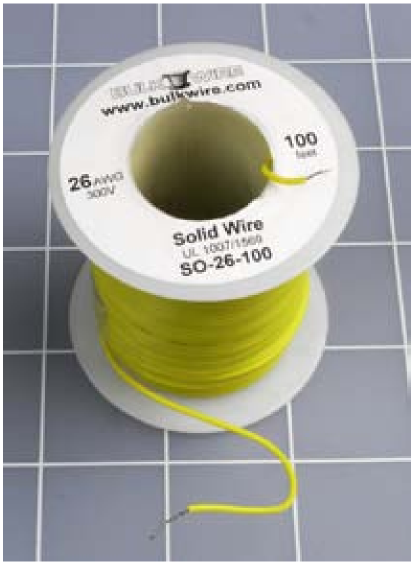

Figure 5-18. *An everyday 100-foot spool of hookup wire is capable of demonstrating the inductive power of a coil.*

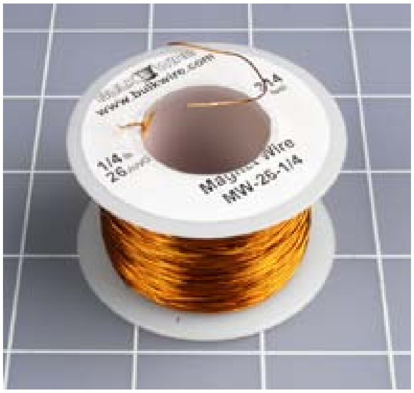

Figure 5-19. *Magnet wire has thinner insulation than hookup wire, allowing the turns to be more densely packed, inducing a more powerful magnetic field.*

Blood Blisters and Dead Media

Neodymium magnets can be hazardous. They're brittle and can shatter if they slam against a piece of magnetic metal (or another magnet). For this reason, many manufacturers advise you to wear eye protection.

Because a magnet pulls with increasing force as the distance between it and another object gets smaller, it closes the final gap very suddenly and powerfully. You can easily pinch your skin and get blood blisters.

If there's an object made of iron or steel anywhere near a neodymium magnet, the magnet will find it and grab it, with results that may be unpleasant, especially if the object has sharp edges and your hands are in the vicinity. When using a magnet, create a clear area on a nonmagnetic surface, and watch out for magnetic objects underneath the surface. My magnet sensed a steel screw embedded in the underside of a kitchen countertop, and slammed itself into contact with the countertop unexpectedly.

Be aware that magnets create magnets. When a magnetic field passes across an iron or steel object, the object picks up some magnetism of its own. Be careful not to magnetize your watch!

Don't use magnets anywhere near a computer, a disk drive, credit cards with magnetic stripes, cassettes of any type, and other media. Also keep magnets well away from TV screens and video monitors (especially cathode-ray tubes). Last but not least, powerful magnets can interfere with the normal operation of cardiac pacemakers.

Figure 5-20. *Three neodymium magnets, 1/4-, 1/2-, and 3/4-inch in diameter. I would have preferred to photograph them standing half-an-inch apart, but they refused to permit it.*

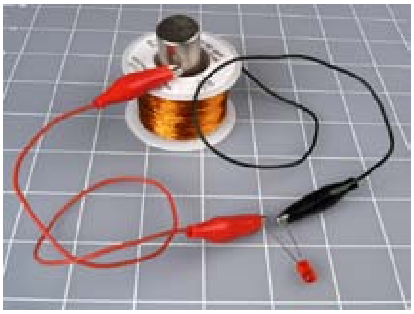

Figure 5-21. *By moving a magnet vigorously up and down through the center of a coil, you generate enough power to make the LED flash brightly.*

Here's another thing to try. Disconnect the LED and connect a 100 µF electrolytic capacitor in series with signal diode, as shown in Figure 5-23. Attach your meter, measuring volts, across the capacitor. If your meter has a manual setting for its range, set it to 20V DC. Make sure the positive (unmarked) side of the diode is attached to the negative (marked) side of the capacitor, so that positive voltage will pass through the capacitor and then through the diode.

Now move the magnet vigorously up and down in the coil. The meter should show that the capacitor is accumulating charge, up to about 10 volts. When you stop moving the magnet, the voltage reading will gradually decline, mostly because the capacitor discharges itself through the internal resistance of your meter.

This experiment is more important than it looks. Bear in mind that when you push the magnet into the coil, it induces current in one direction, and when you pull it back out again, it induces current in the opposite direction. You are actually generating alternating current.

The diode only allows current to flow one way through the circuit. It blocks the opposite flow, which is how the capacitor accumulates its charge. If you jump to the conclusion that diodes can be used to change alternating current to direct current, you're absolutely correct. We say that the diode is "rectifying" the AC power.

Experiment 24 showed that voltage can create a magnet. Experiment 25 has shown that a magnet can create voltage. We're now ready to apply these concepts to the detection and reproduction of sound.

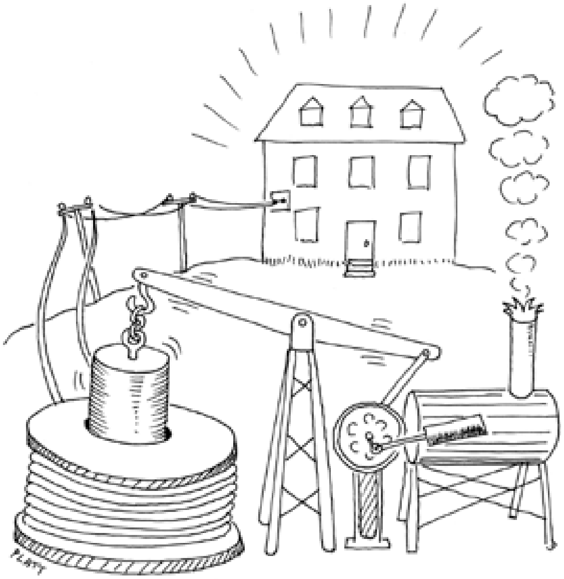

Figure 5-22. *Because inductance increases with the diameter of a coil and with the square of the number of turns, your power output from moving a magnet through the coil can increase dramatically with scale. Those wishing to live "off the grid" may consider this steam-powered configuration, suitable for powering a three-bedroom home.*

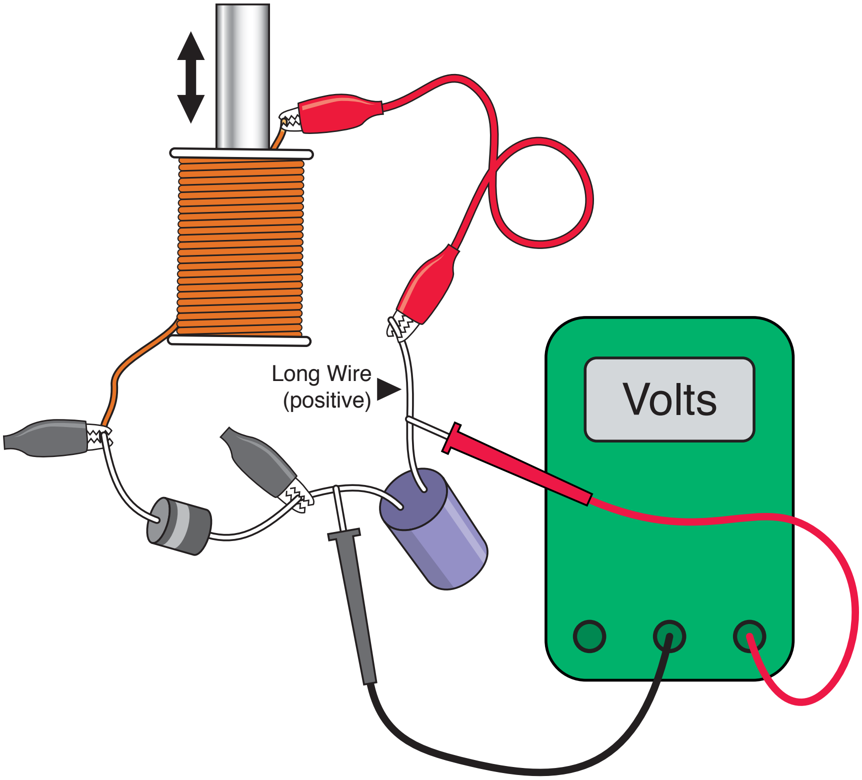

Figure 5-23. *Using a diode in series with a capacitor, you can charge the capacitor with the pulses of current that you generate by moving the magnet through the center of the coil. This demo illustrates the principle of rectifying alternating current.*

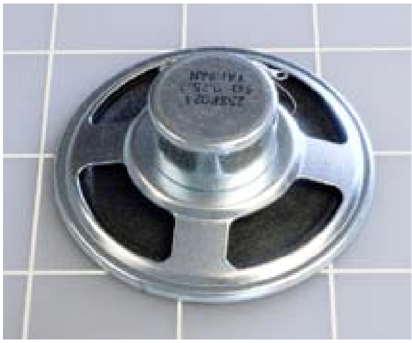

Figure 5-24. *A 2-inch loudspeaker can be instructively destroyed with a utility knife or X-Acto blade.*

Experiment 27: Loudspeaker Destruction

I'd like you to sacrifice a 2-inch loudspeaker, even though it means wasting the $5 or so that it probably costs. Actually, I don't consider this a waste, because if you want to learn how a component works, there's no substitute for actually seeing inside it. You might also have such a speaker already, part of a piece of cast-off personal electronics or toy you have in your basement.

You will need:

- Cheapest possible 2-inch loudspeaker. Quantity: 1. Figure 5-24 shows a typical example.

Procedure

Turn the loudspeaker face-up (as shown in Figure 5-25) and cut around the edge of its cone with a sharp utility knife or X-Acto blade. Then cut around the circular center and remove the ring of black paper that you've created. The result should look like Figure 5-26: you should see the flexible neck of the loudspeaker, which is usually made from a yellow weave. If you cut around its edge, you should be able to pull up the hidden paper cylinder, which has the copper coil of the loudspeaker wound around it. In Figure 5-27, I've turned it over so that it is easily visible. The two ends of this copper coil normally receive power through two terminals at the back of the speaker. When it sits in the groove visible between the inner magnet and the outer magnet, the coil reacts to voltage fluctuations by exerting an up-and-down force in reaction to the magnetic field. This vibrates the cone of the loudspeaker and creates sound waves.

Large loudspeakers in your stereo system work exactly the same way. They just have bigger magnets and coils that can handle more power (typically, as much as 100 watts).

Whenever I open up a small component like this, I'm impressed by the precision and delicacy of its parts, and the way it can be mass-produced for such a low cost. I imagine how astonished the pioneers of electrical theory (such as Faraday and Henry) would be, if they could see the components that we take for granted today. Henry spent days and weeks winding coils by hand to create electromagnets that were far less efficient than this cheap little loudspeaker.

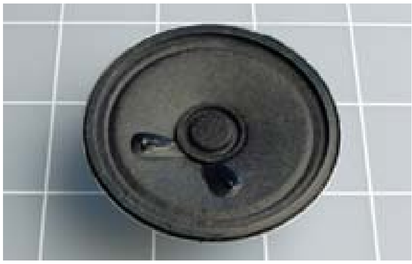

Figure 5-25. *Loudspeaker ready for creative destruction.*

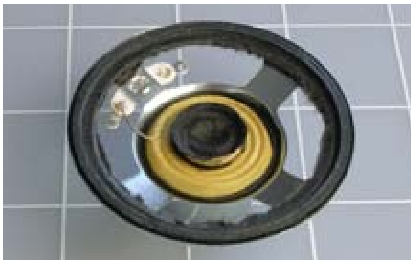

Figure 5-26. *The cone has been removed.*

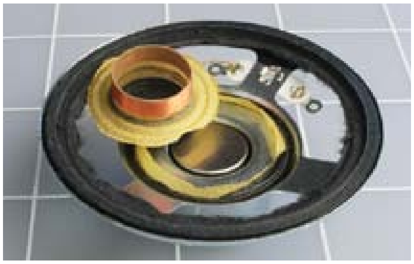

Figure 5-27. *The neck of the cone has been pulled out. Note the coil of copper wire, which fits precisely in the groove between two magnets in the base of the speaker.*

BACKGROUND

Origins of loudspeakers

Loudspeakers utilize the fact that if you run a varying electrical current through a coil situated in a magnetic field, the coil will move in response to the current. This idea was introduced in 1874 by Ernst Siemens, a prolific German inventor. (He also built the world's first electrically powered elevator in 1880.) Today, Siemens AG is one of the largest electronics companies in the world.

When Alexander Graham Bell patented the telephone in 1876, he used Siemen's concept to create audible frequencies in the earpiece. From that point on, sound-reproduction devices gradually increased in quality and power, until Chester Rice and Edward Kellogg at General Electric published a paper in 1925 establishing basic principles that are still used in loudspeaker design today.

At *http://www.radiolaguy.com/Showcase/Gallery-HornSpkr.htm* you'll find photographs of very beautiful early loudspeakers, which used a horn design to maximize efficiency. As sound amplifiers became more powerful, speaker efficiency became less important compared with quality reproduction and low manufacturing costs. Today's loudspeakers convert only about 1% of electrical energy into acoustical energy.

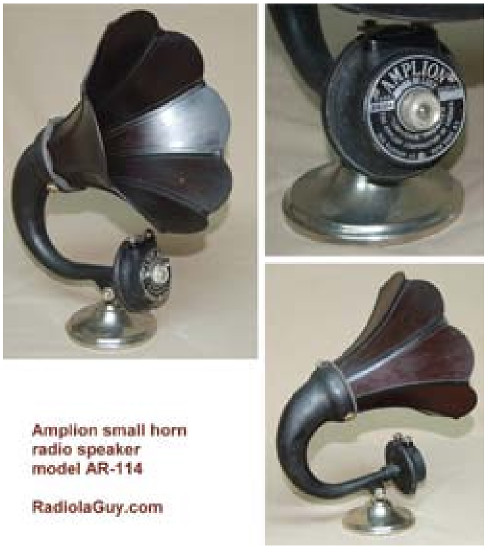

Figure 5-28. *This beautiful Amplion AR-114x illustrates the efforts of early designers to maximize efficiency in an era when the power of audio amplifiers was very limited. Photos by "Sonny, the RadiolaGuy." Many early speakers are illustrated at www.radiolaguy.com. Some are for sale.*

THEORY

Sound, electricity, and sound

Time now to establish a clear idea of how sound is transformed into electricity and back into sound again.

Suppose someone bangs a gong with a stick. The flat metal face of the gong vibrates in and out, creating sound waves. A sound wave is a peak of higher air pressure, followed by a trough of lower air pressure.

The wavelength of the sound is the distance (usually ranging from meters to millimeters) between one peak of pressure and the next peak.

The frequency of the sound is the number of waves per second, usually expressed as hertz.

Suppose we put a very sensitive little membrane of thin plastic in the path of the pressure waves. The plastic will flutter in response to the waves, like a leaf fluttering in the wind. Suppose we attach a tiny coil of very thin wire to the back of the membrane so that it moves with the membrane, and let's position a stationary magnet inside the coil of wire. This configuration is like a tiny, ultra-sensitive loudspeaker, except that instead of electricity producing sound, it is configured so that sound produces electricity. Sound pressure waves make the membrane move to and fro along the axis of the magnet, and the magnetic field creates a fluctuating voltage in the wire.

This is known as a *moving-coil* microphone. There are other ways to build a microphone, but this is the configuration that is easiest to understand. Of course, the voltage that it generates is very small, but we can amplify it using a transistor, or a series of transistors. Then we can feed the output through the coil around the neck of a loudspeaker, and the loudspeaker will recreate the pressure waves in the air. Figures 5-29 through 5-32 illustrate this sequence.

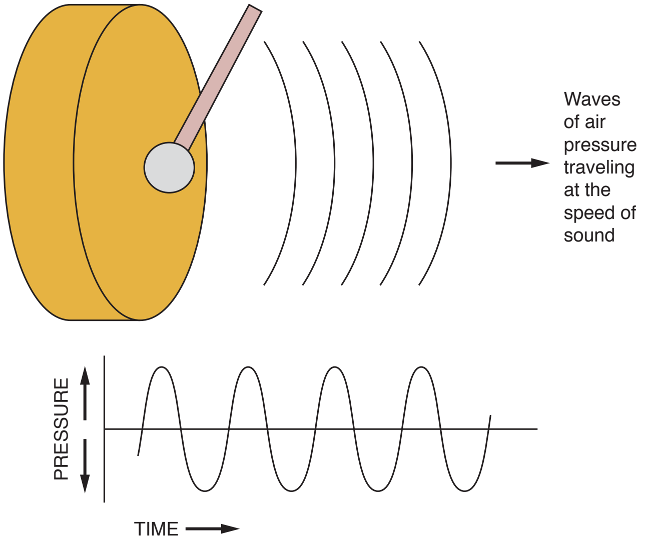

Figure 5-29. *Step 1 in the process of converting sound to electricity, and back again. When the hammer hits the gong, the face of the gong vibrates, creating pressure waves that travel through the air.*

THEORY

Sound, electricity, and sound (continued)

Somewhere along the way, we may want to record the sound and then replay it. But the principle remains the same. The hard part is designing the microphone, the amplifier, and the loudspeaker so that they reproduce the waveforms *accurately* at each step. It's a significant challenge, which is why accurate sound reproduction can be elusive.

Time now to think about what happens inside the wire when it generates a magnetic field. Obviously, some of the power in the wire is being transformed into magnetic force. But just what exactly is going on?

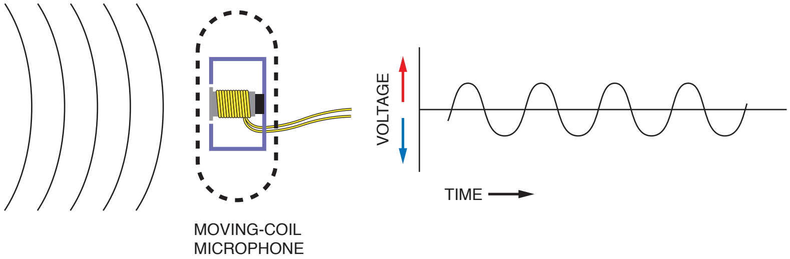

Figure 5-30. *Step 2: the pressure waves penetrate the perforated shell of a microphone and cause a diaphragm to vibrate in sympathy. The diaphragm has a coil attached to it. When the coil vibrates to and fro, a magnet at its center induces alternating current.*

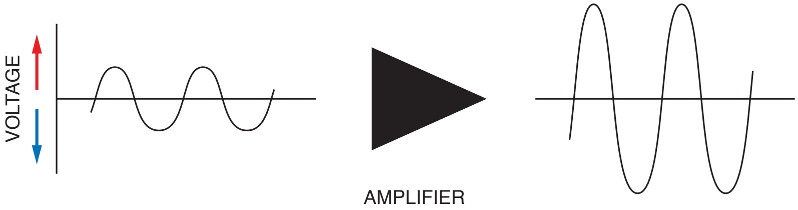

Figure 5-31. *Step 3: the tiny signals from the microphone pass through an amplifier, which enlarges their amplitude while retaining their frequency and the shape of their waveform.*

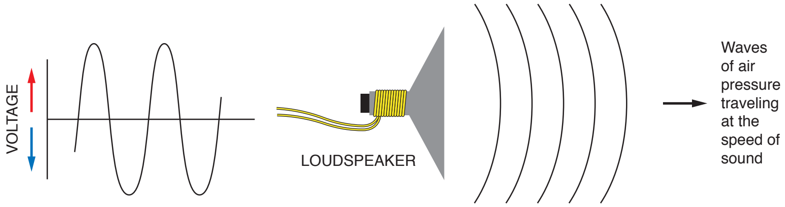

Figure 5-32. *Step 4: the amplified electrical signal is passed through a coil around the neck of a loudspeaker cone. The magnetic field induced by the current causes the cone to vibrate, reproducing the original sound.*

Experiment 28: Making a Coil React

A capacitor will absorb some DC current until it is fully charged, at which point it blocks the flow. There's another phenomenon that I haven't mentioned so far, which is the exact opposite of capacitance. It's known as *self-inductance*, and you find it in any coil of wire. Initially it blocks DC current (it reacts against it), but then its opposition gradually disappears. Here are a few definitions:

Resistance

Constrains current flow and drops voltage.

Capacitance

Allows current to flow initially and then blocks it. This behavior is properly known as capacitive reactance.

Self-Inductance

Blocks the flow of current initially and then allows it. This is also often referred to as *inductive reactance*. In fact, you may find the term "reactance" used as if it means the same thing, but since self-inductance is the correct term, I'll be using it here.

In this experiment, you'll see self-inductance in action.

You will need:

- LEDs, low-current type. Quantity: 2.
- Spool of hookup wire, 26-gauge, 100 feet. Quantity: 1.
- Resistor, 220Ω, rated 1/4 watt or higher. Quantity: 1.
- Capacitor, electrolytic, 2,000 µF or larger. Quantity: 1.
- SPST tactile switch. Quantity: 1.

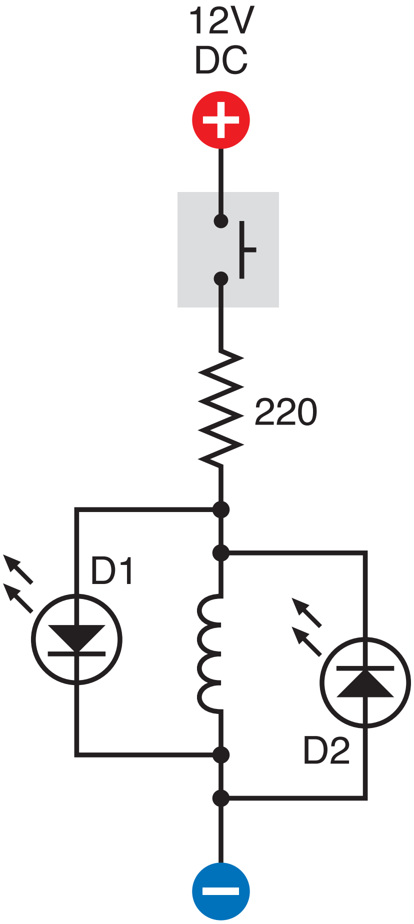

Figure 5-33. *In this demonstration of self-inductance, D1 and D2 are light-emitting diodes. When the switch is closed, D1 flashes briefly because the coil obstructs the initial flow of electricity. When the switch is opened, D2 flashes as the collapsing magnetic field induced by the coil releases another short burst of current.*

Procedure

Take a look at the schematic in Figure 5-33. At first it may not make much sense. The curly symbol is a coil of wire—nothing more than that. So apparently the voltage will pass through the 220Ω resistor, and then through the coil, ignoring the two LEDs, because the coil obviously has a much lower resistance than either of them (and one of them is upside-down anyway).

Is that what will happen? Let's find out. The coil can be a spool of 100 feet of 26-gauge (or smaller) hookup wire, although the spool of magnet wire listed in Experiment 25 will work better, if you have that. Once again, you will need access to both ends of the wire, and if the inner end is inaccessible, you'll need to rewind the coil, leaving the end sticking out.

Now that you have a coil, you can hook it up on your breadboard as shown in Figure 5-34, where the green circle is a tactile switch and the two circular red objects are LEDs. Make sure that you use low-current LEDs (otherwise, you may not see anything) and make sure that one of them is negative-side-up, positive-side-down and the other is positive-side-up, negative-side-down. Also, the 220Ω resistor should be rated at 1/4 watt or higher, if possible (see the following caution).

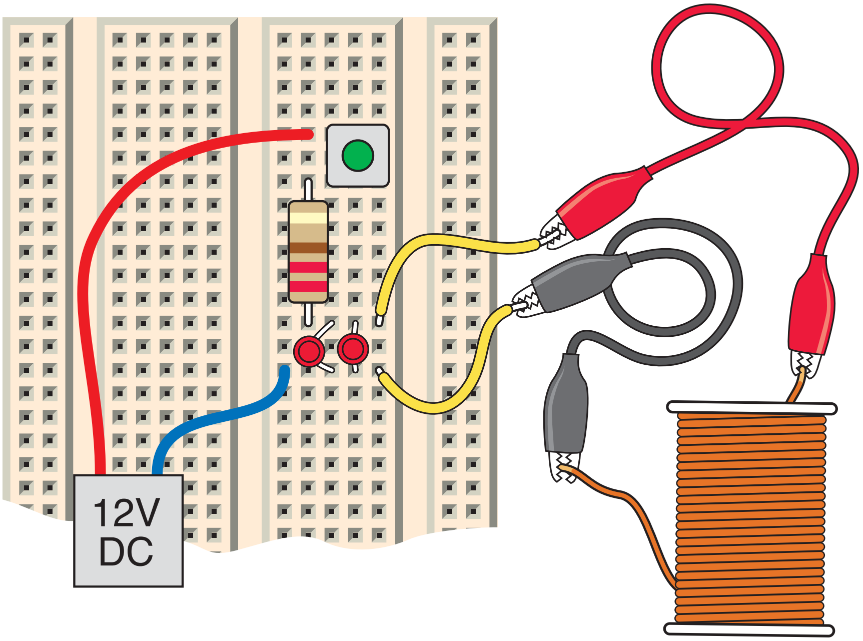

Figure 5-34. *The breadboarded version of the schematic in Figure 5-33 shows a simple way to set it up for a quick demo. The green button is a tactile switch. The two red LEDs should be placed so that the polarity of one is opposite to the polarity of the other.*

Hot Resistors

You'll be passing about 50mA through the 220Ω resistor, while the current is flowing. At 12 volts, this works out at 0.6 watts. If you use a 1/8-watt resistor, you will be overloading it, and it will get quite hot and may burn out. If you use a 1/4-watt resistor, it will still get hot, but is unlikely to burn out, as long as you don't press the button for more than a second or two.

Don't run the circuit without the coil of wire; you'll be trying to pass more than 50mA through the LEDs.

When you press the button, one LED should flash briefly. When you release the button, the other LED should flash.

What's happening here? The coil possesses self-inductance, which means that it reacts against any sudden change in the flow of electricity. First it fights it, and during that brief moment, it blocks most of the current. Consequently, the current looks for an alternative path and flows through D1, the lefthand LED in the schematic. (D2 doesn't respond, because it can pass current only in the opposite direction.)

Meanwhile, the voltage pressure overcomes the coil's self-inductance. When the self-inductance disappears, the resistance of the coil is no more than 10 ohms—so now the electricity flows mostly through the coil, and because the LED receives so little, it goes dark.

When you disconnect the power, the coil reacts again. It fights *any* sudden changes. After the flow of electricity stops, the coil stubbornly sustains it for a moment, because as the magnetic field collapses, it is turned back into electricity. This residual flow of current depletes itself through D2, the LED on the right.

In other words, the coil stores some energy in its magnetic field. This is similar to the way a capacitor stores energy between two metal plates, except that the coil blocks the current initially and then lets it build up, whereas the capacitor sucks up current initially, and then blocks it.

The more turns of wire you have in your coil, the more self-inductance the coil will have, causing your LEDs to flash more brightly.

Here's one last variation on this experiment to test your understanding of electrical fundamentals. Remove the 220Ω resistor, and substitute a 1K resistor (to protect your LED from sustained current). Remove the coil, and substitute a very large capacitor—ideally, about 4,700 μF. (Be careful to get its polarity the right way around.) What will you see when you press the button? Note that you will have to hold it down for a couple of seconds to get a result. And what will you see when you release the button? Remember: the behavior of capacitance is opposite to the behavior of self-inductance.

THEORY

Alternating current concepts

Here's a simple thought experiment. Suppose you set up a 555 timer to send a stream of pulses through a coil. This is a primitive form of alternating current.

We might imagine that the self-inductance of the coil will interfere with the stream of pulses, depending how long each pulse is, and how much inductance the coil has. If the pulses are too short, the self-inductance of the coil will tend to block them. Maybe if we can time the pulses exactly right, they'll synchronize with the time constant of the coil. In this way, we can "tune" a coil to allow a "frequency" to pass through it.

What happens if we substitute a capacitor? If the pulses are too long, compared with the time constant of the capacitor, it will tend to block them, because it will have enough time to become fully charged. But if the pulses are shorter, the capacitor can charge and discharge in rhythm with the pulses, and will seem to allow them through.

I don't have space in this book to get deeply into alternating current. It's a vast and complicated field where electricity behaves in strange and wonderful ways, and the mathematics that describe it can become quite challenging, involving differential equations and imaginary numbers. However, we can easily demonstrate the audio filtering effects of a loudspeaker and a coil.

Experiment 29: Filtering Frequencies

In this experiment, you'll see how self-inductance and capacitance can be used to filter audio frequencies. You're going to build a crossover network: a simple circuit that sends low frequencies to one place and high frequencies to another.

You will need:

- Loudspeaker, 8Ω, 5 inches in diameter. Quantity: 1. Figure 5-35 shows a typical example.
- Audio amplifier, STMicroelectronics TEA2025B or similar. Quantity: 1. See Figure 5-36.

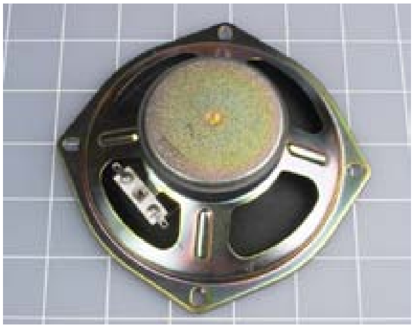

Figure 5-35. To hear the effects of audio filters using coils and capacitors, you'll need a loudspeaker capable of reproducing lower frequencies. This 5-inch model is the minimum required.

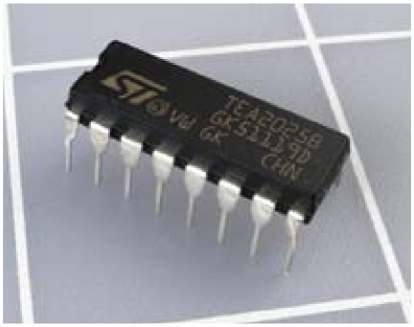

Figure 5-36. This single chip contains a stereo amplifier capable of delivering a total of 5 watts into an 8Ω speaker when the two channels are combined.

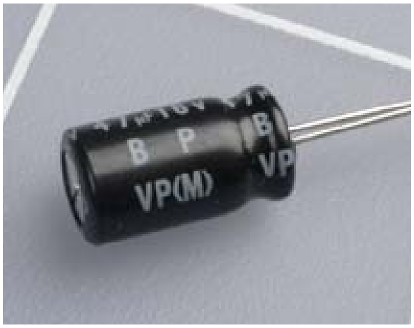

Figure 5-37. A nonpolarized electrolytic capacitor, also known as a bipolar capacitor, looks just like an electrolytic capacitor, except that it will have "NP" or "BP" printed on it.

- Nonpolarized electrolytic capacitors (also known as bipolar). 47 µF. Quantity: 2. A sample is shown in Figure 5-37. They should have "NP" or "BP" printed on them to indicate "nonpolarized" or "bipolar."
- Nonpolarized electrolytic capacitors (also known as bipolar). 100 µF. Quantity: 5. (Because you'll be working with audio signals that alternate between positive and negative, you can't use the usual polarized electrolytic capacitors. If you want to avoid the trouble and expense of ordering nonpolarized capacitors, you can substitute two regular electrolytics in series, facing in opposite directions, with their negative sides joined in the middle. Just remember that when you put capacitors in series, their total capacitance is half that of each individual component. Therefore, you would need two 220 µF electrolytics in series to create 110 µF of capacitance. See Figure 5-38.)
- Potentiometer, with audio taper if possible. 100K. Quantity: 1.
- Coil, for crossover network. Quantity: 1. You can search a source such as eBay for keywords "crossover" and "coil," but if you can't find one at a reasonable price, you can make do with a spool of 100 feet of 20-gauge hookup wire.
- Plastic shoebox. Quantity: 1.

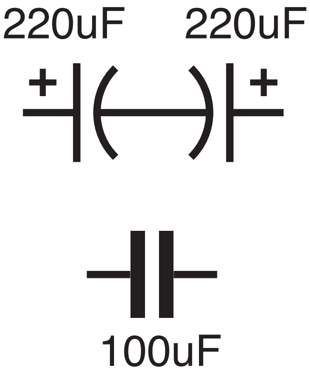

Figure 5-38. You can make a nonpolarized electrolytic capacitor by putting two regular electrolytics in series. (In fact, that's what you'd find if you opened a real nonpolarized capacitor.) The symbol at the bottom is roughly equivalent to the pair of symbols at the top; bear in mind that two capacitors in series have a total capacitance that is half that of each of them.

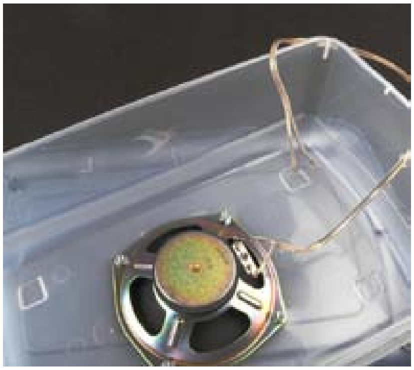

Figure 5-39. *A resonant enclosure is necessary if you want to hear some bass (lower frequencies) from your speaker. A cheap plastic shoebox is sufficient for demo purposes.*

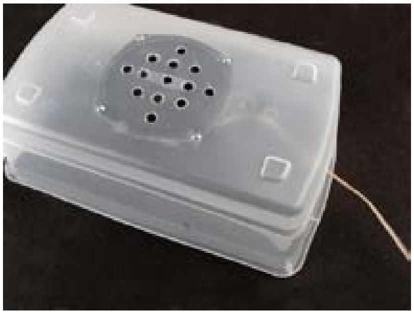

Figure 5-40. *Drill some half-inch holes in the bottom of the box, then bolt the speaker in place, running a wire out through a hole in one end. Snap on the lid, and you're ready for not-quite-high-fidelity audio.*

Procedure

The purpose of the audio amplifier chip is to provide enough power to get a decent amount of sound out of your loudspeaker. The purpose of using a 5-inch speaker is to enable you to hear lower-frequency sounds than the baby speakers that we have used previously. Bass notes have long wavelengths that small speakers are not able to generate effectively.

Maybe you remember from building the intrusion alarm that a speaker makes much more noise if you prevent the sound waves from the back of the cone from cancelling the sound waves from the front of the cone. The obvious way to achieve this is by enclosing the speaker in a box. I suggest a plastic box, because they're cheap, and we don't care too much about sound quality as long as we can hear at least some of the low frequencies. Figure 5-39 shows the speaker bolted into the bottom of a plastic box, and Figure 5-40 shows the box turned upside-down after snapping its lid into place.

Normally, a speaker should be mounted in a cabinet of heavy, thick material that has a very low resonant frequency—below the limits of human hearing. To minimize the resonance of the shoebox, you can put some soft, heavy fabric inside it before you snap the lid on. A hand towel or some socks should be sufficient to absorb some of the vibration.

Adding an Amplifier

Back in the 1950s, you needed vacuum tubes, transformers, and other power-hungry heavyweight components to build an audio amplifier. Today, you can buy a chip for about $1 that will do the job, if you add a few capacitors around it, and a volume control. The TEA2025B that I'm recommending is intended for use in cheap portable cassette players and CD players, and can work in stereo or mono mode, from a power supply ranging from 3 to 9 volts. With 9 volts and the two sides of the chip bridged together to drive one 8Ω speaker, it can generate 5 watts of audio power. That doesn't sound much compared with a typical home theater system rated at 100 watts per channel, but because loudness is a logarithmic scale, 5 watts will be quite enough to irritate any family members in the same room—and possibly even in other rooms.

If you can't find the TEA2025B chip, you can use any alternative listed as an audio amplifier. Try to find one that is designed to drive an 8Ω speaker with up to 5 watts in mono mode. Check the manufacturer's data sheet to see where you attach capacitors around it. Note carefully whether some of the capacitors have no polarity marked, even though they have fairly high values, such as 100 µF. These capacitors must function regardless of which way the alternating current is flowing, and I've marked them "NP" in my schematic in Figure 5-41, meaning "nonpolarized." (You may find them identified as "bipolar" or "BP" in parts catalogs.) As noted in the shopping list, you can put two 220 µF capacitors in series, negative-to-negative, to get the same effect as a single 100 µF nonpolarized capacitor.

For this project, it's essential to include the regular 100 µF electrolytic smoothing capacitor across the power supply. Otherwise, the amplifier will pick up and—yes, amplify—small voltage spikes in the circuit.

Input from headphone jack on audio device

Figure 5-41. *The audio amplifier chip should be wired with capacitors around it as shown, "NP" denoting the ones that are not polarized. The acronym "BP," meaning bipolar, is also often used to mean the same thing. The output from pins 2 and 15 of the chip can be passed through a coil or a 10 µF capacitor to demonstrate audio filtering.*

The input shown in the schematic can receive a signal from a typical media player, such as a portable MP3 player, CD player, or cassette player. To connect its headphone jack to the breadboard, you can use an adapter that converts it to a pair of RCA-type audio jacks, and then stick a wire into one of them as shown in Figure 5-42. The wire will connect to the 33K resistor on the breadboard circuit. The chromed neck of the RCA jack (which is sometimes gold-plated, or at least gold-colored) *must* be connected with the negative side of your power supply on the breadboard; otherwise, you won't hear anything. You can ignore the second output on the adapter, because we're working in mono, here, not stereo.

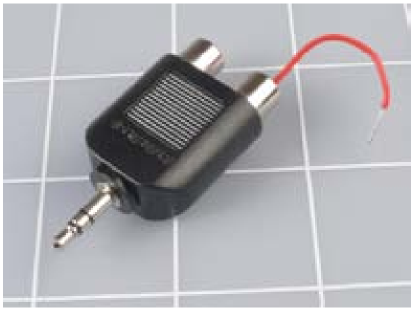

Figure 5-42. *To sample the output from the headphone socket of a music player, you can use this adapter and push the stripped end of a piece of hookup wire into one of the sockets. Then use alligator clips on a jumper wire to connect the audio to your breadboarded circuit. Don't forget to use an additional jumper wire to connect the outside of the socket to the negative side of the power supply on the breadboard. Because we're only using one speaker, the amplifier is connected to only one of the stereo outputs from your player. The other is ignored.*

The 33K resistor is necessary to protect the amplifier from being overdriven. If you don't get enough volume using your music player, decrease the 33K value. If the music is too loud and distorted, increase the value. You can also try omitting or increasing the 10K resistor next to it, which is included in an effort to reduce background hum noise.

I've shown two switches at the top of the schematic: one to bypass a coil, the other to bypass a capacitor. You can use alligator clips instead, as long as you can easily compare the sound when each of the components is inserted into the circuit.

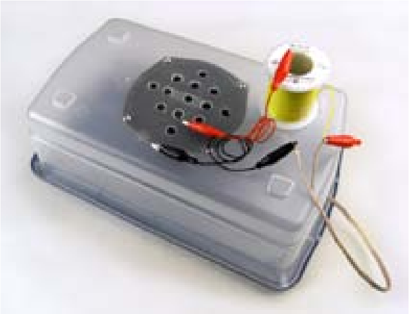

Figure 5-43. *The red and black alligator clips, lying on top of the shoebox, should connect with the output from your amplifier chip. The red jumper wire passes the signal through a coil of hookup wire on its way to the speaker. Note the change in sound when you short out the coil.*

Figure 5-43 shows a coil consisting of a spool of hookup wire being used. The red and black alligator clips resting loose on top of the shoebox will go to the output from the chip (on pins 2 and 15). There is no polarity; it doesn't matter which clip goes to which pin.

Begin by turning the volume control on your music source *all the way down* before you apply power. Don't be surprised if you hear humming or crackling noises when you activate the amplifier; it will pick up any stray voltages, because in this simple experiment, I haven't suggested that you should shield the input, and the amplifier circuit can pick up noise, as its wires can act like antennas.

Note that you may also get additional unwanted sound if you use the amplifier on a conductive desktop surface. Remove any aluminum foil or conductive foam for this project.

Make sure that your player is playing music, and slowly turn up its volume control until you hear it. If you don't hear anything, you'll have to check for circuit errors.

Now comes the interesting part. Insert the 100-foot spool of hookup wire between one output from the amplifier, and one input of the speaker (it doesn't matter which one), or if you used switches, open the switch that bypasses the coil. You should find that the music loses all its high-end response. By comparison, if you disconnect the coil and substitute a 10 µF capacitor, you should find that the music sounds "tinny," meaning that it loses all its low range, leaving only the high frequencies.

You've just tested two very simple filters. Here's what they are doing:

- The coil is a low-pass filter. It passes low frequencies but blocks high frequencies, because brief audio cycles don't have time to overcome the coil's self-inductance. A bigger coil eliminates a wider range of frequencies.
- The capacitor is a high-pass filter. It passes high frequencies and blocks low frequencies because longer audio cycles can fill the capacitance, at which point the capacitor stops passing current. A smaller capacitor eliminates a wider ranger of frequencies.

You can go a lot farther into filter design, using complex combinations of coils and capacitors to block frequencies at any point in the audible spectrum. Search online for audio filter schematics—you'll find hundreds of them.

Crossover Networks

In a traditional audio system, each speaker cabinet contains two drivers—one of them a small speaker called a *tweeter*, which reproduces high frequencies, the other a large speaker known as a *woofer*, which reproduces low frequencies. (Modern systems often remove the woofer and place it in a separate box of its own that can be positioned almost anywhere, because the human ear has difficulty sensing the direction of low-frequency sounds.)

The schematic that you just looked at and may have constructed is known as a "crossover network," and truly hardcore audiophiles have been known make their own (especially for use in car systems) to go with speakers of their choice in cabinets that they design and build themselves.

If you want to make a crossover network, you should use high-quality polyester capacitors (which have no polarity, last longer than electrolytics, and are better made) and a coil that has the right number of turns of wire and is the right size to cut high frequencies at the appropriate point. Figure 5-44 shows a polyester capacitor.

Figure 5-45 shows an audio crossover coil that I bought on eBay for $6. I was curious to find out what was inside it, so I bought two of them, and took one apart.

First I peeled away the black vinyl tape that enclosed the coil. Inside was some typical magnet wire—copper wire thinly coated with shellac or semitransparent plastic, as shown in Figure 5-46. I unwound the wire and counted the number of turns. Then I measured the length of the wire, and finally used a micrometer to measure the diameter of the wire, after which I checked online to find a conversion from the diameter in mils (1/1,000 of an inch) to American wire gauge.

As for the spool, it was plain plastic with an air core—no iron or ferrite rod in the center. Figure 5-47 shows the spool and the wire.

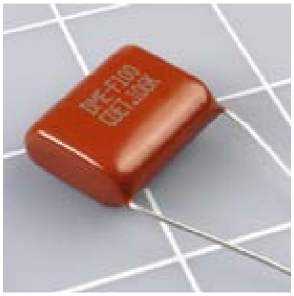

Figure 5-44. *Some nonelectrolytic capacitors have no polarity, such as this high-quality polyester film capacitor. However, they tend to be much more expensive, and are hard to find in values higher than 10 µF.*

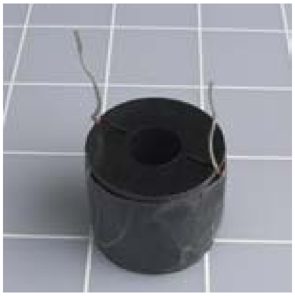

Figure 5-45. *What exotic components may we find inside this high-end audio component that's used with a subwoofer to block high frequencies?*

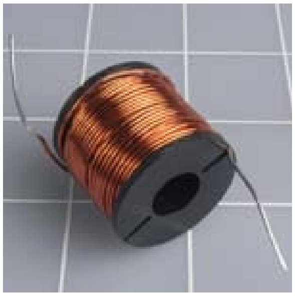

Figure 5-46. *The black tape is removed, revealing a coil of magnet wire.*

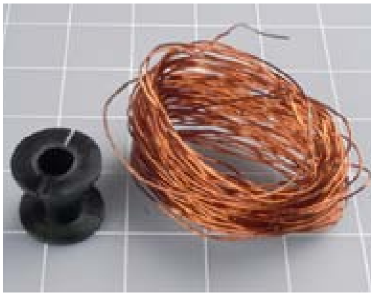

Figure 5-47. *The audio crossover coil consists of a plastic spool and some wire. Nothing more.*

So here's the specification for this particular coil in an audio crossover network. Forty feet of 20-gauge copper magnet wire, wrapped in 200 turns around a spool of 1/16–inch-thick plastic with a hub measuring 7/8 inch in length between the flanges and 1/2-inch external diameter. Total retail cost of materials if purchased separately: probably about $1, assuming you can find or make a spool of the appropriate size.

Conclusion: there's a lot of mystique attached to audio components. They are frequently overpriced, and you can make your own coil if you start with these parameters and adjust them to suit yourself.

Suppose you want to put some thumping bass speakers into your car. Could you build your own filter so that they only reproduce the low frequencies? Absolutely—you just need to wind a coil, adding more turns until it cuts as much of the high frequencies as you choose. Just make sure the wire is heavy enough so that it won't overheat when you push 100 or more audio watts through it.

Here's another project to think about: a color organ. You can tap into the output from your stereo and use filters to divide audio frequencies into three sections, each of which drives a separate set of colored LEDs. The red LEDs will flash in response to bass tones, yellow LEDs in response to the mid-range, and green LEDs in response to high frequencies (or whatever colors you prefer). You can put signal diodes in series with the LEDs to rectify the alternating current, and series resistors to limit the voltage across the LEDs to, say, 2.5 volts (when the music volume is turned all the way up). You'll use your meter to check the current passing through each resistor, and multiply that number by the voltage drop across the resistor, to find the wattage that it's handling, to make sure the resistor is capable of dissipating that much power without burning out.

Audio is a field offering all kinds of possibilities if you enjoy designing and building your own electronics.

THEORY

Waveforms

If you blow across the top of a bottle, the mellow sound that you hear is caused by the air vibrating inside the bottle, and if you could see the pressure waves, they would have a distinctive profile.

If you could slow down time and draw a graph of the alternating voltage in any power outlet in your house, it would have the same profile.

If you could measure the speed of a pendulum swinging slowly to and fro in a vacuum, and draw a graph of the speed relative to time, once again it would have the same profile.

That profile is a *sine wave*, so called because you can derive it from basic trigonometry. In a right-angled triangle, the sine of an angle is found by dividing the length of the side opposite the angle by the length of the hypoteneuse (the sloping side of the triangle).

To make this simpler, imagine a ball on a string rotating around a center point, as shown in Figure 5-48. Ignore the force of gravity, the resistance of air, and other annoying variables. Just measure the vertical height of the ball and divide it by the length of the string, at regular instants of time, as the ball moves around the circular path at a constant speed. Plot the result as a graph, and there's your sine wave, shown in Figure 5-49. Note that when the ball circles below its horizontal starting line, we consider its distance negative, so the sine wave becomes negative, too.

Why should this particular curve turn up in so many places and so many ways in nature? There are reasons for this rooted in physics, but I'll leave you to dig into that topic if it interests you. Getting back to the subject of audio reproduction, what matters is this:

- Any sound can be broken down into a mixture of sine waves of varying frequency and amplitude.

Or, conversely:

- If you put together the right mix of audio sine waves, you can create *any sound at all*.

Suppose that there are two sounds playing simultaneously. Figure 5-50 shows one sound as a red curve, and the other as pale blue. When the two sounds travel either as pressure waves through air or as alternating electric currents through a wire, the amplitudes of the waves are added together to make the more complex curve, which is shown in black. Now try to imagine dozens or even hundreds of different frequencies being added together, and you have an idea of the complex waveform of a piece of music.

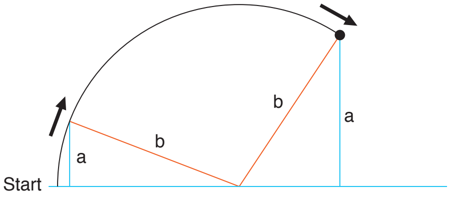

Figure 5-48. *If a weight on the end of a string (length b, in the diagram) follows a circular path at a steady speed, the distance of the weight from a horizontal center line (length a, in the diagram) can be plotted as a graph relative to time. The graph will be a sine wave, so called because in basic trigonometry, the ratio of a/b is the sine of the angle between line b and the horizontal baseline, measured at the center of rotation. Sinewaves occur naturally in the world around us, especially in audio reproduction and alternating current.*

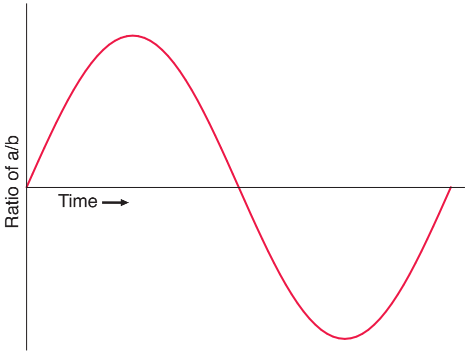

Figure 5-49. *This is what a "pure" sinewave looks like.*

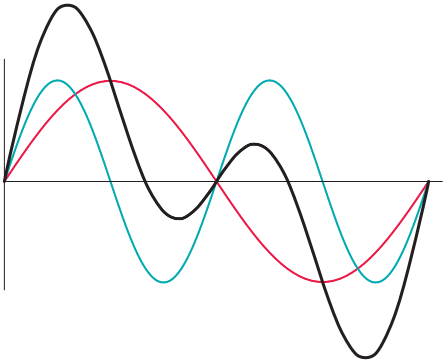

Figure 5-50. *When two sinewaves are generated at the same time (for instance, by two musicians, each playing a flute), the combined sound creates a compound curve. The blue sinewave is twice the frequency of the red sinewave. The compound curve (black line) is the sum of the distances of the sinewaves from the baseline of the graph.*

THEORY

Waveforms (continued)

You can create your own waveform as an input for your audio amplifier with the basic astable 555 timer circuit shown in Figure 5-51. You have to be careful, though, not to overload the amplifier input. Note the 680K series resistor on the output pin of the timer. Also note the 500Ω potentiometer.

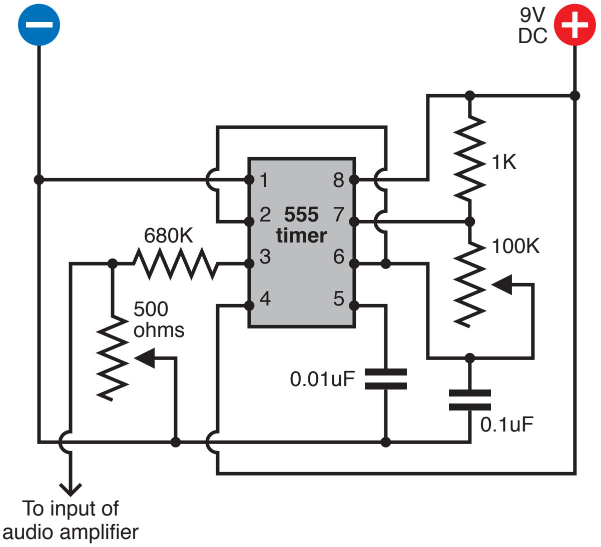

Figure 5-51. *A 555 timer is wired in astable mode using the component values shown here to generate a wide range of audible frequencies when the 100K potentiometer is adjusted. After the output is reduced in power, it can feed into the amplifier chip that was used previously.*

Disconnect your music player and connect the output from the 555 circuit to the input point (the 33K resistor) in the amplifier circuit shown earlier in Figure 5-41. You don't have to worry about a separate connection on the negative side as long as the 555 timer shares the same breadboard and the negative side of its power supply.

Make sure that the 500Ω potentiometer is turned all the way to short the output from the timer to the negative side of the power supply. This functions as your volume control. Also make sure the 100K potentiometer is in the middle of its range. Switch on the power and slowly turn up the 500Ω potentiometer until you hear a tone.

Now adjust the 100K potentiometer to create a low-pitched note. You'll find that it doesn't have a "pure" sound. There are some buzzing overtones. This is because the 555 timer is generating square waves such as those shown in Figure 5-52, not sine waves, and a square wave is actually a sum of many different sine waves, some of which have a high frequency. Your ear hears these harmonics, even though they are not obvious when you look at a square-shaped waveform.

Route one of the connections to your loudspeaker through your spool of hookup wire, and now you should hear a much purer tone, as the buzzing high frequencies are blocked by the self-inductance of the coil. Remove the coil and substitute the 10 μF capacitor, and now you hear more buzzing and less bass.

You've just taken a small step toward sound synthesis. If this subject interests you, you can go online and search for oscillator circuits. For a thorough understanding of the relationship between waveforms and the sounds you hear, you'll really need an oscilloscope, which will show you the shape of each waveform that you generate and modify.

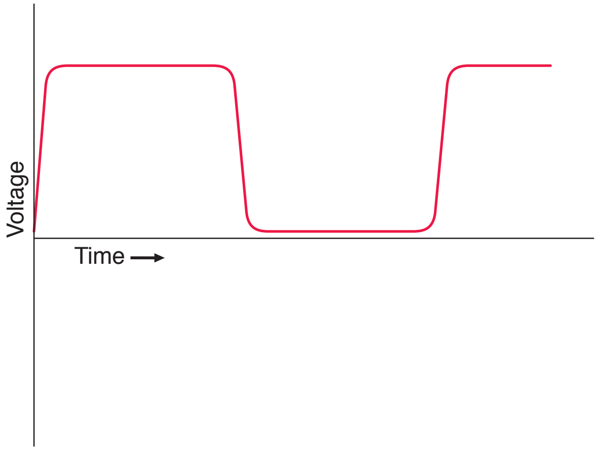

Figure 5-52. *The output from a 555 timer is either "on" or "off," with a very fast transition between those two states. The result is an almost perfect square wave. Theoretically, this can be disassembled into a complex set of sine waves that have many different frequencies. The human ear hears the high frequencies as harsh overtones.*

Experiment 30: Fuzz

Let's try one more variation on the circuit in Experiment 28. This will demonstrate another fundamental audio attribute: distortion.

You will need:

- One more 100K potentiometer.
- Generic NPN transistors: 2N2222 or similar. Quantity: 2.
- Various resistors and capacitors.

BACKGROUND

Clipping

In the early days of "hi-fi" sound, engineers labored mightily to perfect the process of sound reproduction. They wanted the waveform at the output end of the amplifier to look identical with the waveform at the input end, the only difference being that it should be bigger, so that it would be powerful enough to drive loudspeakers. Even a very slight distortion of the waveform was unacceptable.

Little did they realize that their beautifully designed tube amplifiers would be abused by a new generation of rock guitarists whose intention was to create as much distortion as possible.

The most common form of waveform abuse is technically known as "clipping." If you push a vacuum tube or a transistor to amplify a sine wave beyond the component's capabilities, it "clips" the top and bottom of the curve. This makes it look more like a square wave, and as I explained in the section on waveforms, a square wave has a harsh, buzzing quality. For rock guitarists trying to add an edge to their music, the harshness is actually a desirable feature.

Figure 5-53. *This Vox Wow-Fuzz pedal was one of the early stomp boxes, which deliberately induced the kind of distortion that audio engineers had been trying to get rid of for decades.*

The first gadget to offer this on a commercial basis was known as a "fuzz box," which deliberately clipped the input signal. An early fuzz box is shown in Figure 5-53. The clipping of a sine wave is shown in Figure 5-54.

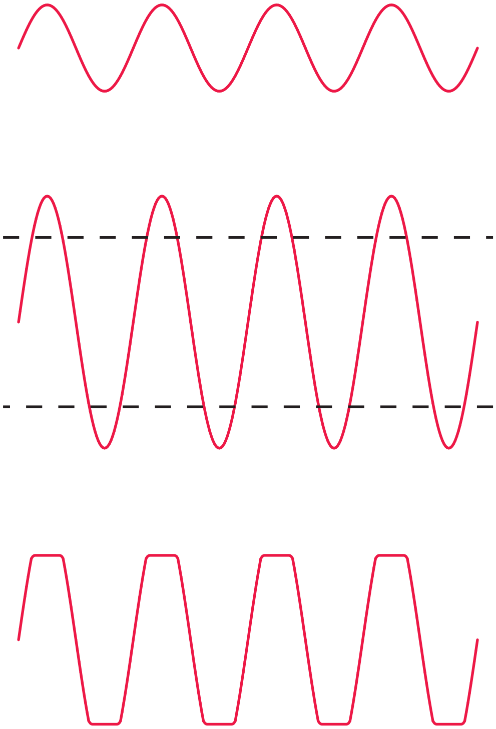

Figure 5-54. *When a sinewave (top) is passed through an amplifier which is turned up beyond the limit of its components (shown as dashed lines, center), the amplifier chops the wave (bottom) in a process known as "clipping." The result is close to a square wave and is the basic principle of a fuzz box commonly used to create a harsh guitar sound.*

Schematic

The output from the 555 timer is a square wave, so it already sounds quite "fuzzy," but we can make it more intense to demonstrate the clipping principle. I've redrawn the whole circuit in Figure 5-55, as several components have changed. The principal alteration is the addition of two NPN transistors.

If you assemble this circuit on your breadboard, note carefully that the 33K and 10K resistors at the bottom of the amplifier chip have been removed, and there's now just an 820Ω resistor in that location. The bottom of the adjacent 0.22 µF capacitor is still the input point for the amplifier, and if you follow the connection around to the middle of the schematic, you'll find it leading to a 100K potentiometer. This is your "fuzz adjuster."

The two NPN transistors are arranged so that the one on the left receives output from the 555 timer. This signal controls the flow of electricity through the transistor from a 33K resistor. This flow, in turn, controls the base of the righthand transistor, and the flow of current through that is what ultimately controls the amplifier.

When you power up the circuit, use the 100K potentiometer attached to the 555 timer to adjust the frequency (as before) and crank the "fuzz adjuster" potentiometer to hear how it adds increasing "bite" to the sound until ultimately it becomes pure noise.

The two transistors act as amplifiers. Of course, we didn't need them for that purpose—the input level for the amplifier chip was already more than adequate. The purpose of the lefthand transistor is simply to overload the righthand transistor, to create the "fuzz" effect. And when you turn up the output from the transistors with the "fuzz adjuster," eventually they overload the input of the amplifier chip, creating even more distortion.

If you want to tweak the output, try substituting different values for the 1K resistor and the 1 µF capacitor that are positioned between the emitter of the righthand transistor and the negative side of the power supply. A larger resistor should overload the transistor less. Different capacitor values should make the sound more or less harsh.

You can find literally thousands of schematics online for gadgets to modify guitar sound. The circuit I've included here is one of the most primitive. If you want something more versatile, you should search for "stomp box schematics" and see what you can find.

Figure 5-55. *For a quick demo of clipping, insert a couple of transistors between the output from the 555 timer and the input of the amplifier chip. One transistor overdrives the other, so that when you adjust the potentiometer at the center of the circuit, you hear an increasingly harsh, distorted sound.*

BACKGROUND

Stomp-box origins

The Ventures recorded the first single to use a fuzz box, titled "The 2,000 Pound Bee," in 1962. Truly one of the most awful instrumentals ever made, it used distortion merely as a gimmick and must have discouraged other musicians from taking the concept seriously.

Ray Davies of the Kinks was the first to embody distortion as an integral part of his music. Davies did it initially by plugging the output from one amp into the input of another, supposedly during the recording of his hit "You Really Got Me." This overloaded the input and created clipping—the basic fuzz concept. From there it was a short step to Keith Richards using a Gibson Maestro Fuzz-Tone when the Rolling Stones recorded "(I Can't Get No) Satisfaction" in 1965.

Today, you can find thousands of advocates promoting as many different mythologies about "ideal" distortion. In Figure 5-56, I've included a schematic from Flavio Dellepiane, a circuit designer in Italy who gives away his work (with a little help from Google AdSense) at *http://www.redcircuits.com*. Dellepiane is self-taught, having gained much of his knowledge from electronics magazines such as the British *Wireless World*. In his fuzz circuit, he uses a very high-gain amplifier consisting of three field-effect transistors (FETs), which closely imitate the rounded square-wave typical of an overdriven tube amp.

Dellepiane offers dozens more schematics on his site, developed and tested with a dual-trace oscilloscope, low-distortion sinewave oscillator (so that he can give audio devices a "clean" input), distortion meter, and precision audio volt meter. This last item, and the oscillator, were built from his own designs, and he gives away their schematics, too. Thus his site provides one-stop shopping for home-audio electronics hobbyists in search of a self-administered education.

Before fuzz, there was tremolo. A lot of people confuse this with vibrato, so let's clarify that distinction right now:

- Vibrato applied to a note makes the frequency waver up and down, as if a guitarist is bending the strings.
- Tremolo applied to a note makes its volume fluctuate, as if someone is turning the volume control of a guitar up and down very quickly.

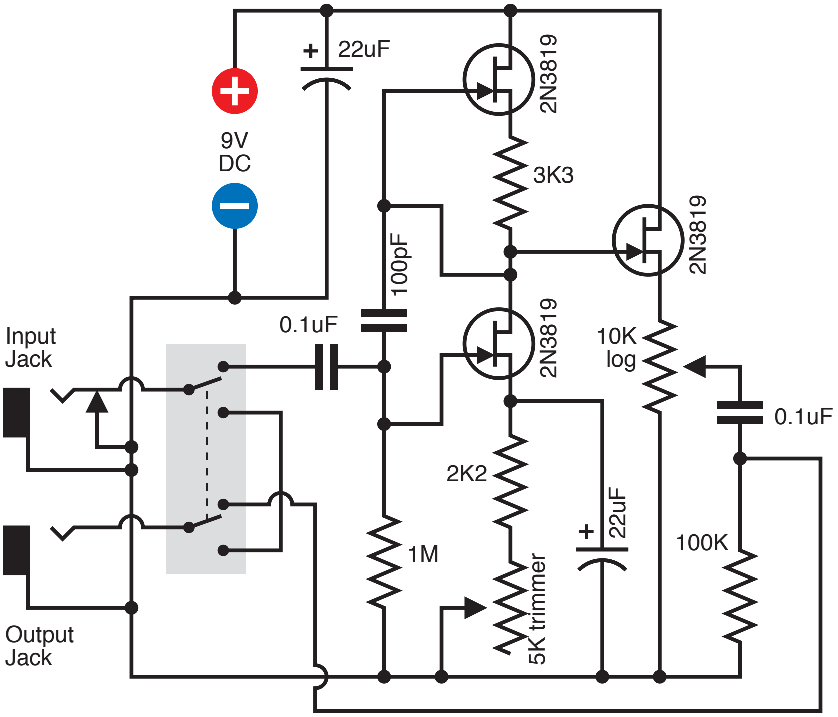

Figure 5-56. *This circuit designed by Flavio Dellepiane uses three transistors to simulate the kind of distortion that used to be created by overloading the input of a tube amplifier.*

BACKGROUND

Stomp-box origins (continued)

Harry DeArmond sold the first tremolo box, which he named the Trem-Trol. It looked like an antique portable radio, with two dials on the front and a carrying handle on top. Perhaps in an effort to cut costs, DeArmond didn't use any electronic components. His steam-punkish Trem-Trol contained a motor fitted with a tapered shaft, with a rubber wheel pressing against it. The speed of the wheel varied when you turned a knob to reposition the wheel up and down the shaft. The wheel, in turn, cranked a little capsule of "hydro-fluid," in which two wires were immersed, carrying the audio signal. As the capsule rocked to and fro, the fluid sloshed from side to side, and the resistance between the electrodes fluctuated. This modulated the audio output.

Today, Trem-Trols are an antique collectible. When industrial designer Dan Formosa acquired one, he put pictures online at *http://www.danformosa.com/dearmond.html*. And Johann Burkard has posted an MP3 of his DeArmond Trem-Trol so you can actually hear it: *http://johannburkard.de/blog/music/effects/DeArmond-Tremolo-Control-clip.html*.

The idea of a mechanical source for electronic sound mods didn't end there. The original Hammond organs derived their unique, rich sound from a set of toothed wheels turned by a motor. Each wheel created a fluctuating inductance in a sensor like the record head from a cassette player.

It's easy to think of other possibilities for motor-driven stomp boxes. Going back to tremolo: imagine a transparent disc masked with black paint, except for a circular stripe that tapers at each end. While the disc rotates, if you shine a bright LED through the transparent stripe toward a light-dependent resistor, you would have the basis for a tremolo device. You could even create never-before-heard tremolo effects by swapping discs with different stripe patterns. Figures 5-57 and 5-58 show the kind of thing I have in mind. For a real fabrication challenge, how about an automatic disc changer?

Today's guitarists can choose from a smorgasbord of effects, all of which can be home-built using plans available online. For reference, try these special-interest books:

- *Analog Man's Guide to Vintage Effects* by Tom Hughes (For Musicians Only Publishing, 2004). This is a guide to every vintage stomp box and pedal you can imagine.
- *How to Modify Effect Pedals for Guitar and Bass* by Brian Wampler (Custom Books Publishing, 2007). This is an extremely detailed guide for beginners with little or no prior knowledge. Currently it is available only by download, from sites such as *http://www.openlibrary.org*, but you may be able to find the previous printed edition from secondhand sellers, if you search for the title and the author.

Of course, you can always take a shortcut by laying down a couple hundred dollars for an off-the-shelf item such as a Boss ME-20, which uses digital processing to emulate distortion, metal, fuzz, chorus, phaser, flanger, tremolo, delay, reverb, and several more, all in one convenient multi-pedal package. Purists, of course, will claim that it "doesn't sound the same," but maybe that's not the point. Some of us simply can't get no satisfaction until we build our own stomp box and then tweak it, in search of a sound that doesn't come off-the-shelf and is wholly our own.

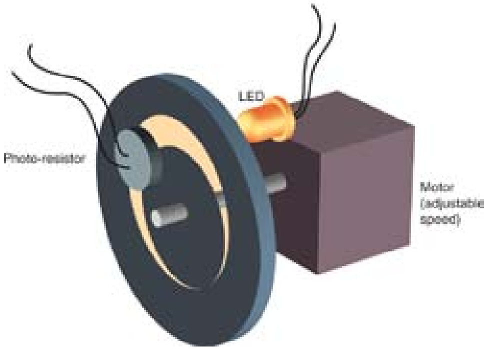

Figure 5-57. *Although electromechanical audio devices are obsolete now, some unexplored possibilities still exist. This design could create various tremolo effects, if anyone had the patience to build it.*

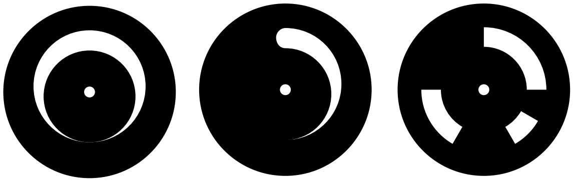

Figure 5-58. *Different stripe patterns could be used in conjunction with the imaginary electromechanical device in Figure 5-57 to create various tremolo effects.*

Experiment 31: One Radio, No Solder, No Power

Time now to go back one more time to inductance and capacitance, and demonstrate an application which also makes use of the way that waveforms can be added to each other. I want to show you how a simple circuit with no power supply at all can receive AM radio signals and make them audible. This is often known as a crystal radio, because the circuit includes a germanium diode, which has a crystal inside it. The idea dates back to the dawn of radio, but if you've never tried it, you've missed an experience that is truly magical.

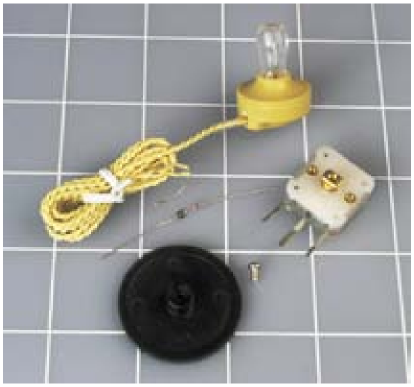

Figure 5-59. *Just add wire and a coil, and this is all you need to receive AM radio signals. The black disc becomes the tuning dial, after it is screwed onto the variable capacitor (right). This is actually an optional extra. A germanium diode (center) rectifies the radio signal. The high-impedance earphone (top) creates a barely audible sound.*

You will need:

- Rigid cylindrical object, such as a vitamin bottle. Quantity: 1.
- 22-gauge hookup wire, solid-core. Quantity: 60 feet.
- 16-gauge wire, stranded. Quantity: 100 feet.
- Polypropylene rope ("poly rope") or nylon rope. Quantity: 10 feet.
- Germanium diode. Quantity: 1.
- High-impedance headphone. Quantity: 1.

The diode and headphone can be ordered from *http://www.scitoyscatalog.com*. You cannot use a modern headphone of the type you wear with an MP3 player.

Some of these items are shown in Figure 5-59.

First, you need to make a coil. It should be about 3 inches in diameter, and you can wind it around any empty glass or plastic container of that size, so long as it's rigid. A soda bottle or water bottle isn't suitable, because the cumulative squeezing force of the turns of wire can deform the bottle so that it isn't circular anymore.

I chose a vitamin bottle that just happened to be exactly the right size. To remove the label, I softened its adhesive with a heat gun (lightly, to avoid melting the bottle) and then just peeled it off. The adhesive left a residue, which I removed with Xylol (also known as Xylene). This is a handy solvent to have around, as it can remove "permanent" marker stains as well as sticky residues, but you should always use latex or nitrile gloves to avoid getting it on your skin, and minimize your exposure the fumes. Because Xylol will dissolve some plastics, clearly it's not good for your lungs.

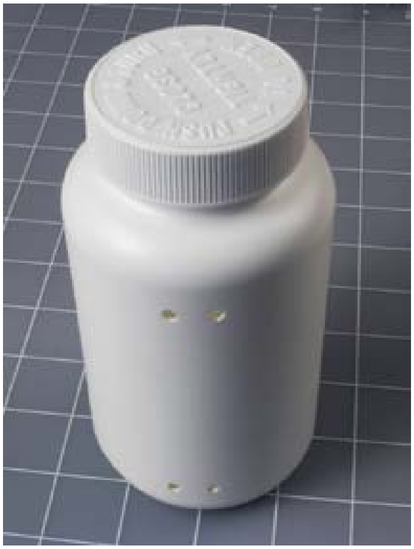

Figure 5-60. *A large, 3-inch diameter empty vitamin bottle makes an ideal core for a crystal radio coil. The drilled holes will anchor wire wrapped around the bottle.*

After you prepare a clean, rigid bottle, drill two pairs of holes in it, as shown in Figure 5-60. You'll use them to anchor the ends of the coil.

Now you need about 60 feet of 22-gauge solid-core wire. If you use magnet wire, its thin insulation will allow the turns of the coil to be more closely spaced, and the coil may be slightly more efficient. But everyday vinyl-insulated wire will do the job, and is much easier to work with.

Begin by stripping the first 6 inches of insulation from the end of the wire. Now measure 50 inches along the insulated remainder and apply your wire strippers at that point, just enough to cut the insulation without cutting the wire. Use your two thumb nails to pull the insulation apart, revealing about a half-inch of bare wire, as shown in Figure 5-61. Bend it at the center point and twist it into a loop, as shown in Figure 5-62.

You just made a "tap," meaning a point where you will be able to tap into the coil after you wind it. You'll need another 11 of these taps, all of them spaced 50 inches apart. (If the diameter of the bottle that you'll be using as the core of your coil is not 3 inches, multiply its diameter by 16 to get the approximate desired spacing of taps.)

After you have made 12 taps, cut the wire and strip 6 inches off that end. Now bend the end into a U shape about a half-inch in diameter, so that you can hook it through the pair of holes that you drilled at one end of the bottle. Pull the wire through, then loop it around again to make a secure anchor point.

Now wind the rest of the wire around the bottle, pulling it tightly so that the coils stay close together. When you get to the end of the wire, thread it through the remaining pair of holes to anchor it as shown in Figure 5-63. The completed coil is shown in Figure 5-64.

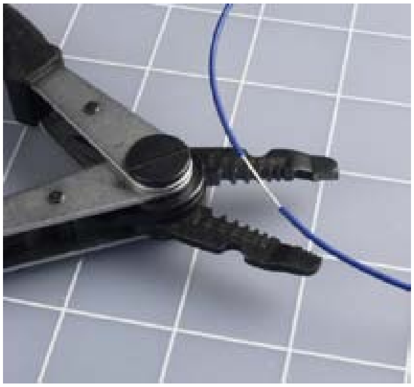

Figure 5-61. *Wire strippers expose the solid conductor at intervals along a 22-gauge wire.*

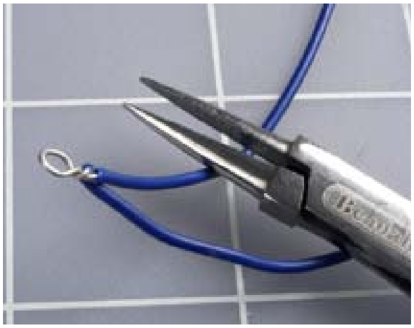

Figure 5-62. *Each exposed section of wire is twisted into a loop using sharp-nosed pliers.*

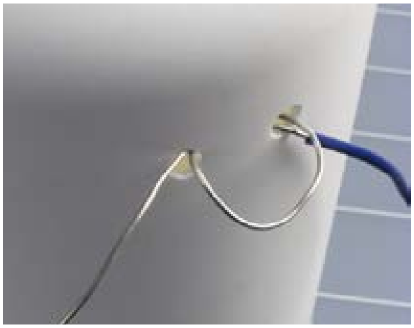

Figure 5-63. *The stripped end of the wire is secured through the holes drilled in the bottle.*

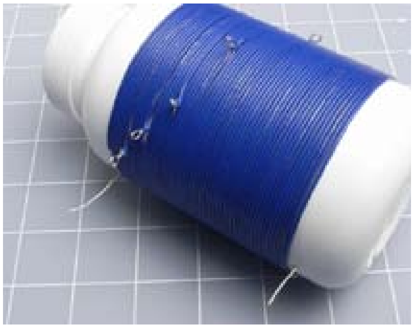

Figure 5-64. *The completed coil, wrapped tightly around the bottle.*

Your next step is to set up an antenna. If you live in a house with a yard outside, this is easy: just open a window, toss out a reel of 16-gauge wire while holding the free end, then go outside and string up your antenna by using polypropylene rope ("poly rope") or nylon rope, available from any hardware store, to hang the wire from any available trees, gutters, or poles. The total length of the wire should be about 100 feet. Where it comes in through the window, suspend it on another length of poly rope. The idea is to keep your antenna wire as far away from the ground or from any grounded objects as possible.

If you live in an apartment where you don't have access to a yard outside, you can try stringing your antenna around the room, hanging the wire from more pieces of poly rope. The antenna should still be about 100 feet long, but obviously it won't be in a straight line.

Hook the free end of your antenna to one end of your coil. At this point, you also need to add a germanium diode, which functions like a silicon-based diode but is better suited to the tiny voltages and currents that we'll be dealing with. The other end of the diode attaches to one of the wires leading to a high-impedance

High Voltage!

The world around us is full of electricity. Normally we're unaware of it, but a thunderstorm is a sudden reminder that there's a huge electrical potential between the ground below and the clouds above.

If you put up an outdoor antenna, never use it if there is any chance of a lightning strike. This can be extremely dangerous. Disconnect the indoor end of your antenna, drag it outside, and push the end of the wire into the ground to make it safe.

earphone. *A normal modern earphone or headphone will not work in this circuit.* The return wire from the headphone is connected to a jumper wire, the other end of which can be clipped to any of the taps in your coil.

One last modification, and you'll be ready to tune in. You have to ground the jumper wire. By this I mean connect it to something that literally goes into the ground. A cold-water pipe is the most commonly mentioned option, but (duh!) this will work only if the pipe is made of metal. Because a lot of plumbing these days is plastic, check under the sink to see if you have copper pipes before you try using a faucet for your ground.

Another option is to attach the wire to the screw in the cover plate of an electrical outlet, as the electrical system in your house is ultimately grounded. But the sure-fire way to get a good ground connection is to go outside and hammer a 4-foot copper-clad grounding stake into reasonably moist earth. Any wholesale electrical supply house should be able to sell you a stake. They're commonly used to ground welding equipment.

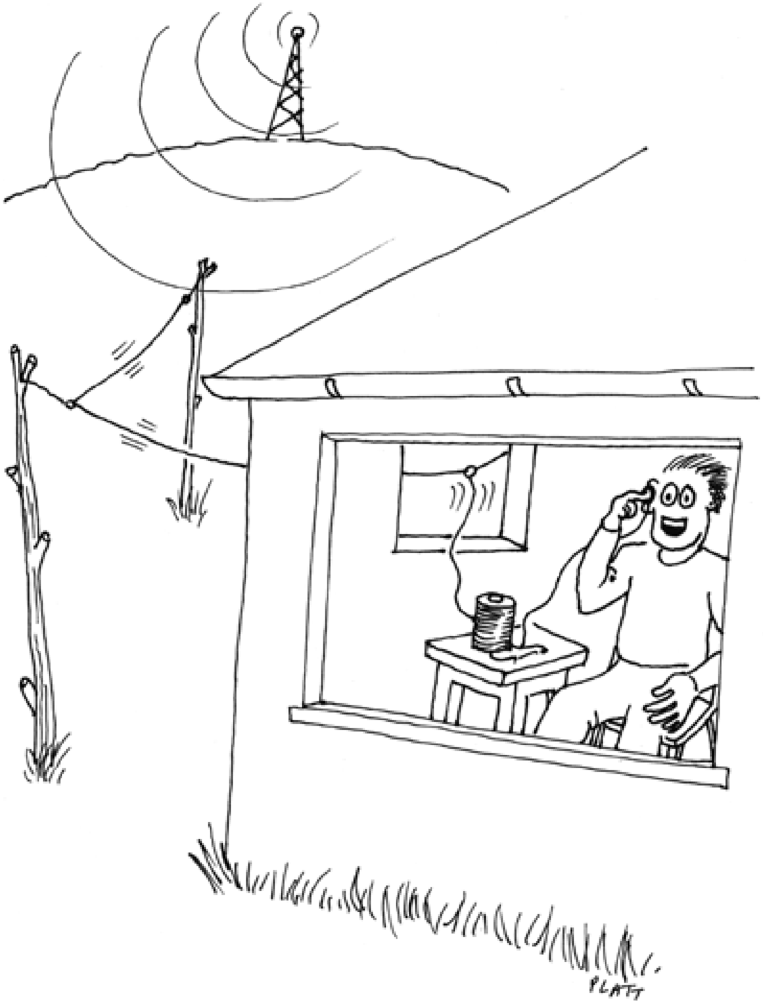

Figure 5-85. *The simple pleasure of picking up a radio signal with ultra-simple components and no additional power.*

Figures 5-66 and 5-67 show the completed radio.

If you've managed to follow these instructions (one way or another), it's time to tune your radio to the nearest station. Move the alligator clip at the end of your patch cord from one tap to another on your coil. Depending on where you live, you may pick up just one station, or several, some of them playing simultaneously.

It may seem that you're getting something for nothing here, as the earphone is making noise without any source of power. Really, though, there is a source of power: the transmitter located at the radio station. A large amplifier pumps power into the broadcasting tower, modulating a fixed frequency. When the combination of your coil and antenna resonates with that frequency, you're sucking in just enough voltage and current to energize a high-impedance headphone.

The reason you had to make a good ground connection is that the radio station broadcasts its signal at a voltage relative to ground. The earth completes the circuit between you and the transmitter. For more information on this and other concepts relating to radio, see the upcoming section "Theory: How radio works."

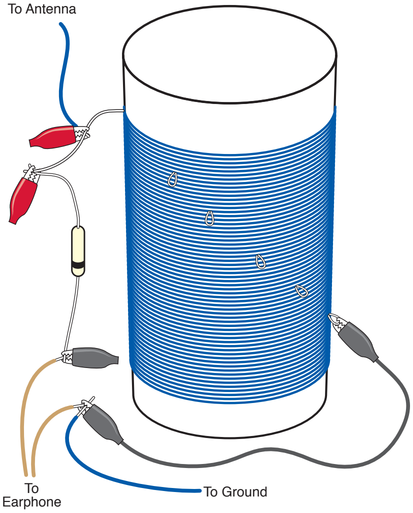

Figure 5-66. *A signal from the antenna can pass through the coil to ground. If the jumper wire is attached to an appropriate tap on the coil, it resonates with the radio signal, just powerfully enough to energize the earphone which is wired in series with a diode.*

Enhancements

The higher your antenna is, the better it should work. In my location, this is a major problem, as I live in a desert area without any trees. Still, just stringing the wire out of my window and tethering it (with rope) to the front bumper of my car enabled me to pick up a faint radio signal.

To improve the selectivity of your radio, you can add a variable capacitor, as shown in the following section. This allows you to "tune" the resonance of your circuit more precisely. Variable capacitors are uncommon today, but you can find one at the same specialty source that I recommended for the earphone and the germanium diode: the Scitoys Catalog (*http://www.scitoyscatalog.com*).

This source is affiliated with a smart man named Simon Quellan Field, whose site suggests many fun projects that you can pursue at home. One of his clever ideas is to remove the germanium diode from your radio circuit and substitute a low-power LED in series with a 1.5-volt battery. This didn't work for me, because I live 40 miles from the nearest AM broadcaster. If you're closer to a transmitter, you may be able to see the LED varying in intensity as the broadcast power runs through it.

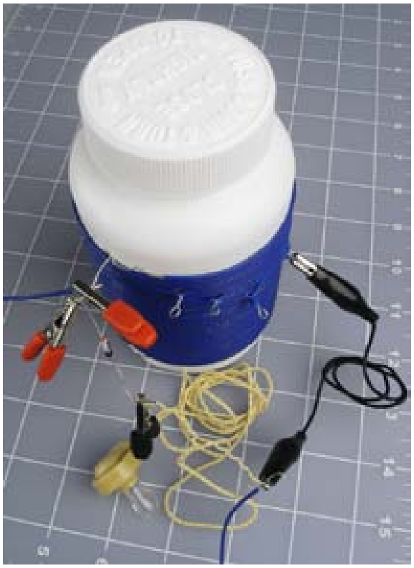

Figure 5-67. *The real-life version of Figure 5-66.*

THEORY

How radio works

When electrical frequencies are very high, the radiation they create has enough energy to travel for miles. This is the principle of radio transmission: A high-frequency voltage is applied to a broadcasting antenna, relative to the ground.

When I say "ground" in this instance, I literally mean the planet beneath us. If you set up a receiving antenna, it can pick up a faint trace of the transmission relative to the ground—as if the earth is one huge conductor. Actually the earth is so large and contains so many electrons, it can function as a common sink, like a gigantic version of the file cabinet that I suggested you should touch to get rid of static electricity in your body before touching a CMOS logic chip.

To make a radio transmitter, I could use a 555 timer chip running at, say, 850 kHz (850,000 cycles per second), and pass this stream of pulses through an amplifier to a transmission tower; if you had some way to block out all the other electromagnetic activity in the air, you could detect my signal and reamplify it.

This was more or less what Marconi (shown in Figure 5-68) was doing in 1901, after he had purchased rights to Edison's wireless telegraphy patent, although he had to use a primitive spark gap, rather than a 555 timer, to create the oscillations. His transmissions were of limited use, because they had only two states: on or off. You could send Morse code messages, and that was all.

Figure 5-68. *Marconi, the great pioneer of radio (photograph from Wikimedia Commons).*

Five years later, the first true audio signal was transmitted by imposing lower audio frequencies on the high-frequency carrier wave. In other words, the audio signal was "added" to the carrier frequency, so that the power of the carrier varied with the peaks and valleys of the audio.

At the receiving end, a very simple combination of a capacitor and a coil detected the carrier frequency out of all the other noise in the electromagnetic spectrum. The values of the capacitor and the coil were chosen so that their circuit would "resonate" at the same frequency as the carrier wave. Figures 5-69 and 5-70 illustrate these concepts.

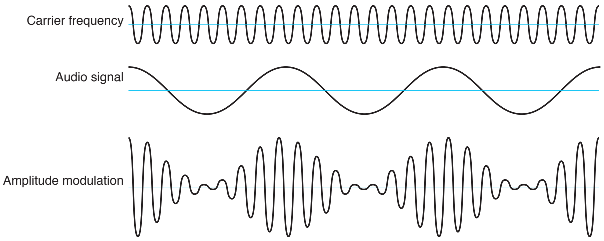

Figure 5-69. *When an audio signal (middle) is combined electronically with a high carrer frequency (top), the result looks something like the compound signal at the bottom. In actuality, the carrier frequency would be much higher compared with the audio frequency, by a radio of perhaps 1,000:1.*

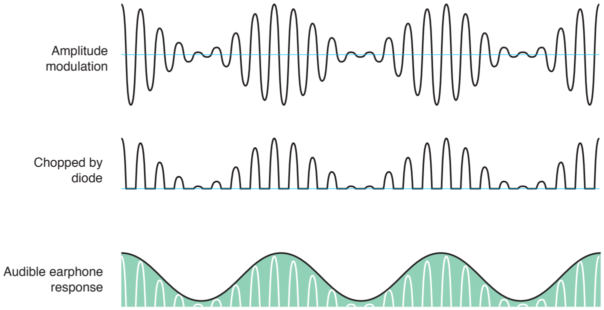

Figure 5-70. *When the compound signal is passed through a diode, only the upper half remains. An earphone cannot react fast enough to reproduce the high carrier frequency, so it "rides" the peaks and thus reproduces the audio frequency.*

The schematic in Figure 5-71 shows the simple circuit that you built by wrapping a coil around an empty vitamin bottle. When a positive pulse was received by the antenna, it resonated with the antenna and the coil, provided that the antenna was long enough and the coil was tapped at the appropriate number of turns.

THEORY

How radio works (continued)

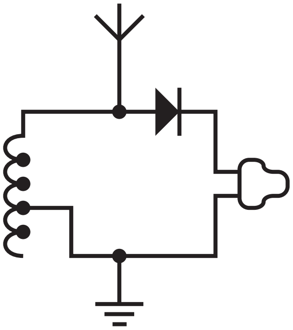

Figure 5-71. *An antenna at the top of the schematic picks up faint electromagnetic radiation from a distant transmitter. The coil at the left side is tapped at intervals so that its resonance can be adjusted to match the carrier frequency of the radio signal. Other frequencies are grounded (at the bottom of the schematic). The diode passes the "top half" of the signal to the earphone at the right, which is incapable of responding fast enough to reproduce the carrier frequency, and thus filters it out, leaving only the audio frequencies that were superimposed on it.*

By adding a capacitor, you can tune the circuit. Now an incoming pulse from the transmitter is initially blocked by the self-inductance of the coil, while it charges the capacitor. If an equally negative pulse is received after an interval that is properly synchronized with the values of the coil and the capacitor, it coincides with the capacitor discharging and the coil conducting. In this way, the right frequency of carrier wave makes the circuit resonate in sympathy. At the same time, audio-frequency fluctuations in the strength of the signal are translated into fluctuations in voltage in the circuit.

What happens to other frequencies pulled in by the antenna? The lower ones pass through the coil to ground; the higher ones pass through the capacitor to ground. They are just "thrown away."

The righthand half of the circuit samples the signal by passing it through a germanium diode and an earphone. The power from the transmitter is just sufficient to vibrate the diaphragm in the earphone, after the diode has subtracted the negative half of the signal.

Look back at the diagram of the amplitude-modulated signal. You'll see that it fluctuates up and down so rapidly, the earphone cannot possibly keep up with the positive-negative variations—hence the need for the diode. It will remain hesitating at the midpoint between the highs and lows, producing no sound at all. The diode solves this problem by subtracting the lower half of the "audio envelope," leaving just the positive spikes of voltage. Although these are still very small and rapid, they are now all pushing the diaphragm of the earphone in the same direction, so that it averages them out, approximately reconstructing the original sound wave.

Figure 5-72 shows how the circuit can be enhanced with a variable capacitor, to tune it without needing to tap the coil at intervals.

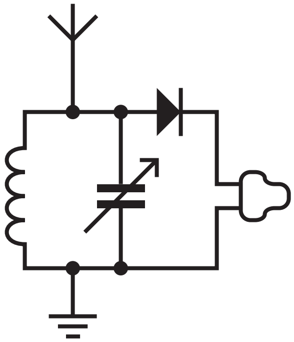

Figure 5-72. *By adding a capacitor to the circuit, its resonance can be tuned more precisely. The diagonal arrow indicates that a variable capacitor is used.*

The radio can pull in the stations on the AM (amplitude-modulated) waveband that happen to be most powerful in your area. The waveband ranges from 300 kHz to 3 MHz. If you find yourself interested in radio, your next step could be to build a powered radio using a couple of transistors. Alternatively you could build your own (legal) low-power AM transmitter. There's an ultra-simple kit available from *http://www.scitoys.com* consisting of just two principal components: a crystal oscillator, and a transformer, shown in Figure 5-73. That's all it takes.

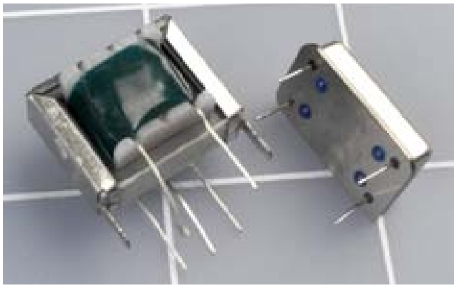

Figure 5-73. *An AM radio transmitter can be made from just two components: a transformer (left) and a crystal oscillator (right), available from http://www.scitoys.com.*

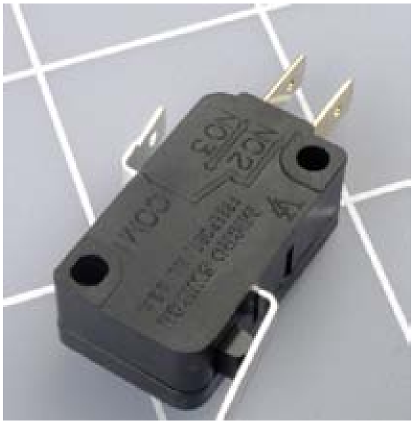

Figure 5-74. *A microswitch has a small button (at the front, righthand side in this picture) that is often actuated by a pivoted metal lever. The switch can respond to a very light pressure, but can handle relatively high currents.*

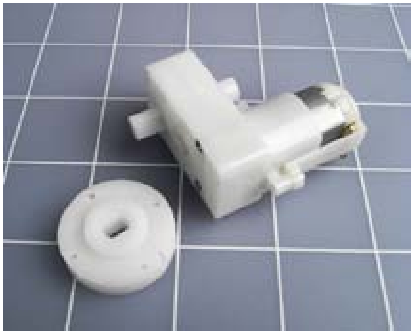

Figure 5-75. *For the Little Robot Cart, I found this 5-volt motor, which is supplied with a disc that fits its output shaft. The combination cost less than $10.*

Experiment 32: A Little Robot Cart

Robotics is another application of electronics that deserves a book in itself—or several books. So, once again, I'm going to give you an introduction followed by some points that you can follow if you want to go further. As always, I will start with the simplest possible device, which in the world of robotics is a cart that finds its way around your living room.

You will need:

- SPST or SPDT microswitches requiring minimal pressure to activate them. A force between 0.02 and 0.1 newtons would be ideal. Quantity: 2. See Figure 5-74.
- DC gear-motor, rated for any voltage between 5 and 12, drawing a maximum of 100mA in its free-running state, output shaft turning between 30 and 60 RPM. Quantity: 1. A motor is shown in Figure 5-75.
- Disc or arm that fits securely onto your motor shaft. Quantity: 1.
- 555 timer. Quantity: 1.
- DPDT nonlatching relay rated for the same voltage as your motor. Quantity: 1.
- 1/4-inch plywood or plastic, one piece about 2 feet square.
- #4 sheet-metal screws, 5/8 inch or 3/4 inch long. Quantity: 2 dozen.
- #6 bolts, 3/4 inch long, with nylon-insert lock nuts. Quantity: 2 dozen.
- 1/4-inch bolts, 1 inch long, with nuts, to mount the wheels. Quantity: 4.

I'm not specifying one particular motor, because if I did, it might not be available by the time you read this. Motors aren't like logic chips, which have retained their basic function throughout various improvements over a period of several decades. Motors come and go, and many that you may run across will be surplus parts that will never been seen again. Search online for "gearmotor" or "gearhead motor" and find one as close as possible to the specification that I have provided. The mechanical power output of the motor shouldn't be important, because we won't be requiring it to do much work.

The important consideration when you buy your motor is that you should also obtain something that fits onto its output shaft. Typically, this will be a disk or arm that can be screwed into place. To this you can then add a larger wheel of your own, which you can cut with a hole saw or make from the screw-on lid of a jar, or anything else circular that you may find in the house.

A larger wheel will make your cart move faster than a smaller wheel, but will reduce its torque, thus limiting its power to overcome obstacles.

This brings me to my next topic: fabrication. Although this is an electronics book, motors are electromechanical devices, and you have to be able to install them in some kind of a machine to get any interesting results. You can use plywood to complete the two little robotics projects here (ideally, the kind of thin, high-quality plywood sold by hobby stores) but I recommend something that looks better and is easier to work with: ABS plastic. Before you start on the robotic cart, you may want to check the section "Fundamentals: All about ABS."

FUNDAMENTALS

All about ABS

Unless you think the steampunk movement isn't going back far enough, you probably don't want your autonomous robot cart to resemble a relic from before the 1800s. Therefore, wood may not be the best construction material. Metal can look nice, but is not easy to work with. For quick results that have a twentieth-century look (maybe even a 21st-century look), plastic is the obvious choice, and I feel that ABS is the best type of plastic to use, because it provides such quick, easy results. ABS stands for "acrylonitrile butadiene styrene." Lego® blocks are made of ABS. Car-stereo installers and model-railroad buffs use it. You can use it, too. You can saw it, drill it, sand it, whittle it, and drive screws into it, and it won't warp, split, or splinter. It's washable, doesn't need to be painted, and will last almost forever.

Delrin is another type of plastic, but tends to cost more and is a little tougher to drill and cut. It's a matter of personal preference. ABS machines fairly well, but when you drill it, for example, it can "catch" on the bit and the piece will spin with the bit due to the way that plastic chips off with the bit. Delrin is self-lubricating and has better melting properties under the heat of machining, so it drills and cuts much more cleanly and easily than ABS.

Where to find ABS

Pieces of ABS a couple of feet square are available from online sources such as *http://hobbylinc.com* or estreetplastics (an eBay store), but you'll save money if you can truck on down to your nearest plastic supply house and buy it like plywood, in sheets measuring 4 by 8 feet. To discover whether you have a nearby plastic supply house, search for "plastic supply" in your yellow pages or Google Local.

Piedmont Regal Plastics has many supply centers around the nation, but you'll have to collect it yourself, and they may not be willing to cut small pieces. You can check online at *http://www.piedmontplastics.com* for their locations.

Stock colors of ABS include black, white, and "natural," which is beige. Sheets usually are textured on one side, which is the side that should face outward, as it is more scratch-resistant than the smooth side.

Because you won't be adding paint or other finishes, you'll have to be careful not to scuff the plastic or scratch it while working. Clean your bench thoroughly before you begin, taking special care to remove any metal particles, which tend to become embedded in the plastic. Use wooden shims in the jaws of your vise, and avoid resting the plastic accidentally on any sharp tools or screws. Working with ABS requires a clean environment and a very gentle touch.

Cut with Care

You can saw ABS, but if you use a table saw, the plastic will tend to melt and stick to the blade. These smears will get warm and sticky when you feed the next piece of plastic into the saw, and the result will be extremely unpleasant. The whirling blade will grab the plastic and hurl it at you powerfully enough to break bones. This is known as "kickback" and is a very serious risk when sawing plastic.

If you have extensive experience using a table saw, you are actually more vulnerable, because the reflexes and cautions you have developed while dealing with wood will not be adequate for working with plastic. Please take this warning seriously!

Your first and most obvious precaution is to use a plastic-cutting blade, which has a larger number of thicker teeth to absorb the heat. The blade I have used is a Freud 80T, but there are others. If you use a blade that is not suitable, you will see it starting to accumulate sticky smears. This is the only warning you will get. Clean that blade with a solvent such as acetone, and never use it for ABS again.

Regardless of other precautions, always wear gloves and eye protection when using a table saw, and stand to one side when feeding materials into it. Personally, after one episode of kickback that I thought had broken my arm, I prefer not to use a table saw on plastic at all.

For long, straight cuts, the alternatives include:

- *Panel saw (big and expensive, but safe and accurate).*
- *Miniature handheld circular saw with a blade around 4 inches in diameter, guided with a straight edge clamped to the sheet.*
- *Hand saw. This is my old-school preference. My favorite is a Japanese pull-to-cut saw, which makes very clean cuts: the Vaughan Extra-Fine Cross-Cut Bear Saw, 9-1/2 inches, 17 tpi (teeth per inch). If you use one of these, be careful to keep your free hand out of the way, as the saw can easily jump out of the cut. Because it is designed to cut hard materials such as wood, it has no difficulty cutting soft flesh. Gloves are strongly recommended.*

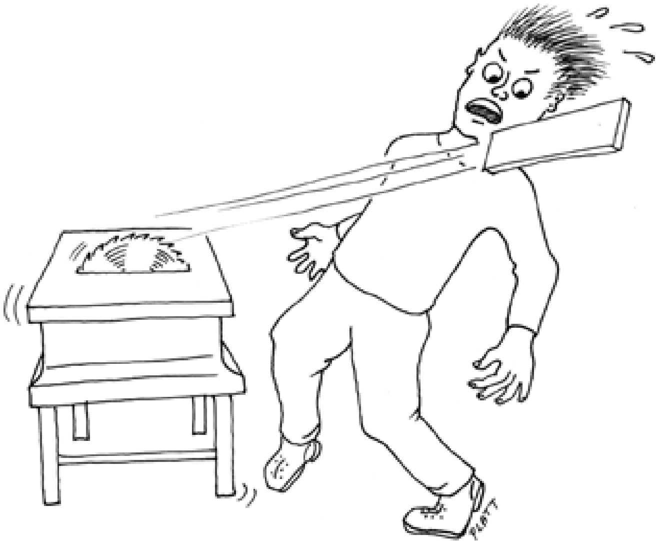

Figure 5-76. *The perils of kickback. Plastic easily sticks to the blade of a table saw, which will hurl it at you unexpectedly. Use other tools to cut plastic.*

Curving Cuts

Curving cuts involve relatively little danger, although eye protection and gloves are still advisable. My preferred tools:

- Band saw with a 3/8- or 1/4-inch blade designed for thin wood or plywood.
- Jigsaw. I have a special liking for the DeWalt XRP using Bosch blades that are designed for hardwood or plastic. This will cut complex curves in ABS as easily as scissors cutting paper.

No matter what type of saw you use, you'll have to clean ragged bits of plastic off the cut afterward, and the absolutely necessary item for this purpose is a deburring tool, available from *http://www.mcmaster.com* and most other online hardware sources. A belt sander or disc sander is ideal for rounding corners, and a metal file can be used to remove bumps from edges that are supposed to be straight.

Figures 5-77 through 5-80 show various cutting tools. Figure 5-81 shows a deburring tool, and Figure 5-82 shows a disc sander.

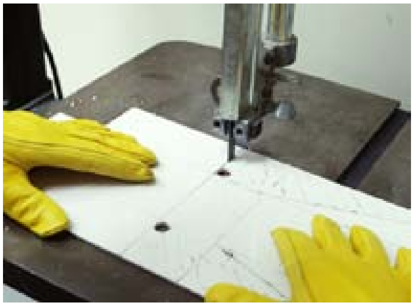

Figure 5-77. *A band saw is an ideal tool for cutting complex shapes out of ABS plastic. You can often find them secondhand for under $200.*

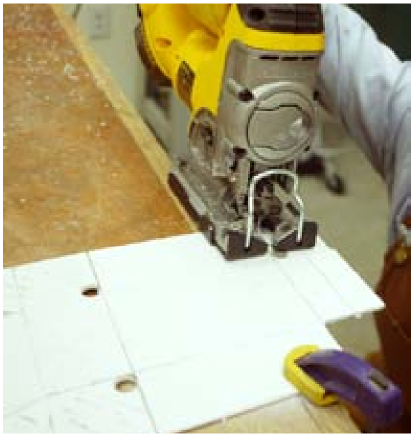

Figure 5-80. *This DeWalt jigsaw can run at very slow speeds, enabling precise and careful work with plastic.*

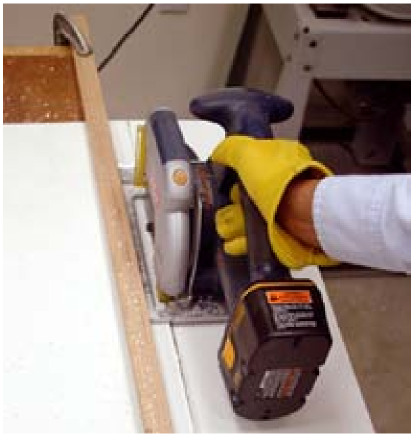

Figure 5-78. *A handheld circular saw, running along a straight-edge, is much safer than a table saw for cutting plastic, and can produce comparable results.*

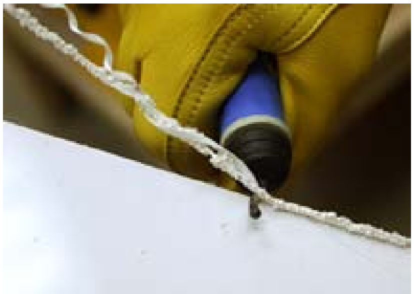

Figure 5-81. *A deburring tool will clean and bevel the sawn edge of a piece of plastic in just a couple of quick strokes.*

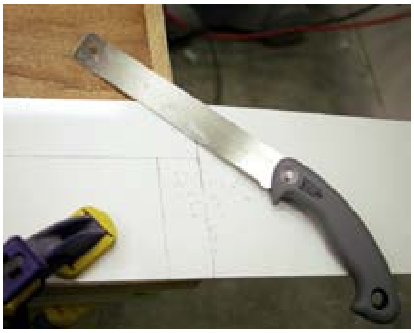

Figure 5-79. *This Japanese-style saw cuts when you pull it, rather than when you push it. After some practice, you can use it to make very accurate cuts. Because ABS is so soft, minimal muscle-power is required.*

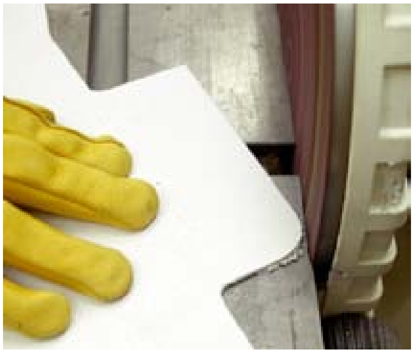

Figure 5-82. *A belt sander or disc sander is the ideal tool for rounding corners when working with ABS plastic.*

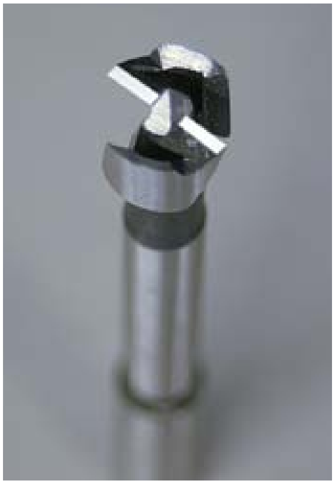

Figure 5-83. *A Forstner drill bit makes clean, precise holes; a large regular drill bit will chew up ABS plastic and make a mess.*

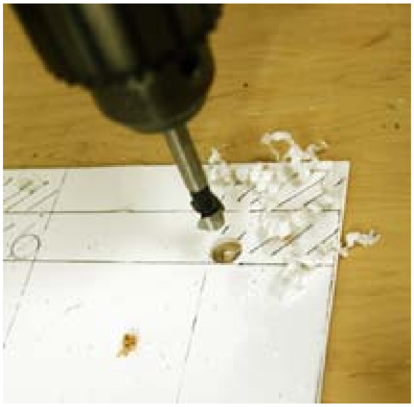

Figure 5-84. *By drilling holes at any location where two bends intersect, you reduce the risk of the plastic fissuring.*

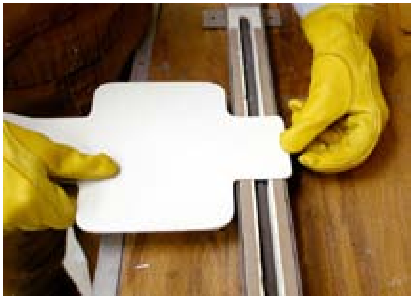

Figure 5-85. *Making clean, precise bends in ABS is simply a matter of resting the plastic over a bender that consists of an electric heating element.*

Making Plans

I like to use drawing software to create plans, and I try to print them at actual scale. I tape them to the smooth side of a piece of white or natural-color ABS, then use an awl to prick through the plan into the soft surface beneath. I remove the paper and connect the awl marks by drawing onto the plastic using a pencil or a fine-point water-soluble pen. Its lines can be wiped away later with a damp cloth. Don't use a permanent marker, as the solvents that you will need to clean it may dissolve the plastic.

Because ABS will tend to open a fissure when you bend it at any inside corner where you don't have a smooth radius, you need to drill holes at these locations, as shown in the cart plans in Figure 5-92 on page 275.

A regular half-inch drill bit is too aggressive; it will tend to jam itself into the plastic within one turn of the drill. Use Forstner bits (shown in Figures 5-83 and 5-84) to cut nice smooth circles.

Note that the heat from bending will tend to make any marks on the plastic permanent.

Bending It

A big advantage of plastic over wood is that you can make complex shapes by bending them, instead of cutting separate pieces and joining them with nails, screws, or glue. Unfortunately, bending does require an appropriate bender: an electric heating element mounted in a long, thin metal enclosure that you place on your workbench. The bender I use is made by FTM, a company that offers all kinds of neat gadgets for working with plastic. Their cheapest bender, shown in Figure 5-85, is just over $200 with a 2-foot element. You can get a 4-foot model for about $50 more. Check them out at *http://thefabricatorssource.com*.

Avoid Burns While Bending

A plastic bender will inflict serious burns if you happen to rest your hand on it accidentally, and because it has no warning light, you can easily forget that you have left it plugged in. Use gloves!

To bend plastic, lay it over the hot element of a plastic bender for a brief time (25 to 30 seconds for 1/8-inch ABS, 40 to 45 seconds for 3/16-inch, and up to a minute for 1/4-inch). If you overheat the plastic, you'll smell it, and when you turn it over you'll find it looks like brown melted cheese. Naturally you should learn to intervene before the plastic reaches that point.

ABS is ready to bend when it yields to gentle pressure. Take it off the bender and bend it *away* from the side that you heated. If you bend it toward the hot side, the softened plastic will bunch up inside the bend, which doesn't look nice.

You can work with it for about half a minute, and when you have it the way you want it, spray or sponge water onto it to make it set quickly. Alternatively, if you need more time, you can reheat it. The amount of force necessary to bend the sheet increases in proportion with the length of the bend, so a long bend can be difficult, and I usually insert it into a loose vise, push it a bit, move it along to the next spot, and push it again.

Because plastic bending is very similar to making shapes in origami, it's a good idea to model your projects in paper before you commit yourself to ABS.

If you decide that you don't want to spend money on a bender, don't abandon plastic just yet—you can use screws to assemble separate sections with greater ease and convenience than if you were working with wood.

Making 90-Degree Joints

Driving screws into the edge of a piece of plywood will almost always separate its layers, but ABS has no layers (or grain, either), and never splits or shatters. This means that you can easily join two pieces at 90° using small screws (#4 size, 5/8-inch long).

Figures 5-86 through 5-90 show the procedure for joining 1/8-inch (or thicker) ABS to 1/4-inch ABS, which I regard as the minimum thickness when you're inserting screws into its edge:

1. Mark a guideline on the thinner piece of plastic, 1/8 inch from its edge. For #4 screws, drill holes using a 7/64-inch bit. If you're using flat-headed screws, countersink the holes very gently.

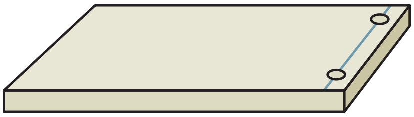

Figure 5-86

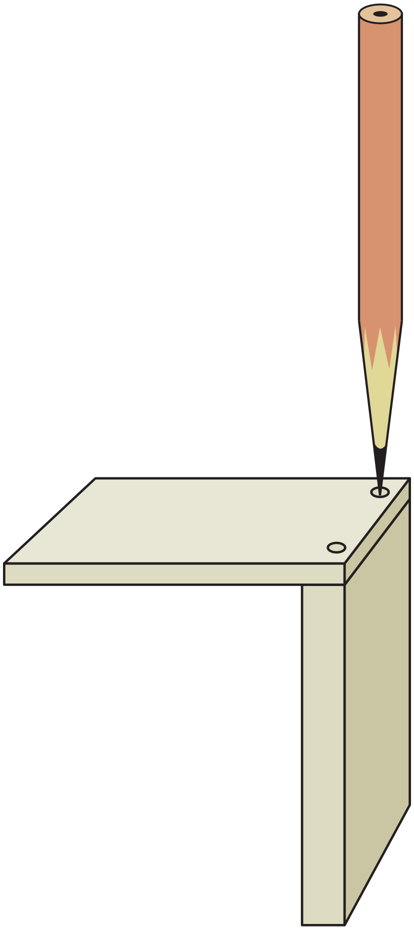

Figure 5-87

2. Hold or clamp the pieces in place and poke a pen or pencil through the holes to mark the edge of the 1/4-inch plastic beneath.
3. Remove the thin plastic, clamp the 1/4-inch plastic in a vise, and drill guide holes for the screws at each mark, centered within the thickness of the plastic. Because ABS does not compress like wood, the holes must be larger than you may expect; otherwise, the plastic will swell around the screw. A 3/32-inch bit is just right for a #4 screw.
4. Assemble the parts. Be careful not to overtighten the screws; it's easy to strip the threads that they cut in the soft plastic.

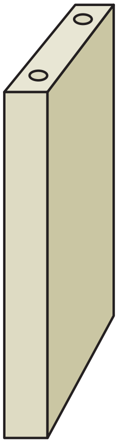

Figure 5-88

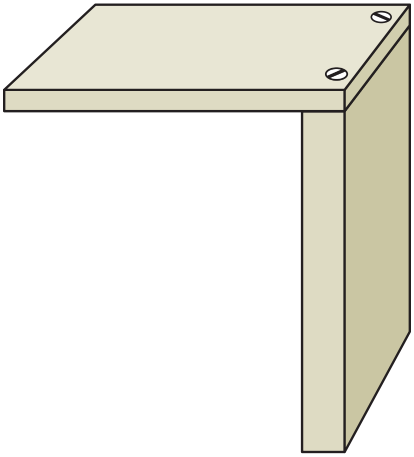

Figure 5-89. *Figures 5-86 through 5-89 illustrate four steps to join two pieces of ABS using #4 sheet-metal screws. Cut 7/64-inch holes on a line 1/8 inch from the edge of the first piece, then mark through the holes to the edge of the second piece. Drill 3/32-inch holes that are precisely centered in the edge, then screw the pieces together.*

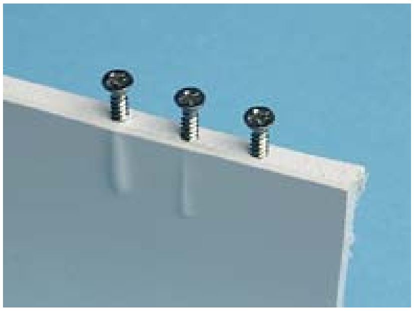

Figure 5-90. *Three #4 screws driven into the edge of ABS, using a 1/16-inch guide hole, a 5/64-inch guide hole, and a 3/32-inch guide hole. respectively Because the first two guides holes were too small, the plastic swelled around the screw (but did not break).*

Framing Your Cart

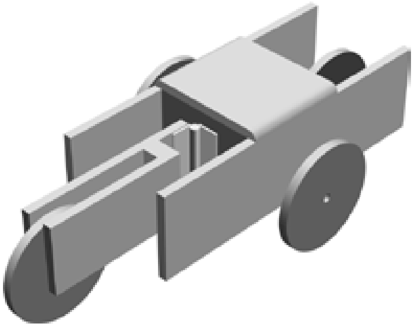

Figure 5-91. *If you have 3D rendering software, it can be a great way to test the feasibility of a construction project before you start cutting materials and trying to fit pieces together. This rendering was a proof-of-concept for the Little Robot Cart.*

For reasons that will soon be apparent, I've chosen an unusual diamond-shaped configuration of wheels. In the rendering shown in Figure 5-91, the front wheel (at the far end of the cart) applies power, the rear wheel (at the near end of the cart) steers the cart when backing up, and the side wheels prevent it from falling over.

Depending on the type of motor that you buy, you'll have to improvise a way to mount it in the front section of the cart. Don't be afraid to use kludges such as cable ties, duct tape, or even rubber bands to attach the motor to the frame. We're making a rough prototype, here, not a thing of beauty (although if you decide you like the cart, you can always rebuild it beautifully later).

The plan in Figure 5-92 shows the pieces that you will need. Part A is the body of the cart. If you're going to bend it from ABS, you should drill half-inch holes, with a forstner bit, at the four inside corners, so that these corners have rounded edges. If you simply saw the plastic to make sharp 90° corners, the plastic may develop fissures at the corners when you bend it. If you don't have a plastic bender and don't feel inclined to buy one, you can make Part A from three separate rectangles and then screw them together.

Figure 5-92. *These sections of 1/4-inch plastic can be assembled to create the simple cart described in Experiment 31.*

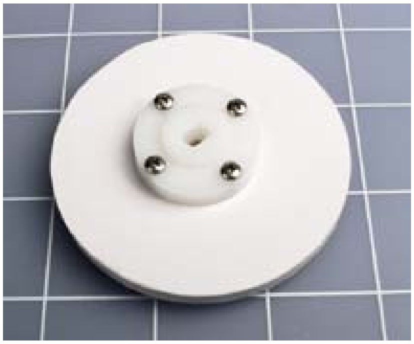

Figure 5-93. *A 3-inch wheel is screwed to the disc that mates with the drive shaft of the motor.*

Part B is a wheel, of which you will need four. I cut them using a 3-inch hole saw. The front wheel is screwed to whatever disc or arm you obtained to mate with the shaft of your motor. See Figure 5-93.

Parts C, D, and E assemble to form a yoke in which the rear wheel is mounted. I used a 2-inch hinge to pivot the yoke. The hinge is mounted on Part F, which is a partition located midway in the frame of the cart. The photographs in Figures

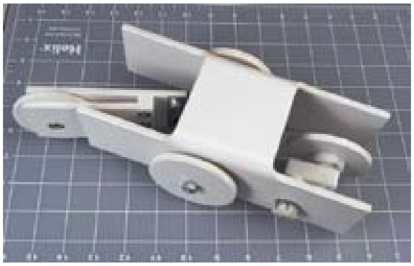

Figure 5-94. *The assembled body of the cart, before adding control electronics. The wheel at the righthand end will pull the cart from left to right. The hinged trailing wheel will allow the cart to move in a relatively straight line when it moves forward, but will tend to turn it when it backs up.*

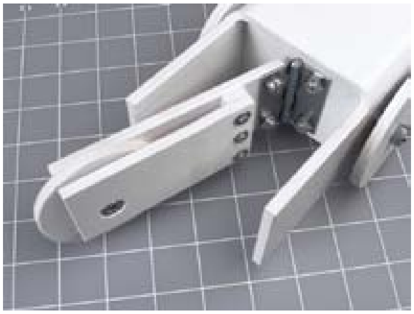

Figure 5-95. *A closeup of the hinged trailing wheel, which rotates freely and can flip from side to side with minimal friction.*

5-94 and 5-95 will help to make this clear. Initially, when you install Part F, use only two screws, one each side, so that you can adjust its angle a little. This will be necessary to optimize the contact of the wheels with the floor.

The side wheels and rear wheel must spin freely, but on the other hand, they shouldn't wobble. I simply tightened the nuts on the bolts that serve as axles for the wheels, until there was maybe half a millimeter of clearance. I added a drop of Loctite to stop the nuts from getting loose.

The plans don't show precisely where to drill holes for the axle bolts, because the location will depend on the size of your wheels. You can figure this out as you go along. Just make sure that the side wheels aren't mounted too low. We don't want them to lift the front wheel or the rear wheel off the floor. If the side wheels are a fraction higher off the ground than the front and rear wheels, that's good.

If you have tile or wood floors, your cart may acquire better traction if you wrap a thick rubber band around each disc that you use for the drive wheel and the steering wheel.

The most important aspect of the construction is to place microswitches where they'll be triggered when the cart runs into something. I placed mine at the front corners, as shown in Figures 5-96 and 5-97. And that brings me to the electronics.

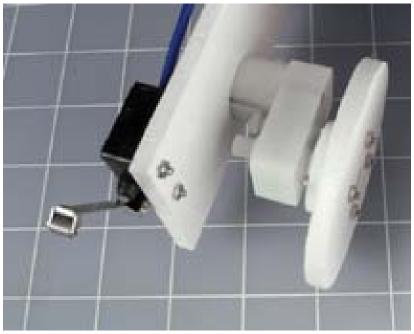

Figure 5-96

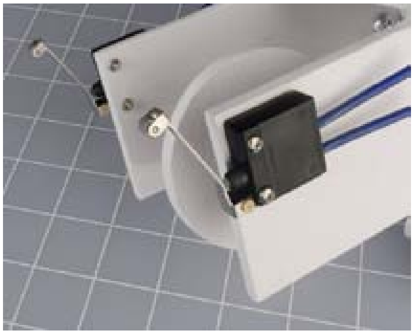

Figure 5-97. *Two microswitches with metal arms are mounted on each side of the cart, where they will sense any obstacle.*

The Circuit

The schematic is very, very simple, with only four principal components: two microswitches that sense obstacles in front of the cart, one relay, and one 555 timer. You will also need a small power switch, a battery or battery pack, and a resistor, and capacitors to go with the timer. A trimmer potentiometer will allow you to adjust the "on" time of the 555 timer, which will determine how long the cart takes to back up. See Figure 5-98.

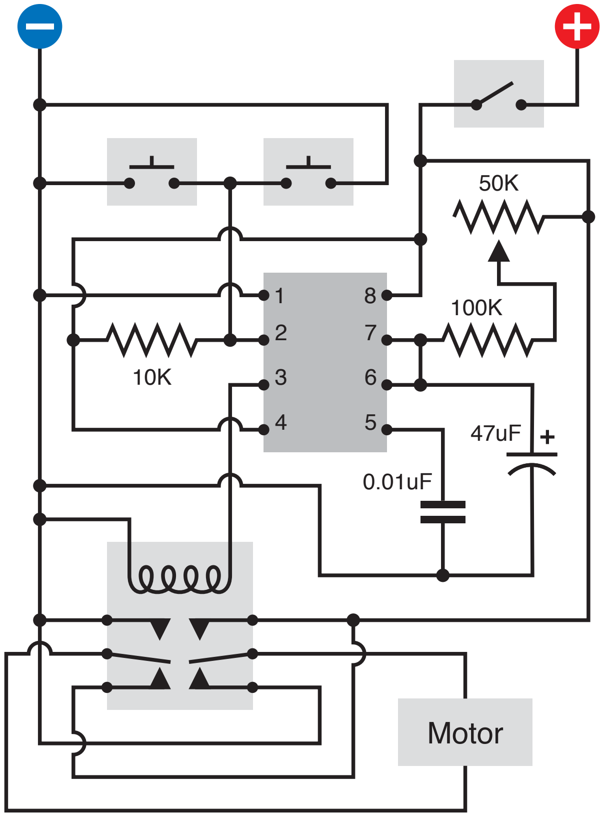

Figure 5-98. *This ultrasimple schematic is all the cart needs to enable it to back up when it hits an obstacle.*

The motor I chose requires 5 volts, so I had to use a voltage regulator with a 9-volt battery. If your motor uses 6 volts, you can wire four AA batteries to it directly. If you have a 12-volt motor, you can use two 9-volt batteries in series, supplying power through a 12-volt voltage regulator.

Assemble the components, mount them on the cart, and switch it on, and it should move forward slowly in a more-or-less straight line. If it moves backward, reverse your connection to the terminals on the motor.

When the cart bumps into something, either of the microswitches will connect negative voltage to the input pin of the 555 timer. This triggers the timer, which runs in monostable mode, generating a single pulse lasting about 5 seconds, which closes the relay, which is wired so that it reverses the voltage to the motor.

When the voltage is reversed to a simple DC motor, it runs backward. So the cart backs up. Because the rear wheel is mounted in a yoke that pivots, the yoke will tend to flip one way or the other, causing the cart to describe an arc as it moves backward. At the end of the timer cycle, the relay relaxes and the cart starts moving forward again. In forward mode, the rear wheel just follows along without applying any steering force, so the cart tends to follow a straight line—until it hits another obstacle, at which point it backs up, and tries another path.

FUNDAMENTALS

All about limit switches

The most obvious enhancement for your cart would be a better steering mechanism. You could use another motor to take care of this, with a pair of limit switches. Because limit switches are a basic, important idea in conjunction with motors, I'll explain them in detail.

Figure 5-99 shows three successive views of a motor with an arm attached to it, which can press either a lower pushbutton or an upper pushbutton. Both of the pushbuttons are normally closed, but will open when pressed by the motor arm. These buttons are the limit switches. Typically you would use microswitches for this purpose, just like the ones that I suggested as barrier-sensors at the front of the cart.

In addition, there's a DPDT relay that is activated by a simple on/off switch at the righthand side. On the cart, the 555 timer takes the place of the on/off switch, by feeding power to the relay.

Suppose that the motor begins with the arm pointing downward, as shown in the top view in Figure 5-99, and the motor is wired so that when it receives negative voltage at its lower terminal and positive at its upper terminal, it rotates counter-clockwise. This is what happens when the on/off switch closes and sends power to the DPDT relay. Positive voltage from the relay contacts cannot pass through the upper diode, but can pass through the upper limit switch, which is closed. Negative voltage cannot pass through the lower limit switch, because it's open, but can pass through the lower diode. So, the motor starts to turn counterclockwise. During the midpoint of its arc, it receives power through both of the limit switches.

Finally, the motor arm reaches the upper switch, and opens it. This prevents positive voltage from reaching the motor through that switch, and the positive voltage is also blocked by the upper diode. So, at this time, the motor stops.

Now suppose that the on/off switch is opened, as in the top view in Figure 5-100. The relay loses its power, so its contacts relax. The voltage to the motor is now reversed. Negative voltage passes through the upper diode, while positive voltage reaches the motor through the lower limit switch. The motor starts running clockwise, until its arm hits the lower switch, opening it and cutting off power to the motor.

Limit switches are necessary, because if you continue to apply voltage to a simple DC motor that is unable to turn, the motor sucks more current, gets hot, and may burn out.

You can easily see how this kind of system could be used to control the cart's steering. Even though the motor has only two positions, these are sufficient to make the cart turn when going backward, and proceed straight ahead when going forward.

To reduce power consumption, the DPDT relay could be replaced with a two-coil latching relay. The circuit would then have to be revised so that the relay is flipped to and fro by a pulse to each of its coils.

FUNDAMENTALS

All about limit switches (continued)

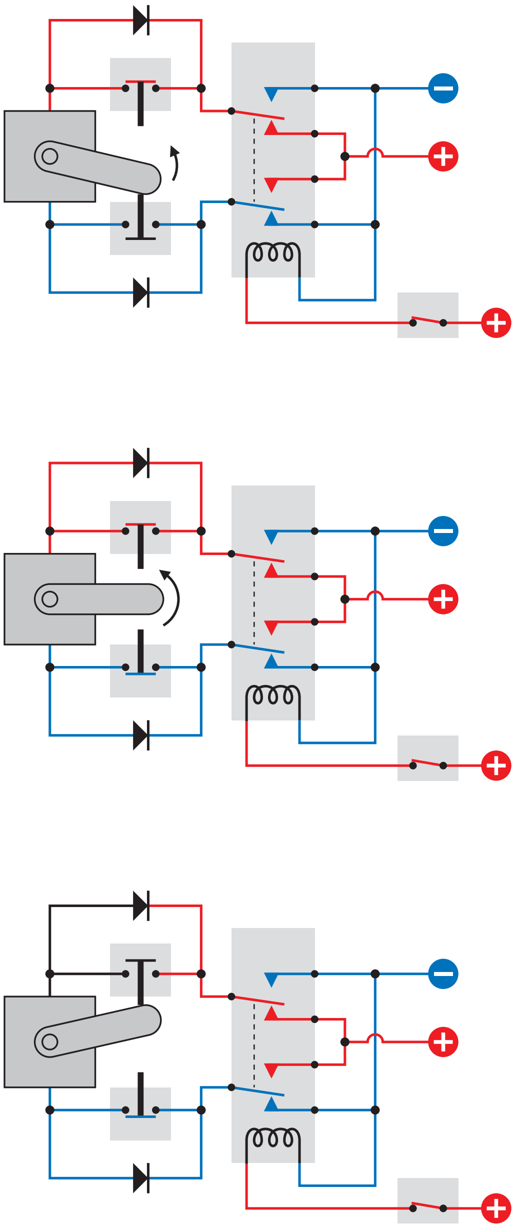

Figure 5-99. *The three diagrams, from top to bottom, show three snapshots of a motor controlled by a DPDT relay and two limit switches. When the on/off switch at bottom-right sends power to the relay, the lower relay contacts cause the motor to run counterclockwise until it stops itself as its arm opens the upper limit switch.*

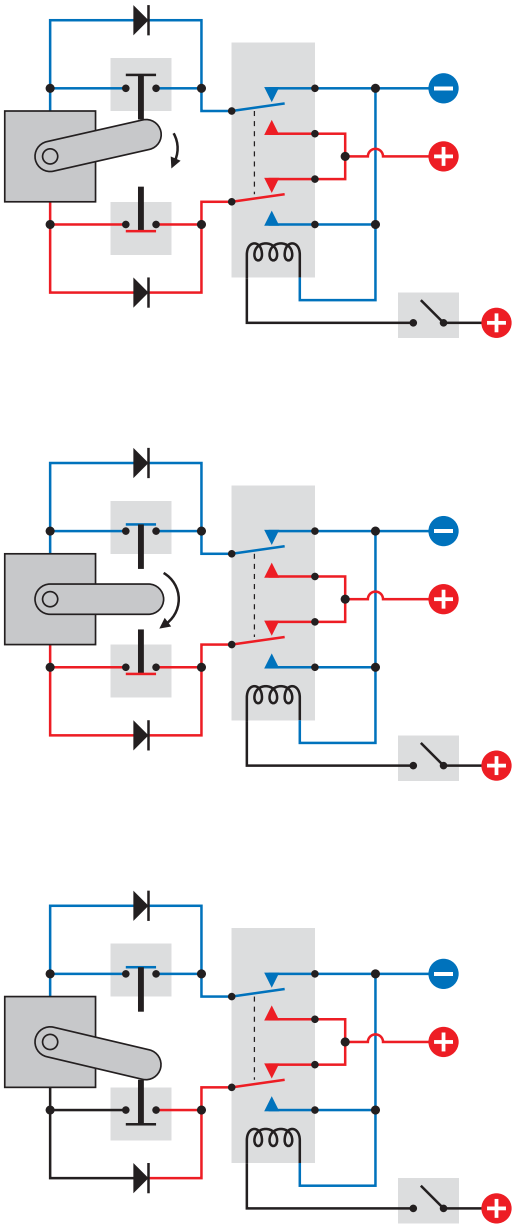

Figure 5-100. *When the on/off switch at bottom-right opens, the relay connects its upper contacts. This causes the motor to run clockwise until its arm opens the lower limit switch. Limit switches avoid the overheating and possible damage that are likely when power is delivered to a motor that is prevented from turning.*

FUNDAMENTALS

All about motors

Brushed DC motor

This is the oldest, simplest design for an electric motor, shown in very simplified form in Figure 5-101. Coils are attached to a shaft where they can interact with stationary magnets around them. The magnetic attraction turns the shaft a little, at which point the next coil on the shaft is energized to turn the shaft a little more, and then the next coil—and so on. To make this happen, electricity has to be fed into the coils by "brushes," often consisting of soft carbon pads that conduct power to a hub, known as a commutator, divided into sections, each of which is connected to a separate coil.

This basic design has several advantages if we want to build a small motorized gadget, such as a miniature robot or even a model airplane:

- Widely available
- Low cost
- Simple
- Reliable
- Will run in reverse when voltage reverses

In addition, brushed motors are often sold with reduction gearing built in. Such units are known as *gearhead motors* or *gear motors*. They free you from the need to use your own gears or belts to adjust the output speed yourself. You simply choose the motor that fits your specification.

DC stepper motor

This requires a controller, consisting of some electronics to tell the motor to rotate its shaft in small, discrete steps. The advantages of a stepper motor are:

- Precise positioning of the shaft
- Precise speed adjustment

Stepper motors are ideal for devices such as computer printers, where the paper has to roll up by a precise distance and the print head has to move laterally by an equally precise distance, but they are also useful in robots. If the motor is small enough to draw less than 200mA and will run on 12 volts or less, you can control it with pulses from a 555 timer. I'll describe stepper motors in more detail in Experiment 33.

Servo motor

This is generally used in conjunction with a programmable microcontroller, which sends instructors to rotate the motor shaft to a specific position and then hold it there. I'll mention servo motors when I introduce you to microcontrollers, but we won't be dealing with them in detail.

Other types of motors exist, including brushless DC motors (which require a different type of controller and are found in computer disk drives and CD players), and AC motors (including synchronous motors, which synchronize their rotation with the frequency of AC voltage, and were used extensively in clocks, before clocks mostly became digital).

In this book, I'll be talking mostly about brushed DC motors and DC stepper motors.

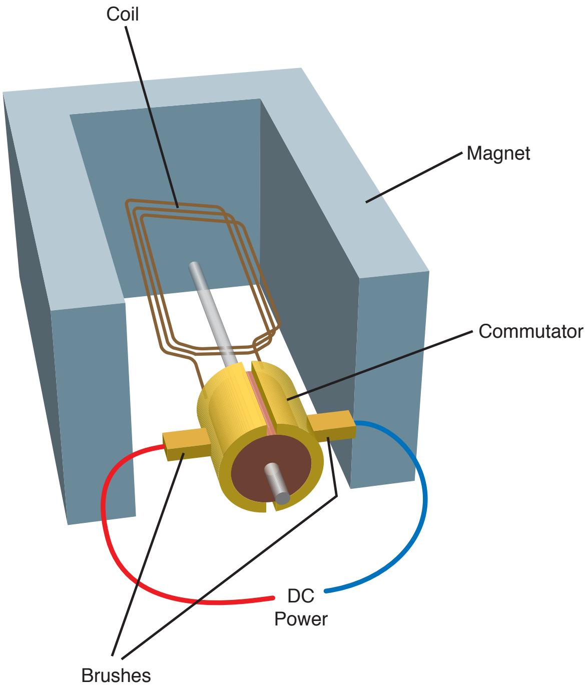

Figure 5-101. *The basic principle of a simple DC motor. The commutator passes electricity through a coil, creating a magnetic field that interacts with a magnet around the motor. The coil turns, and the commutator turns with it, until the electric field through the coil is reversed. This causes the process to repeat. In reality, a motor is likely to have a commutator formed from multiple segments, connected with multiple coils. The principle, however, remains the same.*

Take-home messages from this experiment include the following:

- You can buy simple DC motors with reduction gearing built in, providing your choice of RPM. Literally hundreds of websites will sell you small motors for robotics projects.
- When you reverse the voltage to a DC motor, the motor runs in reverse.
- A DPDT relay can be wired so that when it closes its contacts, it reverses a power supply to a motor.
- You can use two limit switches and a pair of diodes to stop a motor at two positions. In each of its stopping positions, the motor consumes no power and you won't have the risk of it burning out.

What other projects can you imagine using this simple set of techniques?

Mechanical Power

In the United States, the turning force, or torque, of a motor is usually measured in pound-feet or ounce-inches. In Europe, the metric system is used to measure torque in dynes.

A pound-foot is easy to understand. Imagine a lever pivoted at one end, as shown in Figure 5-102. If the lever is one foot long, and you hang a one-pound weight at the end of it, the turning force is one pound-foot.

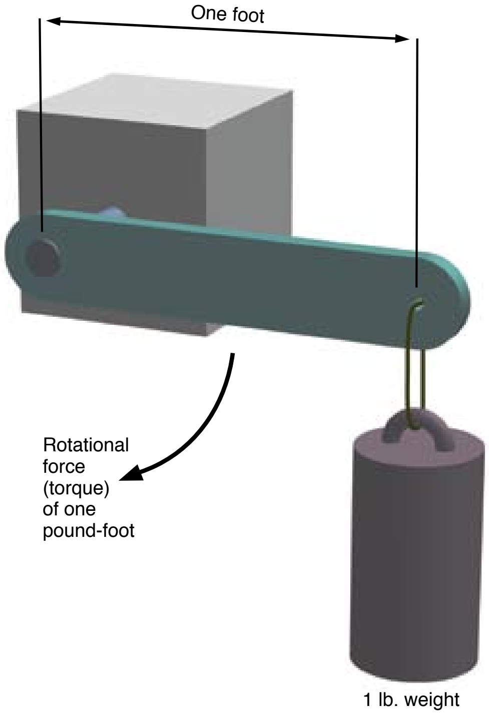

Figure 5-102. *The rotational force created by a motor is known as "torque," and in the United States it is measured in pound-feet (or ounce-inches, for small motors). In the metric system, torque is measured in dynes. Note that the torque created by a motor will vary according to the speed at which the motor is running.*

FUNDAMENTALS

Wire gauges

If you're going to power larger motors, or other components that take more current than LEDs or small relays, you really need to know about wire gauges. In particular, what's the relationship between wire thickness and AWG (American Wire Gauge)? And what gauge of wire should you use for any given current?

You can find numerous charts and tables if you go online, but many of these sources contradict each other, especially on the topic of how much current is safe to run through each gauge of wire.

After making several comparisons (and testing some wire samples myself), I've compiled the table in Figure 5-103, which I recommend as a compromise. Note the following:

- This table applies to solid-core copper wire.
- For stranded wire, or copper that has been tinned (giving it a silver appearance), the number of ohms per foot will *increase*, the number of feet per ohm will *decrease*, and the maximum amperage will *decrease*, probably by around 20%.

The maximum amperage assumes that the wire is insulated, preventing it from radiating heat as effectively as a bare conductor. I am also assuming that the wire is likely to be at least partially enclosed, inside a box or cabinet. At the amperages listed for each gauge of wire, you should expect the wire to become noticeably warm, and personally I would tend to use thicker wire instead of the maximums indicated in the table.

Most tables of this type only tell you the resistance of each gauge of wire in ohms per 1,000 feet. I have included that number but have also expressed the function the other way around, as the number of feet per ohm, as this doesn't require you to do so much arithmetic with decimals.

AWG		Diameter in inches	Ohms per 1,000 ft	Feet per ohm	Maximum amps (insulated)
0000	●	0.46	0.049	20,400	225
000	●	0.41	0.062	16,200	200

26	·	0.016	40.1	25	1.5
28	·	0.013	64.9	15	1.0
30	·	0.010	103.2	10	0.5

Figure 5-103. *American wire gauges (AWG) and their properties.*

THEORY

Calculating voltage drop

Another fact that you often need to know is how much of a voltage drop a particular length of wire will introduce in a circuit. If you want to get maximum power from a motor, you don't want to lose too much voltage in the wires that go to and from the motor.

Voltage drop is tricky, because it depends not only on the wire, but also on how heavily the circuit is loaded. Suppose that you are using 100 feet of 22-gauge wire, which has a resistance of about 1.5 ohms. If you attach it to a 12-volt battery and drive an LED and a series resistor offering a total effective resistance of about 1,200 ohms, the resistance of the wire is trivial by comparison. According to Ohm's Law:

amps = volts / ohms

so the current through the circuit is only about 10mA.

Again, by Ohm's Law:

volts = ohms × amps

so the wire with resistance of 1.5 ohms imposes a voltage drop of 1.5 × 0.01 = 0.015 volts.

Now suppose you're running a motor. The coils in the motor create impedance, rather than resistance, but still if we measure how much current is going through the circuit, we can establish its effective resistance. Suppose the current is 1 amp. Repeating the second calculation:

volts = ohms × amps

So the voltage drop in the wire is now 1.5 × 1 = 1.5 volts! This is illustrated in Figure 5-104.

Bearing these factors in mind, I have compiled a table for you. I've rounded the numbers to just two digits, as variations in the wire that you use make any pretense of greater accuracy unrealistic.

To use this table, you need to know how much current is passing through your circuit. You can calculate it (by adding up all the resistances and dividing it into the voltage that you are applying) or you can simply measure the current with a meter. Just make sure that your units are consistent (all in ohms, amps, and volts, or milliohms, milliamps, and millivolts).

In the table, I have arbitrarily assumed a length of 10 feet of wire. Naturally you will have to make allowances for the actual length of wire in your circuit. The shorter the wire, the less the loss will be. A circuit with only 5 feet of wire, and the same amperage and voltage, will suffer half of the percentage loss shown in the table. A circuit with 15 feet of wire, and the same amperage and voltage, will suffer 1.5 times the percentage loss. So, to use the table:

1. Divide your length of wire by 10. (Make sure that you measure the length in feet.)
2. Use the result to multiply the number in the table.

The table also arbitrarily assumes that you have a 12-volt supply. Again, you will have to make allowances if you are using a different voltage. So, to use the table:

1. Divide 12 by the actual voltage of your power supply.
2. Use the result to multiply the number in the table.

I can summarize those two steps like this:

Percent voltage lost = P × (12 / V) × (L / 10)

where P is the number from the table, V is your power-supply voltage, and L is the length of your wire.

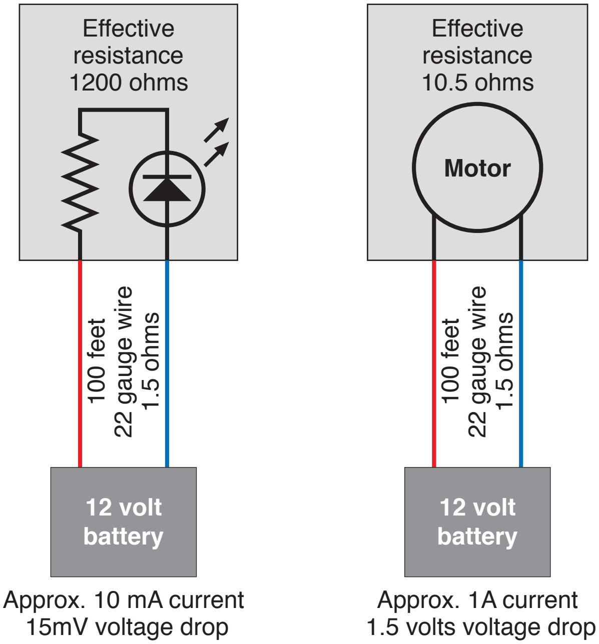

Figure 5-104. *The voltage drop imposed by wiring will depend on the current and the resistance in the circuit. The drop will be greatest when the resistance of the circuit is low and the amperage is high.*

THEORY

Calculating voltage drop (continued)

This table shows the percent voltage lost in a circuit with 10-foot wire at 12 volts.

Wire Gauge	Amperes									
	1	2	3	4	5	6	7	8	9	10
10	0.08	0.17	0.25	0.33	0.42	0.50	0.58	0.67	0.75	0.83
12	0.13	0.27	0.40	0.53	0.66	0.80	0.93	1.1	1.2	1.3
14	0.21	0.42	0.63	0.84	1.1	1.3	1.4	1.5	1.9	2.1
16	0.33	0.67	1.0	1.3	1.7	2.0	2.3	2.7	3.0	3.4
18	0.53	1.1	1.6	2.1	2.7	3.2	3.7	4.3	4.8	5.3
20	0.85	1.7	2.6	3.4	4.3	5.1	6.0	6.8	7.7	8.5
22	1.3	2.7	4.0	5.4	6.7	8.1	9.4	11	12	13
24	2.1	4.3	6.4	8.6	11	13	15	17	19	21
26	3.4	6.8	10	14	17	20	24	27	31	34
28	5.4	11	16	22	27	32	38	43	49	54
30	8.6	17	26	34	43	52	60	69	77	86

Remember, though, that the wire resistance will be higher if you are using stranded copper wire or tinned copper wire, and this will increase the percentage of voltage lost.

Experiment 33: Moving in Steps

Time now to build something more sophisticated: a cart that orients itself toward a light source. I'm going to tell you all you need to get started on this project, but this time I won't go all the way to the end in exhaustive detail. I want you to get into the habit of figuring out the details, improving on plans, and eventually inventing things for yourself.

You will need:

- 555 timers. Quantity: 8.
- Trimmer potentiometer, 2K linear. Quantity: 2.
- LEDs. Quantity: 4. If you get tired of using series resistors to protect LEDs in a 12-volt circuit, consider buying 12-volt LEDs such as Chicago Miniature 606-4302H1-12V, which contain their own resistors built in. However, the schematic in Figure 5-108 assumes that you will use regular 2V or 2.5V LEDs.
- Stepper motor: Unipolar, four-phase, 12-volt. Parallax 27964 or similar, consuming 100mA maximum. Quantity: 2.
- Photoresistors, ideally 500 to 3,000Ω range. Quantity: 2.

- ULN2001A or ULN2003A Darlington arrays by STMicroelectronics. Quantity: 2.
- CMOS octal or decade counter. Quantity: 2.
- Various resistors and capacitors.

Exploring Your Motor

I've specified a unipolar, four-phase, 12-volt motor because this is a very common type. A typical sample is shown in Figure 5-105. If you can't easily find the one that I've listed, you should feel safe in buying any other that has the same generic description. "Unipolar" means that you don't have to switch the power supply from positive to negative and back to positive again, to run the motor. Four-phase means that the pulses that run the motor must be applied in sequence to four separate wires. Because you will be running your motor directly from 555 timers, the lower its power consumption, the better.

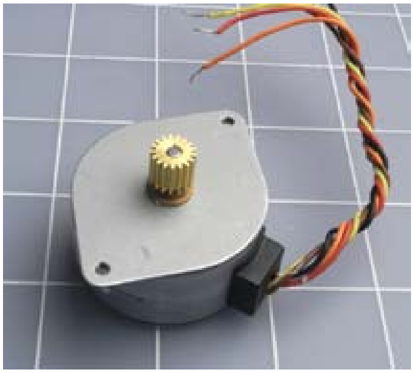

Figure 5-105. *A typical stepper motor. The shaft rotates in steps when negative pulses are applied to four of the wires in sequence, the fifth wire being common-positive.*

First, though, we can apply voltage to the motor without using any other components at all. Most likely it will have five wires already attached, with the ends stripped and tinned, so that you can easily insert them into holes in a breadboard, as shown in Figure 5-106. Check the data sheet for your motor; you should find that four of the wires are used to energize the motor and turn it in steps, while the fifth is the common connection. In many cases, the common connection should be hooked to the positive side of your power supply, while you apply negative voltage to the other four wires in sequence, one step at a time.

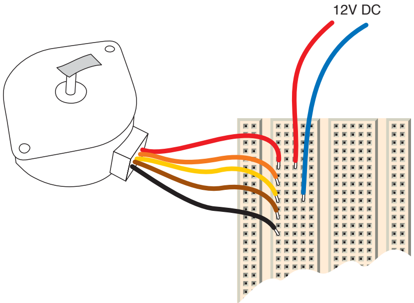

Figure 5-106. *The simplest test of a stepper motor is to apply voltage manually to each of its four control wires, while a piece of duct tape, attached to the output shaft, makes it easy to see how the motor responds.*

The data sheet will tell you in what sequence to apply power to the wires. You can figure this out by trial and error if necessary. One thing to bear in mind: a stepper motor is very tolerant. As long as you apply the correct voltage to it, you can't burn it out.

To see exactly what the motor is doing, stick a piece of duct tape to the end of the shaft. Then apply voltage to wires, one at a time, by moving your negative power connection from one to the next. You should see the shaft turning in little steps.

Inside the motor are coils and magnets, but they function differently from those in a DC motor. You can begin by imagining the configuration as being like the diagram in Figure 5-107. Each time you apply voltage to a different coil, the black quadrant of the shaft turns to face that coil. In reality, of course, the motor turns less than 90° from one coil to the next, but this simplified model is a good way to get a rough idea of what's happening. For a more precise explanation, see the upcoming section "Theory: Inside a stepper motor."

Bear in mind that as long as any of the wires of the motor are connected, it is constantly drawing power, even while sitting and doing nothing. Unlike a regular DC motor, a stepper motor is designed to do nothing for much of the time. When you apply voltage to a different wire, it steps to that position and then resumes doing nothing.

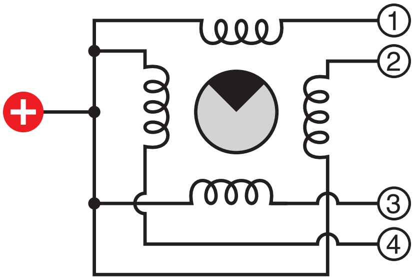

Figure 5-107. *This greatly simplified diagram helps in visualizing the way in which a stepper motor works. In reality, almost all motors rotate by less than 90° in response to each pulse.*

The coil inside the motor is holding the shaft in position, and the power that the motor draws will be dissipated as heat. It's quite normal for the motor to get warm while you're using it. The trouble is, if you use a battery to power it, and you forget that you have it connected, the battery will not hold its charge for long.

Quick Demo

Now that you've proved that your motor is functional, how can you actually run it? You need to send a pulse to each of the four wires in turn, in a rapidly repeating sequence. If you can also adjust the speed of the pulses, so much the better. I'm thinking that for a quick and simple demo, you can handle the challenge simply by using four 555 timers, all of them in monostable mode, with each one triggering the next.

The schematic in Figure 5-108 shows what I have in mind. It looks more complex than it really is. Each timer has the same pattern of components around it, so after you create the first module, you just make three copies of it.

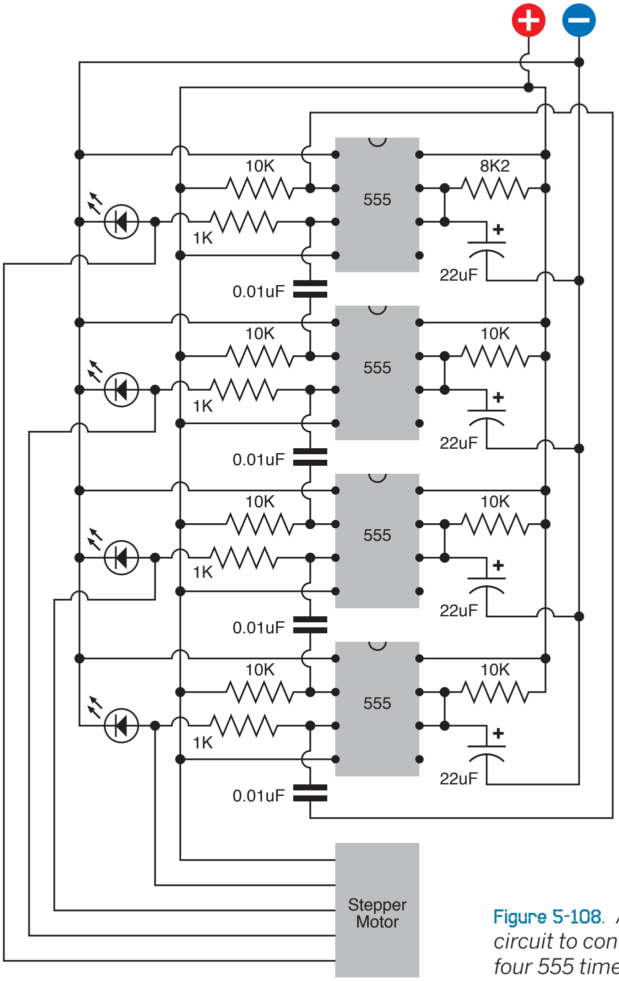

Figure 5-108. *A very quick and simple circuit to control a stepper motor uses four 555 timers, each in monostable mode, triggering each other in a repeating sequence.*

I've used a 10K resistor to pull up the input to each 555, so that the timers are naturally in their quiescent state. A 0.01 µF capacitor links the output from one timer to the input of the next so that they are electrically isolated from each other, and the capacitor just conveys a "spike" of voltage when one timer finishes its "on" cycle, and its output goes low, which triggers the next.

On the righthand side, I've used 10K resistors and 22 µF capacitors to generate a cycle of about a quarter of a second—except that the topmost timer has a 8K2 timing resistor. The reason for this is that when power is first applied, the timers will all be waiting for each other to begin, and timers 2 and 4 or 1 and 3 may fire together. By giving one timer a shorter cycle than the others, I minimize this problem.

The LEDs are included just to give you some visual verification of what's happening. Without them, if you make a wiring error, the motor may turn to and fro erratically, and you won't know why. Initially you can run your circuit with only the LEDs connected, just to make sure it works. Figure 5-109 shows the breadboarded circuit before the motor is plugged in. Then add the motor by plugging its wires into the breadboard, where you'll make connection with the outputs (pins 3) of the timers. See Figure 5-110.

Apply power, and you should see the motor turning in steps, in sequence with the LEDs. If the LED sequence isn't stable:

1. Connect a wire directly from the input (pin 2) of the topmost timer to the positive side of the voltage supply, and wait for the timers to calm down.
2. Restart the sequence by disconnecting the free end of this wire, or (if necessary) touch the free end of it briefly to the negative side of the supply, to trigger the first timer.

One thing you may have noticed, if you're paying very close attention: the common terminal of the motor is connected to positive. Therefore, when each timer flashes positive, that positive signal isn't actually powering the motor. The *low* outputs from the three timers that are *not* firing at any given moment are sinking current from the motor. It seems quite happy with this arrangement. You'll need some theory to understand why.

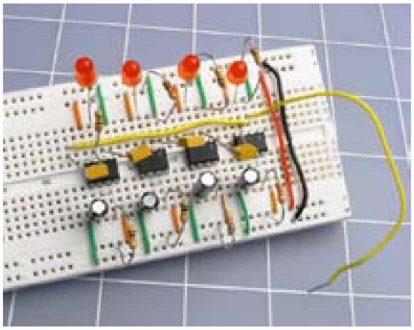

Figure 5-109. *To test the control circuit for errors, four LEDs show the outputs from the four 555 timers. The loose yellow wire at the righthand side connects to pin 2 of the first timer. Touch the free end of this wire to the positive side of the power supply to reset the timers, and then, if necessary, make a brief negative connection with the free end of the wire to restart their sequence.*

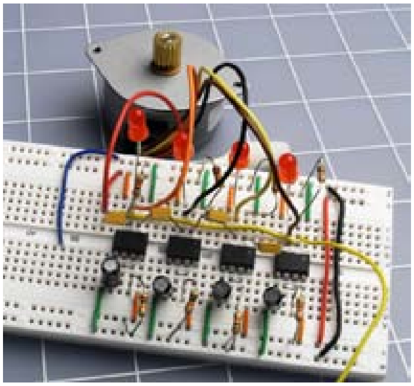

Figure 5-110. *After the circuit has been tested, the motor can be added by hooking its control wires to the outputs of the four 555 timers.*

THEORY

Inside a stepper motor

If you check the Wikipedia entry for stepper motors, you may see a very nice 3D rendering showing a toothed rotor and four coils arrayed around it. Maybe stepper motors used to be manufactured like this once upon a time, but not anymore.

Imagine two horizontal rows of coils. In the space between them is a series of little magnets, like a freight train, that can move left or right, as shown in Figures 5-111 and 5-112. Each coil has two windings, in opposite directions, so that current through one winding will create an upward magnetic force while current through the other will create a downward force. Each row of windings is connected in parallel, so that they switch on and off simultaneously.

In Step 1, the negative connection energizes the upper windings of the upper coils, which creates an upward magnetic force. I've shown this force using blue-green arrows so that you won't mistake it for a flow of electricity. It so happens that this force attracts the north poles of the magnets and repels the south poles, so if the magnets begin in the position shown in Step 1, they will want to move one step to the right.

This brings them to the position shown in Step 2. Now the upper windings of the lower coils are energized, and again, this produces an upward force, which again attracts the north poles and repels the south poles.

This advances the magnets to their location in Step 3. Now the lower windings of the upper coils are energized, producing a downward force. This repels the north poles of the magnets and attracts their south poles. So the magnets keep moving.

They reach the position shown in Step 4. The lower windings of the lower coils are energized, producing a downward force which continues to attract the south poles while repelling the north poles. So the magnets move a final step to the right—which leaves them in the same orientation shown in Step 1. And the process can repeat all over again.

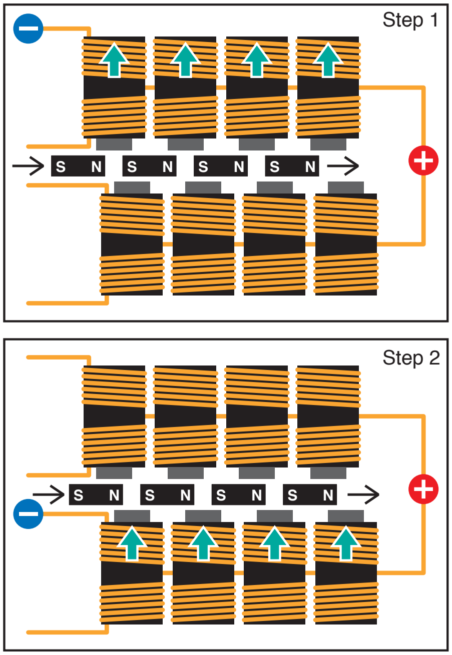

Figure 5-111. *This sequence shows the first two steps as the rotor of a stepper motor (shown as a series of north-south magnets) moves in response to pulses through electromagnets.*

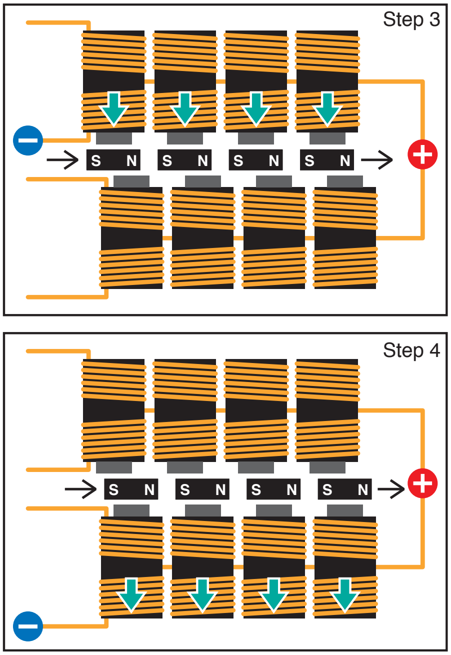

Figure 5-112. *After taking another two steps, the motor will be back where it started at Step 1 in Figure 5-111.*

THEORY

Inside a stepper motor (continued)

In reality, the magnets are not separate from each other. The edge of a rotor is magnetized in zones that alternate between south and north polarity. And instead of multiple coils, there are just four windings that go around all the magnetic cores. But the principle is exactly the same. The 3D rendering gives a general idea, and the photograph shows what I found when I cracked open a typical stepper motor.

Now bear in mind that when this device is driven by a set of 555 timers, we don't just connect negative to one wire at a time on the left, leaving the others floating. In reality, at any given moment, three of the timers have a negative output and the fourth has a positive output. The last diagram in Figure 5-112 shows this situation.

Suppose the top wire is positive while the other three are negative, as shown in Figure 5-113. The positive output does nothing, because it is balanced by the positive power on the other end of the coils. The two negatives attached to the bottom set of coils create equal and opposite forces that cancel each other out (while wasting some power). So the net result is the same as in Step 3.

In fact, you should find that you can disconnect the common wire completely while using the stepper motor with 555 timers, and the motor will still turn, because one of the timers is providing positive power while the others are negative. In fact, you'll be running them more efficiently this way.

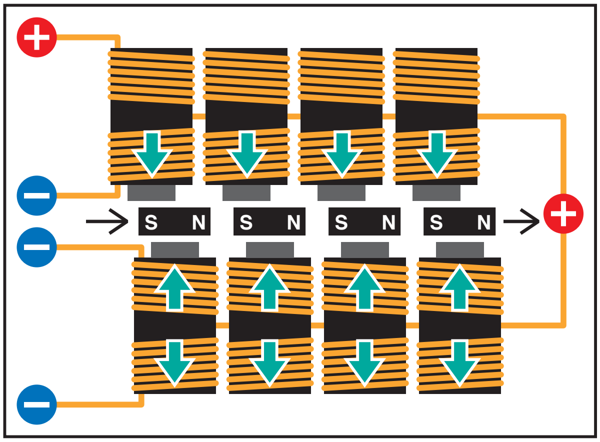

Figure 5-113. *When the motor is driven by four 555 timers, they are activating it by sinking positive voltage from it. The interior workings of the motor look something like this. It's not the most efficient way to do the job.*

Figures 5-114 and 5-115 may help to give you a clearer idea of what the motor actually looks like inside.

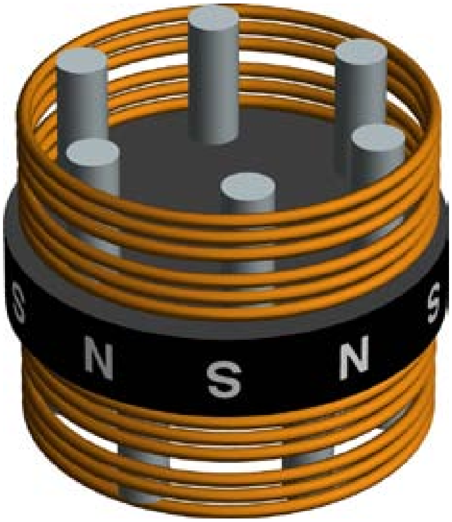

Figure 5-114. *This 3D rendering gives a better idea of what a typical stepper motor looks like inside. The copper coils and gray cylinders are stationary, while the black disc rotates between them.*

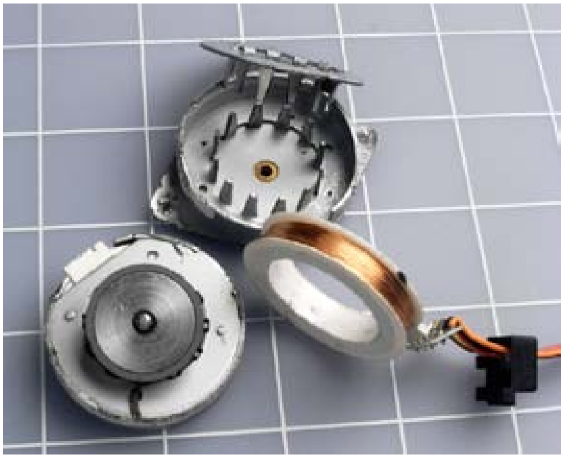

Figure 5-115. *When a stepper motor is broken open, this is what you're likely to find. On the left, the rotor of the motor, which has a magnetized band around its circumference, is still attached to the lower half of the casing. On the right, the upper half of the casing has been opened, and the coil has been removed (actually the winding you can see consists of two coils, wound in opposite directions). The spikes are the magnetic cores that exert force on the rotor.*

Speed Control

If you are a truly exceptionally observant, you may have noticed that I left pin 5 of each of the timers unconnected in the schematic for driving the stepper motor in Figure 5-108. Normally, pin 5 should be grounded through a capacitor to prevent it from picking up stray voltages which can affect the accuracy of the chip.

I left the pins unconnected because I had a plan for them. In fact, changing the timing of the chip is exactly what we want to do now, as a way to change the speed of the stepper motor.

If you tie pin 5 of all four timers together, as shown in Figure 5-116, and put a 2K trimmer potentiometer (shown in Figure 5-117) between them and the negative side of the power supply, you'll find that as you turn the trimmer to reduce its resistance, the timers start to run faster. Figure 5-118 shows the breadboard layout. Eventually, when the resistance goes below around 150 ohms, everything stops. The LEDs go dark, because you've reduced the voltage on pin 5 below the threshold level that the 555 timer finds acceptable.

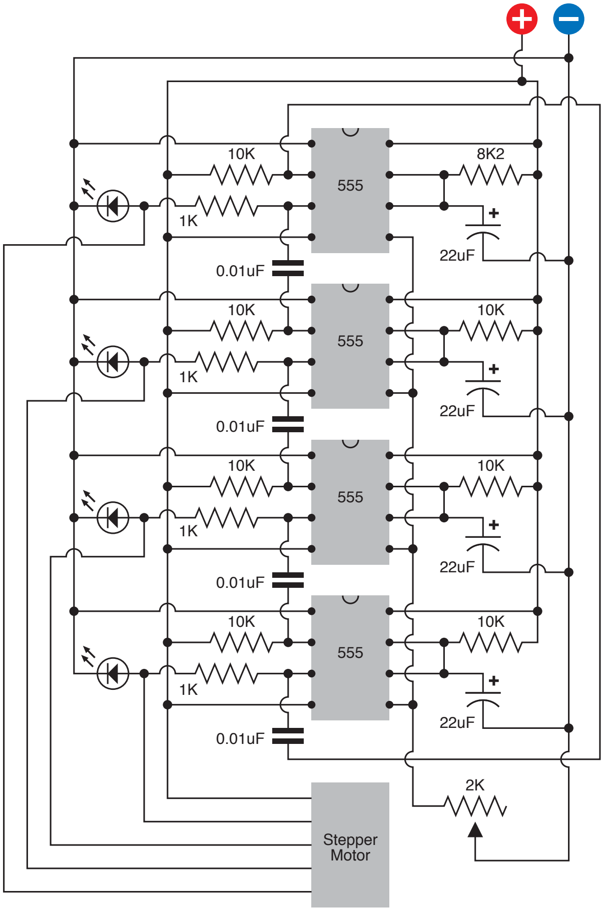

Figure 5-116. *To adjust the speed of the sequence of 555 timers, their control pins (pin 5 on each timer) are linked together and attached to a trimmer potentiometer that adjusts the resistance between the pins and the negative side of the power supply.*

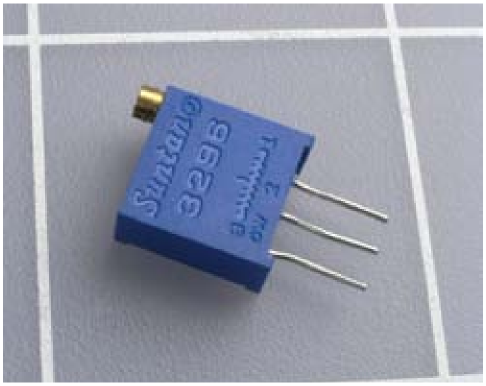

Figure 5-117. *Close-up of a trimmer potentiometer with pins spaced at 1/10 inch for insertion in a breadboard or perforated board. The brass screw, at top-left, turns a worm gear inside the unit, allowing precise adjustment of internal resistance.*

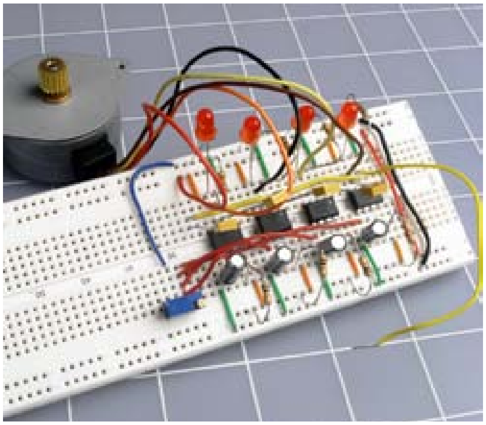

Figure 5-118. *The trimmer potentiometer has been added to the circuit, allowing motor speed control.*

Initially I suggested a step time of 1/4 second just so that you could see what was happening. When you're actually using this circuit, you'll never need it to run as slowly as that. So you can increase the entire range of speeds. Remove the 22 µF timing capacitors and substitute, say, 4.7 µF capacitors, or smaller. Now when you adjust the potentiometer, you'll get a useful range of speed.

Adding Autonomy

Currently, the circuit simply does what you tell it to do. The next step is to make it autonomous—in other words, give it the illusion of making up its own mind. I'm thinking that instead of a trimmer potentiometer, we could substitute a photocell, properly known as a photoresistor. Typically, the resistance of a cadmium sulfide photo resistor is highest in the dark, and lowest when light shines on it.

One problem with photoresistors is that they're not as widely available as many other types of electronic components. If you search Mouser.com, for instance, you'll find virtually nothing. Partly this is because the online search function at Mouser is the weakest feature of the site, and partly it's because Mouser is not oriented toward hobbyists. What you need to do is conduct a "product search." Go to *http://www.google.com/products*, enter the search terms "CdS" and "photocell," and you'll find a bunch of cheap cadmium sulfide components from places you may never have heard of.

Because photoresistors seem to come and go as erratically as DC motors, I am not offering any part numbers. You can buy any product that has an appropriate minimum resistance (in bright light) and maximum resistance (in the dark). If you find a component that ranges from 500 to 3,000Ω, that would be a good choice. If the only ones you can find have a higher minimum than 500Ω, you could consider putting a couple of them in parallel.

Setting Up Your Light Seeking Robot

Why would you want to control the speed of a stepper motor by using a photo resistor? Because the original objective was to build a robot that is attracted to light.

The idea is simple enough: use two stepper motors, each controlling the speed of one wheel of the cart. Use two photoresistors, each controlling the speed of the opposite stepper motor. When the righthand photoresistor picks up more light, its resistance lowers, causing the lefthand set of timers to run faster, which will make the lefthand wheel run faster. Thus, the cart will turn toward the light. Figure 5-119 illustrates the concept.

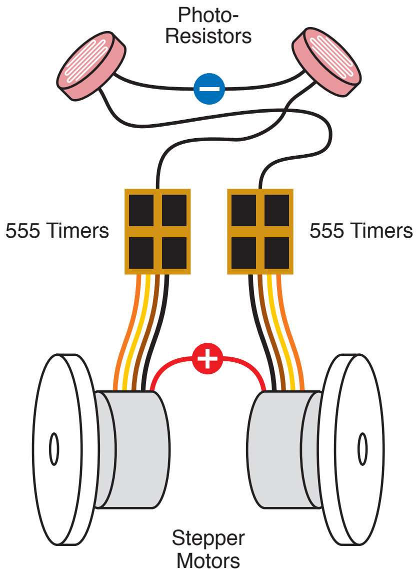

Figure 5-119. *If two photoresistors control the speed of two 555-timer arrays, the difference in speed between one wheel and the other can turn the cart toward a light source.*

Before you start wiring more 555 timers, though, you might consider doing the job with a more appropriate component. The ULN2001A and ULN2003A are chips containing Darlington amplifiers specifically designed to deliver current to inductive loads such as solenoids, relays, and (you guessed it) motors. Each chip has seven inputs that require very little current, and seven outputs that can deliver 500mA each. The inputs are TTL and CMOS compatible (the 2001A has a wider tolerance for voltages than the 2003A) and each channel of the chip functions as an inverter, so that when the input goes high, the output goes low and sinks current. This is of course just what we need for our stepper motor that has a common positive connection.

The ULN2001A is only an amplification device, so you have to precede it with a counter that runs from 1 to 4 and then repeats. You can stick with your 555 timers, as you've already assembled them, or substitute almost any CMOS octal or decade counter that sends its output pulses to a series of pins. Just use the output from the fifth pin as the "carry" output to restart the counting sequence. I suggest a CMOS counter simply because it will run on 12 volts, so you can use the same power supply that suits your stepper motors.

If you switch to CMOS counters, you will still need a pair of 555 timers sending pulses to the counters. The timers will be free-running in astable mode, and your photoresistors will control their speed. Figure 5-120 shows the configuration.

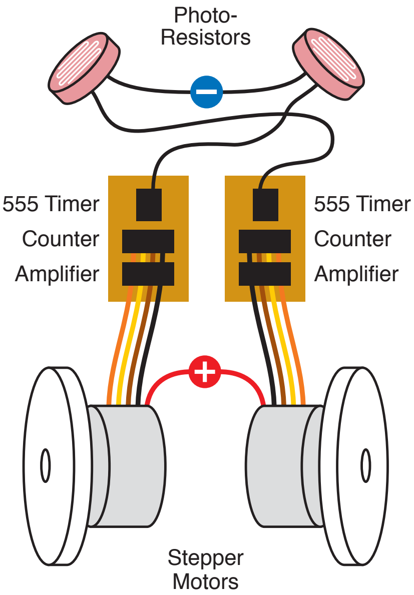

Figure 5-120. *A more efficient way to drive the motors is to use just one timer to set the speed of each, with a counter and amplifier (such as a Darlington array chip) sending the pulses down the wires. The principle is still the same, though.*

One last item: you'll need a 12-volt battery. You can of course put eight AA cells together, but I think you should consider a rechargeable pack from a source such as *http://www.all-battery.com*, which has a section entirely devoted to "robot batteries."

If you put it all together, you should find that when you place your robot cart in a very dimly lit room, it will turn toward the beam from a bright, well-focused flashlight. To get reliable results, you may have to recess each of the photoresistors in little tubes, so that they receive much more light when they face your flashlight than when they face away from it. Figure 5-121 is a 3D rendering of the concept.

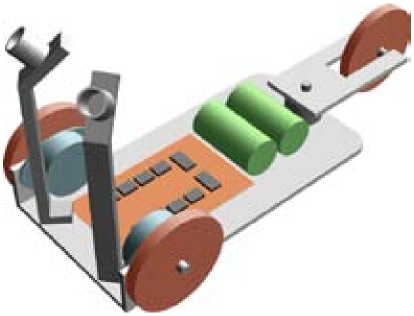

Figure 5-121. *This 3D rendering shows a possible configuration of the light-seeking cart, with two photoresistors enclosed in small tubes to restrict their response to light.*

Another idea is to rewire your cart so that it actually runs away from the light. Can you imagine how this might be done?

Just one more thought: if you use infrared photoresistors, you can control your cart with beams from infrared LEDs, in normal room lighting. If you and a couple of friends all have infrared transmitters, you can get your cart to run from one of you to the next, like an obedient dog.

This takes us about as far as I'm going to go into robotics. I urge you to check out the sites online if you want to pursue the topic further. You can also buy a wide variety of robot kits, although of course I feel that it's more fun to invent or develop things for yourself.

All that's left now is to perform one last introduction: to a device that should make your life much easier, even though the device is much more complicated than anything we have dealt with so far.

Experiment 34: Hardware Meets Software

Throughout this book, in accordance with the goal of *learning by discovery*, I have asked you to do an experiment first, after which I've suggested the general principles and ideas that we can learn from it. I now have to change that policy, because the next experiment involves so much setup that it's only fair to tell you what to expect before you begin the preparations.

We are about to enter the realm of controller chips, often known as MCUs, which is an acronym for micro controller unit. An MCU contains some flash memory, which stores a program that you write yourself. The flash memory is like the memory in a portable media player, or the memory card that you use in a digital camera. It needs no electricity to power it. In addition, the chip has a processor which carries out the instructions in your program. It has RAM to store the values of variables on a temporary basis, and ROM, which tells it how to perform tasks such as sensing a varying voltage input and converting it into digital form for internal use. It also contains an accurate oscillator, so that it can keep track of time. Put it all together, and it's a tiny computer that you can buy for under $5.

Let's suppose that you have a greenhouse where the temperature must never fall below freezing. You set up a temperature sensor, and you have two different heaters. You want to switch on the first heater if the temperature falls below 38° Fahrenheit. But if, for some reason, that heater is broken, you want to switch on the second, backup heater when the temperature goes below 36° Fahrenheit.

Programming a MCU to take care of this can be very simple indeed. You could even add extra features, such as a second temperature sensor, just in case the first one fails, and you could tell the chip to use whichever sensor gives a lower reading.

Another application for a MCU would be in a fairly elaborate security system. The chip could monitor the status of various intrusion sensors, and can take various preprogrammed steps, depending on the sensors' status. You could include delay intervals, too.

Many MCUs have additional useful features built in, such as the ability to control servo motors that turn to a specific angle in response to a stream of pulses. Servos are widely used in radio-controlled model boats, airplanes, and hobby robotics.

Perhaps you are now wondering why, if MCUs can do all this, haven't we been using them all along? Why did I spend so much time describing the development of an alarm system using discrete components, if one chip could have done everything?

There are three answers:

1. MCUs cannot do everything. They need other components to help them interact with the world, such as transistors, relays, sensors, and amplifiers. You need to know how those things work, so that you can make intelligent use of them.
2. MCUs can introduce their own kinds of problems and errors, associated with using software in addition to hardware. I'll have more to say about this later.
3. MCUs have limits and restrictions, most obviously their requirement for a 5-volt regulated power supply, and their inability to source or sink much current from each pin. They also demand that you learn a programming language (which differs from one brand of MCU to the next). And to get the program into the chip, you have to be able to plug it into a computer and do a download, which is not always convenient.

In this experiment, you'll learn how to write a program for a small and simple MCU, and you'll transfer the program into it and see how it works.

BACKGROUND

Origins of programmable chips

In factories and laboratories, many procedures are repetitive. A flow sensor may have to control a heating element. A motion sensor may have to adjust the speed of a motor. Microcontrollers are perfect for this kind of routine task.

A company named General Instrument introduced an early line of MCUs in 1976, and called them PICs, meaning Programmable Intelligent Computer—or Programmable Interface Controller, depending which source you believe. General Instrument sold the brand to another company named Microchip Technology, which owns it today.

"PIC" is trademarked, but is sometimes used as if it's a generic term, like Scotch tape. In this book, I've chosen a range of controllers based on the PIC architecture. They are licensed by a British company named Revolution Education Ltd., which calls its range of chips the PICAXE, for no apparent logical reason other than that it sounds cool.

I like these microcontrollers because they were developed originally as an educational tool and because they are very easy to use. They're cheap, and some of them are quite powerful. Despite their odd name, I think they're the best way to get acquainted with the core concepts of MCUs.

After you play with the PICAXE, if you want to go farther into MCUs, I suggest the BASIC Stamp (which uses a very similar language, but with additional powerful commands) and the very popular Arduino (which is a more recent design, packed with powerful features, but requires you to learn a variant of C language to program it). I'll say more about these chips later.

If you search for "picaxe" on Wikipedia, you'll find an excellent introduction to all the various features. In fact, I think it's a clearer overview than you'll get from the PICAXE website.

Supplies

Figure 5-122 shows some of the chips in the PICAXE range. I'll be telling you how to use the smallest—the 08M—which costs less than $5 and is cheaper than any other MCU that I've found. It has only 256 bytes of memory to store a program (not gigabytes, megabytes, or kilobytes, just 256 bytes!), but you'll be surprised how many possibilities this amount allows for. Figure 5-123 shows a closeup of the 08M with its legs safely embedded in a piece of conductive foam.

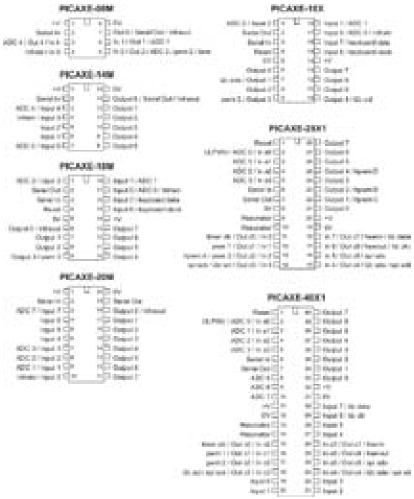

Figure 5-122. *A page from the PICAXE catalog lists only some of the chips that are available. What began as an educational aid has become a useful prototyping tool.*

In the United States, there are three distributors of this chip:

- *http://www.advancedmicrocircuits.com*
- *http://www.phanderson.com/picaxe*
- *http://www.sparkfun.com*

I like P. H. Anderson for its grass-roots hobbyist approach, and they have good prices if you want to buy multiple chips. But SparkFun Electronics offers other associated products that you may find interesting.

All the distributors will want to sell you "starter kits," such as the one in Figure 5-124, perhaps because the PICAXE itself is so cheap that it doesn't offer much of a profit margin. Still, for our purposes, you should buy the chip as a standalone item. And buy two of them, just in case you damage one (for example, by connecting voltage to it incorrectly).

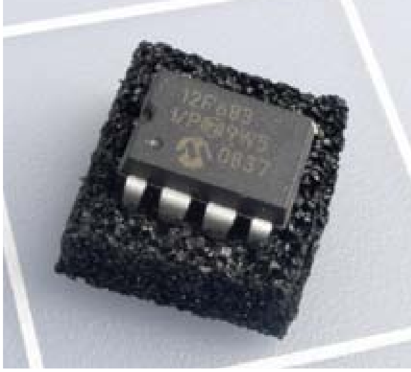

Figure 5-123. *When supplied by one of its American distributors, a PICAXE 08M arrives embedded in a little square of conductive foam. The chip is the same size as a 555 timer but has the power of a tiny computer.*

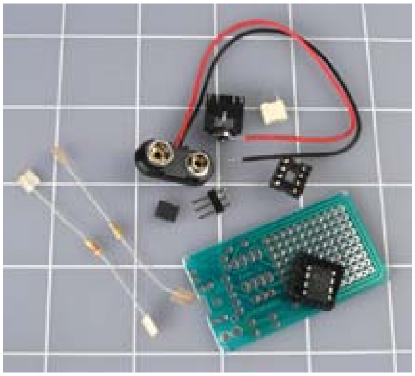

Figure 5-124. *A typical PICAXE kit includes a printed circuit board, which you may not really need, and some other not-entirely-essential items. But the 3.5-mm stereo jack socket (top, center) is absolutely necessary.*

To download your programming instructions into the chip, first you'll type the instructions on a computer, and then you'll feed them through a cable into the PICAXE memory. So you'll need to buy a cable, and you'll need software to help you to write the program.

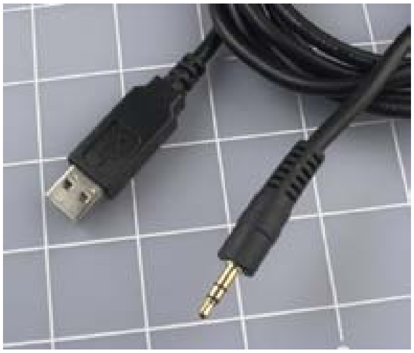

Figure 5-125. *The USB download cable made for use with the PICAXE terminates in a 3.5-mm audio plug. This should not be inserted in any audio device. It establishes a serial connection with a computer, allowing program code to be downloaded into the chip.*

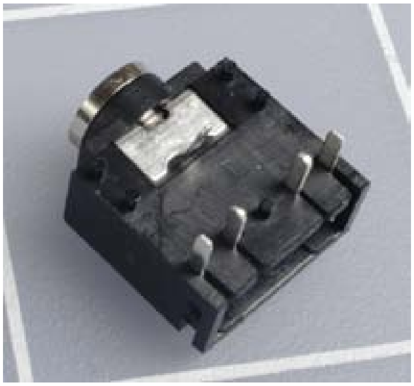

Figure 5-126. *Closeup of the 3.5-mm stereo socket that is used with the USB download cable.*

You can use the PICAXE with a serial cable, but I don't recommend it. The old RS-232 serial communications standard on PCs is pretty much obsolete, and PICAXE has recognized this by offering a USB cable (which contains a serial converter inside its plug). The USB cable is a little more expensive, but is also simpler and compatible with Apple computers. From any of the U.S. distributors, buy USB cable part AXE027, also sold as part PGM-08312 by *http://www.sparkfun.com* (quantity: 1). The cable is shown in Figure 5-125.

To write your software and send it down the wire to the chip, the PICAXE Programming Editor is the tool of choice. It comes in only a Windows version. For those who prefer Mac OS or Linux, you can get a free download of another piece of software known as AXEpad, which has fewer features, but will do the job. All the downloadable software is freely available from *http://www.rev-ed.co.uk/picaxe/software.htm*.

Finally, you need a 3.5-mm stereo audio socket with solder connections. The reason for this is that the manufacturers of the PICAXE have used a stereo audio plug on the free end of their USB cable, and you have to be able to plug it into something. The PICAXE breadboard adapter, SparkFun stock number DEV-08331, contains the necessary stereo socket in addition to a few other little items. Quantity: 1. See Figure 5-126.

Oddly enough, the USB cable is the most expensive item on the list, because of the electronics hidden inside it.

Software Installation and Setup

Now you have to go through a setup procedure. There is no way around this. Here is what you will be doing:

1. Install a driver so that your computer will recognize the special USB cable.
2. Install the Programming Editor software (or AXEpad for Mac/Linux) so that your computer will help you to write programs and then download them into the chip.
3. Mount the PICAXE on your breadboard and add the socket to receive downloads.

These steps are explained in the following sections.

The USB driver

Fair warning: If you go to the PICAXE website and try to use its search function, it probably won't find what you want. Search for "USB Driver," for instance, and it will pretend it has never heard of such a thing.

The PICAXE home page also has irritating drop-down menus that tend to disappear just when you're about to click on them, but at the time of writing, you can bypass these issues by going straight to the Software Downloads section at *http://www.rev-ed.co.uk/picaxe/software.htm*.

Scroll down past all the software until you get to Additional Resources. Look for the AXE027 PICAXE USB Download Cable. At first glance, it looks as if they want to sell you a cable, but in fact this is the list of drivers. Double-click the one appropriate to your computer, and choose a destination on your computer for the download—a place where you will find it easily, such as your desktop.

Be careful not to download the driver for the USB010 USB-Serial adapter by mistake. The USB-Serial adapter is something else entirely.

The download will leave you with a zipped file folder. You will have to unzip it. On Windows XP, right-click the folder and choose "Extract all." View the extracted files and you will find a PDF installation guide. Linux and Mac users can find instructions currently stashed at *http://www.rev-ed.co.uk/docs/AXE027.pdf*.

When installing the driver on a Windows platform, here are a few tips to minimize your exasperation level:

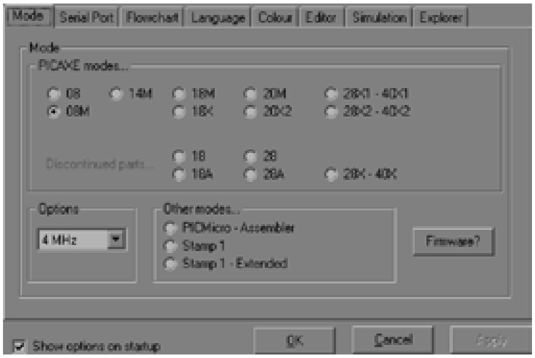
1. Remember, the special USB cable contains some electronics. It is not just a cable, but a device designed for interacting with a PICAXE chip. *Don't try to use it for anything else!*
2. You have to plug the cable into a USB port *before* you install the driver, because your computer will need to verify that the driver matches the cable.
3. You must not attach the PICAXE to the other end of the cable until *after* you have installed the driver.
4. Every USB port on your computer has a separate identity. Whichever one you choose when you first plug in the cable, you should use that port *every time in the future*. Otherwise, you will have to repeat the process of telling your computer what the cable is.
5. Bearing in mind Tip #4, you should avoid using the cable in a standalone USB hub.
6. The cable is fooling the PICAXE into thinking that it's talking to a serial port on your computer. Those "communication" ports are known as COM1, COM2, COM3, or COM4. When you install the driver, the installer will choose one of those COM ports for you, and later you will have to know which one it is. The PDF guide should help you through this procedure. Unfortunately, you cannot skip it.

The Programming Editor software

If you have come this far, you're ready for the next big step, which is much easier. You need the PICAXE Programming Editor, available for free on the Software Downloads web page where you found the USB driver. (If you are using a Mac or Linux, you will need AXEpad, which is on the same web page.)

Downloading and installing the Programming Editor should be simple and painless. Once you have done that, you should find that it has placed a shortcut on your desktop. Double-click it, go to View→Options, and in the window that opens (shown in Figure 5-127), click the Serial Port tab. You should see a dialog box like the one in Figure 5-128. Now make sure that the Programming Editor is looking at the same COM port that was chosen by the USB driver. Otherwise, the Programming Editor won't know where to find your PICAXE chip.

In the Programming Editor, go to View→Options and click the Mode tab, then click the button to select the 08M chip.



Mode

PICAXE modes...

○ 08 ○ 14M ○ 18M ○ 20M ○ 28X1 - 40X1

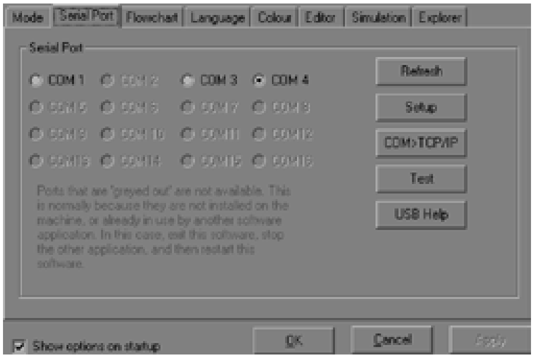
○ Stamp 1 - Extended

☑ Show options on startup

Figure 5-127. *This screenshot shows the options window of the PICAXE Program Editor, which you must use to select the type of chip that you intend to program (in our case, the 08M).*



Serial Port

○ COM 1 ○ COM 2 ○ COM 3 ● COM 4
○ COM 5 ○ COM 6 ○ COM 7 ○ COM 8
○ COM 9 ○ COM 10 ○ COM11 ○ COM12
○ COM13 ○ COM14 ○ COM15 ○ COM16

Ports that are 'greyed out' are not available. This is normally because they are not installed on the machine, or already in use by another software application. In this case, exit this software, stop the other application, and then restart this software.

☑ Show options on startup

Figure 5-128. *Another screenshot of the options window shows the second essential choice that you must make: selection of the COM port that the installer chose on your computer.*

Are we having fun yet? Obviously not, but you're through with software hassles for the time being. The last step before you're ready to use the PICAXE is to mount it, and its socket, on your breadboard.

Setting up the hardware

The PICAXE 08M looks like a 555 timer. (Other chips in the PICAXE range have more pins and more features.) It requires a properly regulated 5 volts, just like the logic chips you dealt with previously. In fact, the PICAXE people are rather emphatic about protecting it from voltage spikes. They want you to use two capacitors (one 100 µF, one 0.1 µF) on either side of an LM7805 regulator. This seems like overkill, but the PICAXE is more inconvenient to replace than a 555 timer. You certainly can't run down to RadioShack to buy one. So let's do what the manufacturer says, just in case, and set up a breadboard as shown in Figures 5-129 and 5-130.

Now for the chip itself. Note that the pins for positive and negative power are *exactly opposite* to those for the 555 timer, so be careful!

Set up your breadboard following the schematic shown in Figure 5-131. Note that I am showing the stereo socket on its underside, because I think that's how you'll have to use it with the breadboard. If you try to stick its pins into the holes in the board, they will fit, but when you insert the plug into the socket, the thickness of the plug will tend to raise the socket up so that it loses contact. I really think the way to go is to solder wires to the pins on the socket and push the wires into the breadboard. See Figure 5-133.

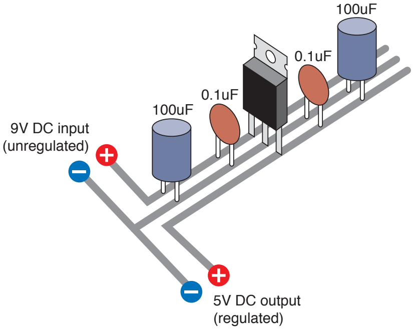


Figure 5-129. *PICAXE documentation specifies a 100 µF and 0.1 µF capacitor on the input side of a 5-volt regulator, and a similar pair of capacitors on its output side. On a breadboard, they can be arrayed like this.*

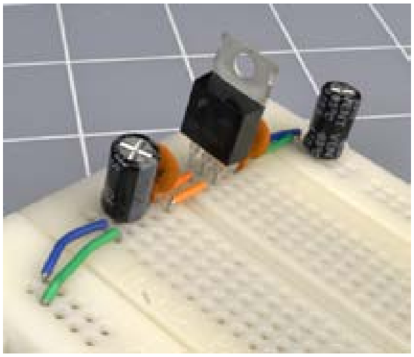

Figure 5-130. *The actual components for power regulation, applied to a breadboard, delivering 5 volts (positive and negative) down each side.*

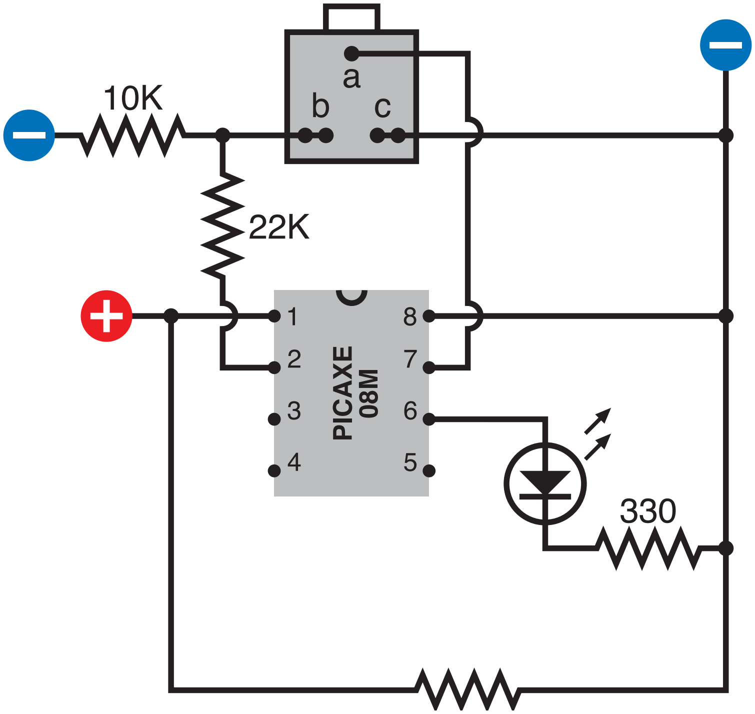

Figure 5-131. *The schematic of a test circuit for the PICAXE 08M shows the underside of the stereo socket, the essential 10K and 22K resistors on the input pin, and an LED to show an output from the chip.*

Be aware that the PICAXE manual shows things differently (although I have retained their labeling convention for the parts of the socket and the parts of the plug, identified as a, b, and c).

One little detail about the socket that is commonly supplied for use with the PICAXE: typically it has two *pairs* of contacts for the connections labeled b and c in the manual, and in my diagram. When you solder a connection, your solder joint should include *both* of the contacts in each pair, as shown in Figure 5-132.

Remember that the PICAXE must have 5 volts DC, and remember that your voltage regular will deliver this voltage reliably only if you give it extra voltage on its input side. If you provide it with 9 volts, that will provide a good amount of headroom.

The 22K and 10K resistors are essential for using the chip; see the following warning note for an explanation. My schematic also includes an LED and a 330Ω resistor, but they are needed only for the test that we'll be making momentarily.

Pin 2 Pull-Down

Always include the 22K resistor and the 10K resistor in the configuration shown in Figure 5-131. These resistors apply correct voltage to the serial connection, and when you're using the PICAXE on its own, they pull down the voltage on pin 2.

If pin 2 is left unconnected (floating), it may pick up random voltages, which the chip can misinterpret as a new program or other instructions, with unpredictable and undesirable results.

The 22K and 10K resistors should be regarded as permanent items accompanying your PICAXE regardless of whether you have it attached to your computer.

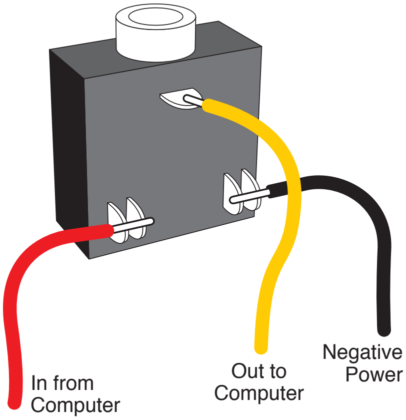

Figure 5-132. *Correct wiring of the socket is essential. When soldering wires to the lower terminals, make sure that you attach the wires to both of the terminals in each pair.*

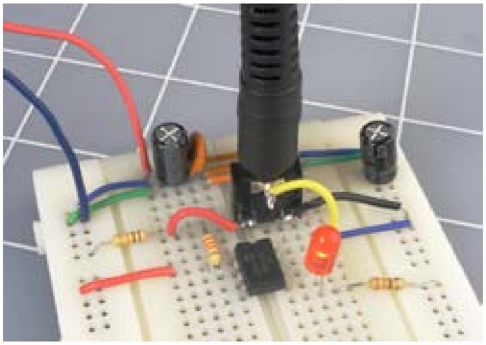

Figure 5-133. *The breadboard version of the test schematic, with the plug of the USB download cable inserted in the socket on the board. The PICAXE chip can now receive a downloaded program, and will immediately start to execute it.*

Verifying the Connection

Follow these steps carefully every time you want to program or reprogram your PICAXE chip:

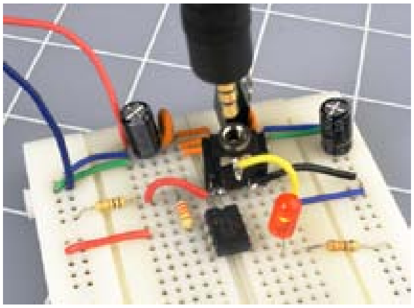

Figure 5-134. *After the program has been downloaded, the plug can be removed, and the program will continue to run, causing the LED to continue flashing.*

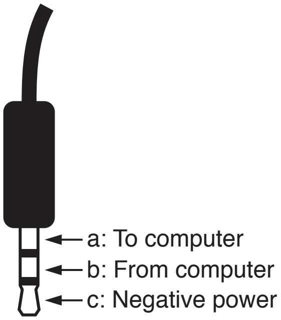
1. Insert the USB plug of your PICAXE cable into the same USB port that you used before.
2. Start the Programming Editor (or AXEpad if you are using a Mac OS or Linux).
3. In the Programming Editor, select View→Options to verify that the editor is using the right COM port and is expecting the 08M PICAXE chip.
4. Plug the stereo plug on the free end of the USB cable into the stereo socket that is now wired into your breadboard. See Figures 5-133 and 5-134.
5. Check your wiring, and then connect your power supply to the breadboard.
6. Click the button labeled “program” in the Program Editor window to tell the software to look for the PICAXE.

What If It Doesn’t Work?

The first thing to do is pull out the plug of the USB cable from the PICAXE breadboard, leaving the other end of the cable attached to your computer. Set your multimeter to measure DC volts, and attach its probes to sections b and c of the plug. See Figure 5-135. Now click the “program” button again, and your meter should show 5 volts briefly coming out of your computer to the plug on the end of the cable.

If you detect the voltage, the software is installed and working properly. In that case, there's a problem on your breadboard, either in the chip or in the wiring around it.

If you cannot detect any voltage, the software probably wasn't installed properly, or is looking for the wrong serial port. Try uninstalling it and reinstalling it.



a: To computer
b: From computer
c: Negative power

Figure 5-135. *The stereo plug on the end of the USB download cable can be used for fault tracing. A multimeter set to measure DC volts can be attached to sections b and c of the plug to establish whether the Programming Editor is sending data through the serial connection.*

Your First Program

Finally you're ready to create your first program. Type the following code into the Programming Editor window:

```
main:
    high 1
    pause 1000
    low 1
    pause 1000
    goto main
```

Be sure to include the colon after the word "main" on the first line. See Figure 5-136 for a screenshot. The indents are created by pressing the Tab key. Their only purpose is to make program listings more legible. The software ignores them.

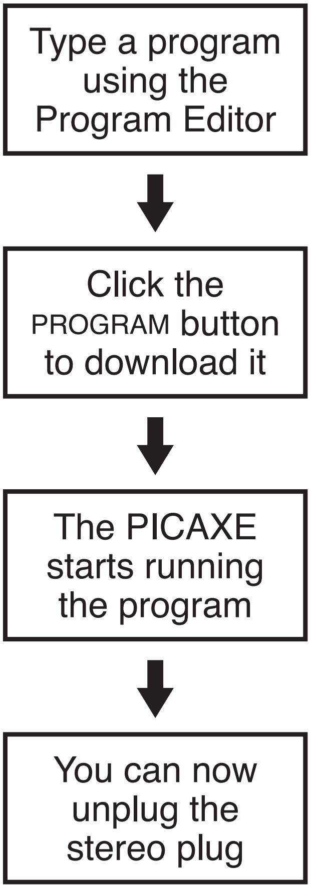
        pause 1000
        low 1
        pause 1000
        goto main
```

Figure 5-136. *This screenshot shows the first test program as it should be displayed by the Programming Editor (on a Windows computer).*

Click the Program button in the Programming Editor to download this program into the chip. As soon as the download is complete, the chip should start flashing the LED, lighting it for 1 second and then switching it off for 1 second. Figure 5-137 shows the steps that you should have followed to program the chip.



Type a program using the Program Editor
Click the PROGRAM button to download it
The PICAXE starts running the program
You can now unplug the stereo plug

Figure 5-137. *Four steps to create and run a program on the PICAXE controller chip.*

Now for the interesting part: disconnect the USB cable from the breadboard. The chip should continue flashing.

Disconnect the power supply from the breadboard and wait a minute or two for the capacitors to lose their charge. Reconnect the power, and the chip will start flashing again.

The program that you downloaded to the chip will remain in the memory inside the chip and will begin running every time power is applied to the chip.

The program doesn't use the usual pin numbers on the chip. It uses what I will call "logic pin numbers." Figure 5-138 shows how they are numbered. Figure 5-139 shows their multiple functions. I have put Logic Pin 0 in parentheses because its main purpose is to send data to the computer through the USB cable. It can do double duty as a digital output, but you have to disconnect it from the USB cable first. It's easy to forget to do this. It's a hassle that I prefer to avoid.

Decoding the Code

Let's take a look at the little program that you typed in. The first line identifies a section of the program. This program only has one section, and we're calling it "main." Any word with a colon after it is the name of a section of a program:

```
main:
```

The second line tells the chip to send a high output from Logic Pin 1:

```
high 1
```

The third line of the program tells the chip to wait for 1,000 milliseconds. This of course is the same as one second:

```
pause 1000
```

The fourth line tells the chip to change Logic Pin 1 back to its low state:

```
low 1
```

The fifth line tells the chip to wait for another 1,000 milliseconds:

```
pause 1000
```

The last line tells the chip to go back to the beginning of the "main" section:

```
goto main
```

Editing

What if you want to change the program? No problem! Use the Programming Editor to change one of the lines in the program. Substitute 100 instead of 1000 milliseconds, for instance. (The `pause` command can be followed by any number up to 65535.) In your program, don't use a thousands comma in any of the numbers that you specify.

Plug the USB cable into the breadboard again, hit the Program button on the screen, and the new version of the program will be automatically downloaded to the chip, overwriting the old version.

What if you want to save the program for future use? Just go to the File menu in the Programming Editor and save the program onto your computer's hard drive. Because the PICAXE uses a variant of the BASIC computer language, it adds a *.bas* filename extension.

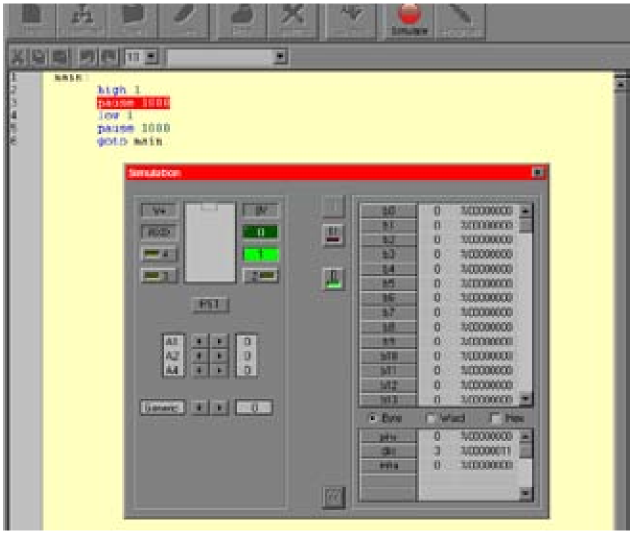
Simulation

If you make a simple typing error, the Programming Editor will find it and stop you from downloading your program. It will leave you to figure out how to fix the line that contains the error.

Even if all the statements in your program are correctly typed, it's a good idea to run a simulation of what they'll do, before you download them. This is easily done: click the "simulate" button on the menu bar of the Programming Editor. A new window will open, displaying a diagrammatic view of the PICAXE chip and showing you the states of its pins. (Note that if you use very short `pause` commands, the simulation won't run fast enough to display the time accurately.) A simulation screenshot is shown in Figure 5-140.

The >> button at the bottom-right corner of the simulation window will open up a list of all the variables in your program. So far, it doesn't have any variables, but it soon will. All the zeros on the righthand side are binary numbers, which you can ignore for now.

You'll need to check the second part of the PICAXE documentation, which contains all the programming statements and their correct syntax. At the time of writing, this is stored at http://www.rev-ed.co.uk/docs/picaxe_manual2.pdf.



```
main:
	high 1
	pause 1000
	low 1
	pause 1000
	goto main
```

Figure 5-140. *This screenshot shows the simulation window that can be opened in the Program Editor to test program code before it is downloaded to the chip. The values of variables are shown in the section on the right. The pin states are shown on the left.*

Loops

Here's another thing I'd like you to try. Rewrite your program code as shown here and download it onto the PICAXE:

```
main:
    for b0 = 1 to 5
        high 1
        pause 200
        low 1
        pause 200
    next
    wait 2
    goto main
```

Note that `b0` is letter b followed by a zero, not letter b followed by letter O. The extra indents once again are added to make the listing easier to understand. The four lines beginning "high 1" and ending "pause 200" will be executed repeatedly. It's helpful to see them as a block.

Watch the light and see what happens. It should flash five times quickly, then wait for two seconds, and then repeat. You just added a *loop* to your program. You can use a loop if you want something to happen more than once.

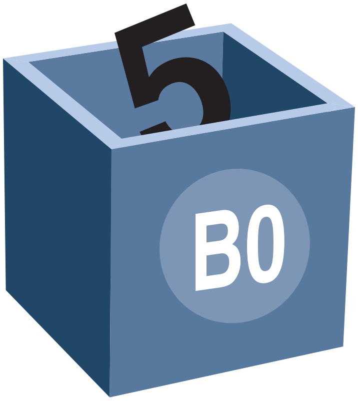


Figure 5-141. *To understand how a program works, visualize a variable as being like a "memory box" with its name on the outside and a number stored on the inside.*

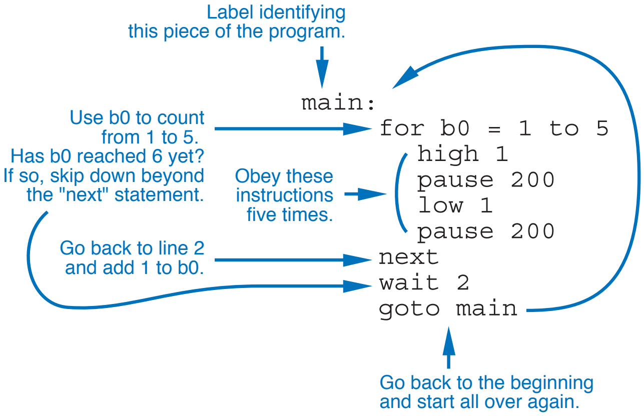
b0 is known as a *variable*. Think of it as being like a little "memory box" with its name, b0, on a label on the outside. Figure 5-141 illustrates this concept. This particular memory box can contain any number from 0 through 255. The loop begins by telling the computer to put number 1 in the box, then process the remaining statements, until the word "next" sends the processor back to the first line, at which point it adds 1 to the contents of b0. If the value of b0 is 5 or less, the loop repeats. If the value is 6, the loop has run five times, so it's over, and the PICAXE skips down to the "wait 2" statement after "next." See Figure 5-142 for an annotated version of the program listing.

"Wait" is a PICAXE command that is measured in whole seconds, so "wait 2" waits for 2 seconds. Then "goto main" begins the procedure all over again.

If your flashing-light demo worked out as planned, it's time to take the next step and make the chip do something more useful.



```
main:
for b0 = 1 to 5
  high 1
  pause 200
  low 1
  pause 200
next
wait 2
goto main
```

Label identifying this piece of the program.
Use b0 to count from 1 to 5. Has b0 reached 6 yet? If so, skip down beyond the "next" statement.
Obey these instructions five times.
Go back to line 2 and add 1 to b0.
Go back to the beginning and start all over again.

Figure 5-142. *The blue annotations explain what the program, on the right, is telling the PICAXE to do.*

FUNDAMENTALS

Basic PICAXE parameters

Here are some of the most useful parameters of the PICAXE:

- The PICAXE requires 5 volts DC, regulated.
- The inputs and outputs of the PICAXE are compatible with 5-volt logic chips. You can attach them directly.
- Each PICAXE pin can sink or source up to 20mA. The whole chip can deliver up to 90mA. This means that you can run LEDs directly from the pins, or a piezo noisemaker (which draws very little current), or a transistor.
- You can use a chip such as the ULN2001A Darlington array (mentioned in the previous experiment) to amplify the output from the PICAXE and drive something such as a relay or a motor.
- The chip executes each line of your program in about 0.1 milliseconds.
- The 08M chip has enough flash memory for about 80 lines of program code. Other PICAXE chips have more memory.
- The PICAXE provides 14 variables named b0 through b13. The "b" stands for "byte," as each variable occupies a single byte. Each can hold a value ranging from 0 through 255.
- No negative or fractional values are allowed in variables.
- You also have 7 double-byte variables, named w0 through w6. The "w" stands for "word." Each can hold a value ranging from 0 through 65535.
- The "b" variables share the same memory space as the "w" variables. Thus:
  - b0 and b1 use the same bytes as w0.
  - b2 and b3 use the same bytes as w1.
  - b3 and b4 use the same bytes as w2.
  - b5 and b6 use the same bytes as w3.
  - b7 and b8 use the same bytes as w4.
  - b9 and b10 use the same bytes as w5.
  - b11 and b12 use the same bytes as w6.
  - b13 and b14 use the same bytes as w7.

  Therefore, if you use w0 as a variable, do not use b0 or b1. If you use b6 as a variable, do not use w3, and so on.
- Variable values are stored in RAM, and disappear when the power is switched off.
- The program is stored in nonvolatile memory, and remains intact when the power is off.
- The manufacturer's specification claims that the nonvolatile memory is rewritable up to about 100,000 times.
- If you want to attach a switch or pushbutton to a pin and use it as an input, you should add a 10K pull-down resistor between the pin and the negative side of the power supply to hold the pin in a low state when the switch is open. Figure 5-143 shows how pull-down resistors should be used in conjunction with a SPST switch or a pushbutton.
- On the 08M chip, if you apply a varying resistance between Logic Pins 1, 2, or 4, and the negative side of the power supply, the chip can measure it and "decide" what to do. This is the "Analog-Digital Conversion" feature—which leads to our next experiment.

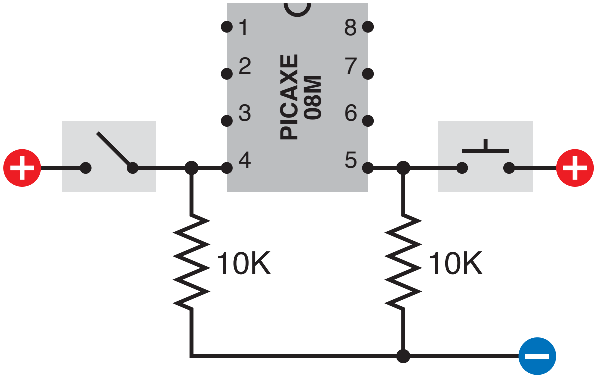


Figure 5-143. *The PICAXE can respond to the state of a switch or button attached to any of its input-capable pins. A 10K resistor must be used to pull down the state of the pin when the contact of the switch or button is open. Otherwise, you may get unpredictable results.*

Experiment 35: Checking the Real World

Often we want a microcontroller to measure something and respond in an appropriate way. For instance, it can measure a low temperature and sound an alarm, as I suggested in the example that I gave earlier.

The PICAXE has three analog-to-digital converters (ADCs) built in, accessible via logic pins 1, 2, and 4, as shown in Figure 5-139. The best way to use them is by applying a potential somewhere between 0 and 5 volts. In this experiment, I'll show you how to calibrate the response of the chip.

You will need:

- Trimmer potentiometer, 2K. Quantity: 1.
- PICAXE 08M chip and associated USB cable and socket. Quantity: 1 of each.

Procedure

Take the same trimmer potentiometer that you used in Experiment 32 and wire its center terminal to Logic Pin 2 of the PICAXE (which is hardware pin 5). The other two terminals of the 2K trimmer go to positive and to negative, respectively. So depending how you set the trimmer, the pin of the PICAXE is directly connected to positive (at one end of the scale), or directly connected to negative (at the other end of the scale), or somewhere in between. See Figure 5-144 for the revised schematic, and Figure 5-145 for a photograph of the breadboarded circuit.

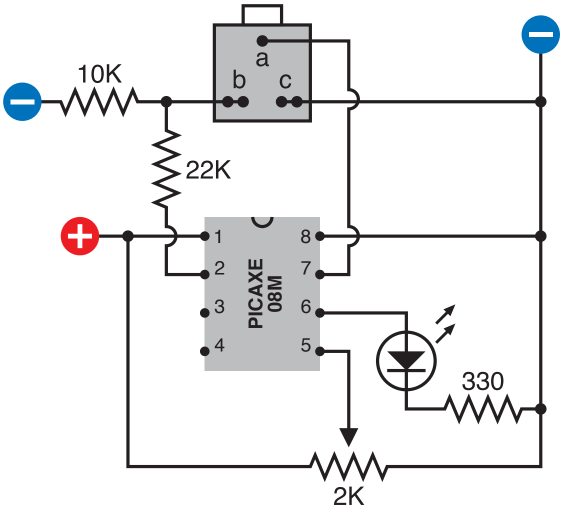

Figure 5-144. *This schematic, drawn in a layout suitable for breadboarding, shows how a 2K potentiometer can be used to apply a varying voltage to one of the pins of the PICAXE that is capable of converting an analog signal to a digital value.*

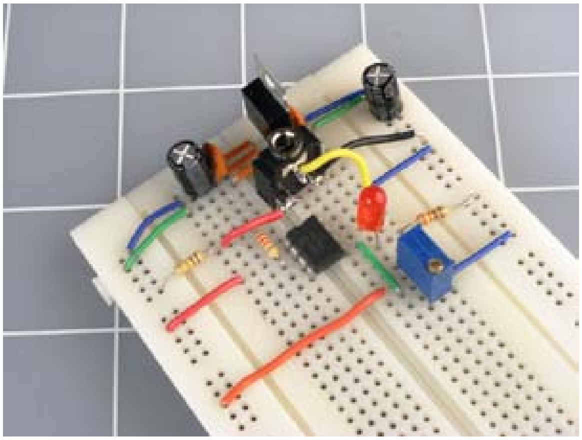

Figure 5-145. *The trimmer potentiometer added to the previously breadboarded circuit.*

Now we need a program to tell the chip what to do. Using the Programming Editor, start a new document. The code should look like this:

```
main:
    readadc 2,b0
    debug b0
    goto main
```

The command "readadc 2,b0" means "read the analog input on Logic Pin 2, convert from analog to digital, and store the result in b0."

The command "debug b0" tells the chip to go into program debugging mode, in which it uses its USB cable to tell the Programming Editor the values of all the variables while the program is running. The variables are displayed in a debugging window.

Download the program, and as the program starts to execute, the debugging window should open. Start adjusting the trimmer while looking at the value of b0, and you'll see b0 change its value.

You can make a table and draw a graph showing the relationship between the resistance between Logic Pin 2 and ground, and the value of b0. Just pull the trimmer off the breadboard, measure its resistance with a meter, then increase its resistance by, say, 200Ω, put it back into the breadboard, and look at the value of b0 again.

This is laborious, but calibrating equipment is always laborious—and in any case, I decided to do it for you. The graph is shown in Figure 5-146. You can also see the raw data numbers in the following table. I was pleased to find that the PICAXE gives a very precise, linear response to the input voltage. In other words, the graph is a straight line.

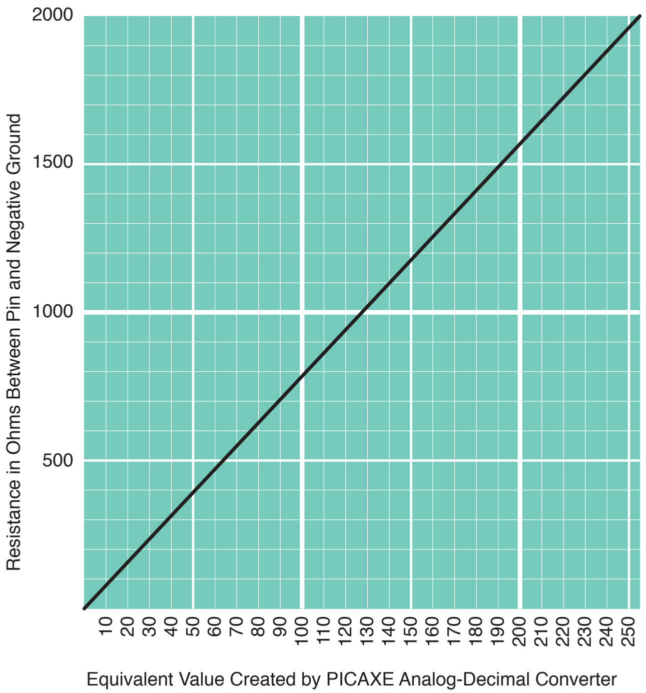

Figure 5-146. *When an ADC input pin is hooked up to a 2K potentiometer, which is connected across the same voltage that powers the chip, you should find that the resistance between the input pin and the negative side of the power supply generates the series of digital values shown on the graph. Note that the potentiometer must have a 2K value, and the power supply is assumed to be precisely 5 volts.*

This table shows measurements made with PICAXE 08M controller.

Resistance (in ohms) between the ADC pin and the negative supply	Equivalent digital value
2000	255
1900	243
1800	230
1700	218
1600	205
1500	192
1400	179
1300	166
1200	154
1100	141
1000	128
900	115
800	102
700	90
600	77
500	64
400	51
300	38
200	26
100	13
0	0

Now we can modify the program to make it do something with the information that it's taking in:

```
main:
    readadc 2,b0
    let w1 = 5 * b0
    high 1
    pause w1
    low 1
    pause w1
    goto main
```

Notice what's happening here. First we get a value in b0, and then on the next line, we do some arithmetic with it. The asterisk means "multiply." So the statement says, "Take whatever value is in b0, multiply by 5, and transfer it to another variable, w1." We have to use a w variable, because when we multiply the value of b0 by 5, we may get a number that is bigger than 255—too big to fit into a byte variable.

Finally, we take variable w1 and use it with a "pause" statement instead of a fixed number value. We're saying to the PICAXE, "pause for whatever number of microseconds you get by checking the value of w1."

So the software checks a variable resistance, turns it into a number, and applies that number to adjust the flashing speed of the LED.

Think back to the need of the cart powered by stepper motors. It was supposed to check two photoresistors, and adjust the speed of each motor accordingly. Well, this PICAXE program is a step in that direction. It can measure voltage on a pin and change the output frequency on another pin. If you had two PICAXE chips, you could wire each of them to a photoresistor and a motor. Then you could adjust the behavior of your cart by editing the second line in the program, where it converts the value of b0 to the value of w1 which will be used in the "pause" command to determine the number of pulses per second. Instead of multiplying by 5 you could multiply by 7 or whatever number gives you the result you need. This leads to an important conclusion: *a big advantage of a programmable chip is that you can make adjustments in software*.

Because the PICAXE 08M actually has more than one ADC input, and has three pins that can be used for output, you might wonder whether you could use just the one chip to control both motors in response to inputs from two sensors. The problem is that the three output pins on the 08M also function as the three ADC input pins. You'd do better to buy one of the more advanced PICAXE chips, such as the 18M, which has more pins to choose from. It uses the same basic set of programming instructions, and doesn't cost much more money.

Also, you should read the PICAXE documentation and look up the "pwmout" command, which is short for "pulse-width modulation output," but you can think of as meaning "power motor output." This is specifically intended to run stepper motors. It establishes an output frequency of pulses that will continue while the chip obeys other instructions in its program.

FUNDAMENTALS

Extra features

A complete guide to the 08M would fill a book of its own, and of course such books already exist (just search the books section of Amazon.com for keyword “picaxe”). But I’ll finish my introduction to the controller by listing some of its extra capabilities, leaving you to look them up and explore them. Then I’m going to suggest one last experiment.

Interrupts

The PICAXE 08M allows you to set one “interrupt.” This feature tells the chip to make a mental note that if a particular event occurs—such as a switch applying voltage to one pin—it should stop doing whatever else it was doing, and respond to the interruption.

Infrared

One pin on the PICAXE 08M can be used to receive infrared signals from a TV-style remote that you can buy from the same suppliers that sell the PICAXE itself. With an infrared sensor attached to the chip, you can issue commands remotely. If you want to build a remote-controlled robot, the chip is specifically designed with this in mind.

Servo motors

Every PICAXE chip has at least one pin that can send a stream of pulses to control a typical servo motor. On the 08M chip, it’s Logic Pin 2. The width of each pulse tells the motor how far to rotate from its center position before stopping. A 555 timer can send this stream, but the PICAXE makes it easier. You can search online for more information about servo motors, which are especially useful for applications such as steering model vehicles, adjusting the flaps on model airplanes, and actuating robots.

Music

The PICAXE has an onboard tone generator that can be programmed with a “tune” command to play tunes that you write using a simple code.

Alphanumeric input/output

The “kbin” programming command is available in the PICAXE models 20X2, 28X1 and 28X2, and 40X1 and 40X2. You can plug a standard computer keyboard into the chip, and it will read the keypresses. You can also attach alphanumeric displays, but these procedures are nontrivial. For instance, when you’re trying to figure out which key someone has pressed on a keyboard, your program has to contain a list of the special hexadecimal codes that the keyboard creates.

Pseudorandom number generation

All PICAXE models can generate pseudorandom numbers using a built-in algorithm. If you initialize the number generator by asking the user to press a button, and you measure the arbitrary time that this takes, you can seed the pseudorandom number generator with the result, and the pseudorandom number generator will have a less repeatable sequence.

Visit *http://www.rev-ed.co.uk/docs/picaxe_manual1.pdf* to learn more.

Experiment 36: The Lock, Revisited

The combination lock that I described in Experiment 20 is especially appropriate for a microcontroller, because it requires a series of operations that resemble a computer program. I'm going to show how this project can be redesigned using a PICAXE 08M, and then leave it to you to consider how some of the other projects in this book could be converted.

You will need:

- The same type of keypad and relay recommended in Experiment 20.
- A transistor or Darlington array to amplify the output from the PICAXE so that it can drive the relay.

Getting the User Input

Any of the input pins on the PICAXE can sense a switch closing. The trouble is that we only have three pins capable of doing this, and even the most advanced PICAXE chip has fewer than 10 such pins. So how can we attach a 10-key keypad to the 08M?

I have a suggestion: attach various resistors to the keypad, so that each key applies a different voltage to one of the ADC pins. Then use the ADC feature to convert the voltage to a number, and use a table of possible numbers to figure out which key is being pressed. This may not be the most elegant solution, but it works!

The keypad can be wired as shown in Figure 5-147. The asterisk key is still being used to supply power, as in the original experiment, while the pound key resets the relay at the end of your computing session, as before.

Current flows through a series of resistors, beginning with one that has a value of 500Ω. Because this is not a standard value, you will either have to make it by combining other resistors in series, or by presetting a trimmer potentiometer. After that, each button is separated from the next button by a 100Ω resistor. Finally, at the end of the chain, a 600Ω resistor separates the last button from the negative side of the power supply. Again, this is not a standard value, and you may have to use a trimmer.

Add up all the resistances and you have 2K, which is the range that the PICAXE wants us to use. When you press a button, you tap into the chain of resistances. Button 9 puts 600Ω between the PICAXE ADC pin and ground. Button 6 is 700Ω, button 3 is 800Ω, and so on. (You may prefer to lay out the buttons so that the resistance progresses in a more logical fashion. That's up to you. I chose to lay them out in the way that would be easiest to visualize on a keypad.)

Now look back at the ADC values that I supplied in the table on page 308. These are the values that you should get when you press various keypad buttons—but you cannot count on them being absolutely precise, because they may vary if your resistor values are not quite accurate, or if your power supply isn't exactly 5 volts. It's not safe to say, for example, that the PICAXE will deliver an ADC conversion value of precisely 77 when the resistance is 600Ω. It's safer to say that the value will be between 71 and 83. If we specify a range as shown in the following table, we have a much better chance of interpreting each button correctly.

Button number		Range
9	600	71–83
6	700	84–96
3	800	97–108
0	900	109–121
8	1000	122–134
5	1100	135–147
2	1200	148–160
7	1300	161–172
4	1400	173–185
1	1500	191–198

Suppose you attach the common pin of your keypad to ADC Logic Pin 2 of the PICAXE. You can now use the Program Editor to write a program that looks like this:

```
getkey:
    readadc 2,b0
    let b1 = 9
    if b0 < 84 then finish
    let b1 = 6
    if b0 < 97 then finish
    let b1 = 3
    if b0 < 109 then finish
    let b1 = 0
    if b0 < 122 then finish
    let b1 = 8
    if b0 < 135 then finish
    let b1 = 5
    if b0 < 148 then finish
    let b1 = 2
    if b0 < 161 then finish
    let b1 = 7
    if b0 < 173 then finish
    let b1 = 4
    if b0 < 186 then finish
    let b1 = 2

finish:
    return
```

What does the word "return" mean at the end? I'll get to that in a second. I want to explain the rest of the routine first.

b0 receives the value supplied by the analog-digital converter when it looks at the keypad. After storing the number in b0, the routine has to figure out which keypad key it matches. The key identity (0 through 9) will be stored in another variable, b1.

The program starts by assigning value 9 to b1. Then it checks to see whether b0 < 84. This means "if b0 is less than 84." If it is, then the routine tells the PICAXE to "finish," which means "jump to the finish: label." But if b0 is *not* less than 84, by default the PICAXE continues on to the next line, which makes a second attempt at guessing which key has been pressed. It assigns number 6 to b1. Now there's another if-then test—and so on. This process of reassigning values to b1 stops only when it gets to the point where b0 is greater than a number in the table.

If you're familiar with other dialects of BASIC, this may seem a bit laborious to you. You may wonder why we can't use a statement such as this:

```
    if b0 > 70 and b0 < 84 then b1 = 9
```

The answer is that PICAXE BASIC isn't sufficiently sophisticated to allow this. An if-then statement has to result in a jump to another section of the program. That's the only permitted outcome.

If you don't have any prior programming experience, the routine may still seem laborious to you, and perhaps a bit puzzling, too. This is understandable, because you're getting a crash course in software design without any formal preparation. Still, the PICAXE Programming Editor can be a big help, because it has its simulation feature. Before you can use this, though, you have to precede the routine that I just supplied with a control routine that you must type above it. The screenshot in Figure 5-148 shows you how it should look.

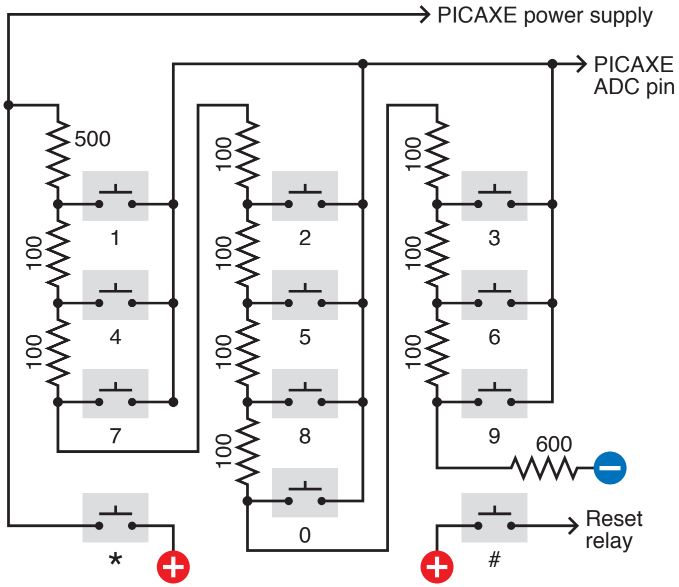

Figure 5-147. *A quick and simple way of attaching a keypad to provide numeric input to the PICAXE uses a chain of resistors totalling 2,000Ω. When a button is pressed, it connects the ADC input pin to a point in the chain. The resistance detected by the input pin can then be converted by the program in the chip to determine which key has been pressed.*

I have chosen an arbitrary combination of 7-4-1 for our combination lock. Using these numbers, the main section of the program looks like this:

```
main:
    low 1
    gosub getkey
    if b1<>7 then main
    gosub getkey
    if b1<>4 then main
    gosub getkey
    if b1<>1 then main
    high 1
    end
```

I should explain that the <> pair of symbols mean "is not equal to." So the fourth line of the program means, "if b1 is not equal to 7."

The value of b1 is supposed to be 7 if the user is putting in the correct combination. So if it's not 7, the user has entered the wrong value, and the if-then statement sends the PICAXE back to the beginning. In fact anytime the user inputs a number that is not in the correct 7-4-1 sequence, the program sends the PICAXE back to the beginning. This is the way the pure-hardware version of this experiment was set up.

But what is this word "gosub"? It means "go to a subroutine." A subroutine is any sequence of program statements that ends with the instruction to "return." So "gosub getkey" tells the PICAXE to mark its current place in the program while it skips to the `getkey:` section of code, which it obeys, until it finds the word "return," which returns it to the place from where it came.

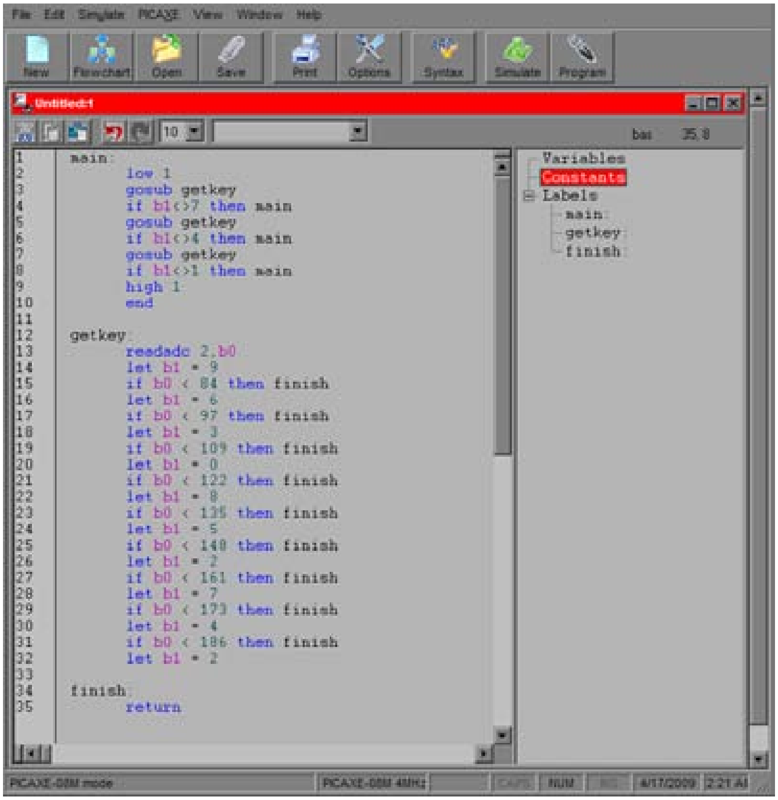
The PICAXE continues in this fashion until it reaches the word "end." I had to insert the word "end" because otherwise the PICAXE will continue executing the program and will fall into the subroutine. "End" stops it from doing so. Figure 5-148 shows a screenshot of the complete listing.

So—is that all? Yes, that's it. If you enter the code into the Programming Editor exactly as I have supplied it, you should be able to run it in simulation mode, and in the simulation window, click the right-arrow beside Logical Pin A2 to increase its value in steps. Each time you pass one of the values in the `getkey:` subroutine, you should see the value for variable b1 change in the display.

This is really all you need to perform the functions of the combination lock. When the PICAXE runs this program, it waits for the correct combination. If it receives the combination, it sends the output from logical pin 1 high; otherwise, logical pin 1 stays low.

The only additional item you need is a transistor or CMOS gate between logical pin 1 and the relay that unlocks the computer, because the PICAXE cannot deliver enough current to operate the relay by itself.

Putting this procedure into a controller chip not only simplifies the circuit, but offers another advantage: you can change the combination simply by rewriting the program and downloading the new version into the chip.



```
main:
        low 1
        gosub getkey
        if b1<>7 then main
        gosub getkey
        if b1<>4 then main
        gosub getkey
        if b1<>1 then main
        high 1
        end

getkey:
        readadc 2,b0
        let b1 = 9
        if b0 < 84 then finish
        let b1 = 6
        if b0 < 97 then finish
        let b1 = 3
        if b0 < 109 then finish
        let b1 = 0
        if b0 < 122 then finish
        let b1 = 8
        if b0 < 135 then finish
        let b1 = 5
        if b0 < 148 then finish
        let b1 = 2
        if b0 < 161 then finish
        let b1 = 7
        if b0 < 173 then finish
        let b1 = 4
        if b0 < 186 then finish
        let b1 = 2

finish:
        return
```

Figure 5-148. *This screenshot shows the complete listing of a program to read a sequence of three keypresses in conjunction with a combination lock. If the sequence is correct, the PICAXE sends a high output from one of its pins. If the sequence is incorrect, the program loops back to the beginning.*

FUNDAMENTALS

Limitations of MCUs

The PICAXE does have some disadvantages. Its voltage requirements alone restrict you from using it with the kind of freedom of a 555 timer.

Also, although I can get an instant result by plugging a 555 timer into a breadboard and adding a couple of resistors and a couple of capacitors, the PICAXE requires me to add a download socket, hook it up to my computer, write a program in the Programming Editor, and download the program.

Some people don't like writing software, or they have difficulty thinking in the relentlessly left-brain way that computer programming requires. They may prefer the hands-on process of assembling hardware.

Other people may have the opposite preference. This of course is a matter of taste, but one thing we know beyond all doubt is that computer programs often contain errors that may not reveal themselves until weeks or months later.

The PICAXE, for instance, doesn't protect you if a number is assigned to a variable that exceeds the limit for that type of variable. Suppose b1=200 and b2=60 and your program tells the PICAXE:

```
    let b3 = b1 + b2
```

The result should be 260, but byte-size variables can only count up to 255. What happens? You will find that b3 acquires a value of 4, without any warning or explanation. This is known as an "overflow error," which can be very difficult to predict, because it happens at runtime, when external factors are in control. The code looks perfectly good; the Programming Editor doesn't find any syntax errors; the simulation behaves properly. But in the real world, days or even months later, an unexpected set of circumstances results in an input that causes the overflow, and because the code is residing inside the chip at this point, you may have a hard time figuring out what on earth went wrong.

Software has its problems. Hardware has its advantages.

FUNDAMENTALS

Unexplored territory

If you've taken the time to complete most of the projects in this book with your own hands, you have gained a very rapid introduction to the most fundamental areas of electronics.

What have you missed along the way? Here are some topics that remain wide open for you to explore. Naturally you should search online if they interest you.

The informal, learning-by-discovery approach that I have used in this book tends to be light on theory. I've avoided most of the math that you'd be expected to learn in a more rigorous course on the subject. If you have mathematical aptitude, you can use it to gain a much deeper insight into the way in which circuits work.

I didn't deal much with computer architecture, either. We didn't go very far into binary code, and you didn't build a half-adder, which is a great way to learn how computers function on the most fundamental level. Perhaps you should think about assembling one.

I avoided going deeply into the fascinating and mysterious properties of alternating current. Here again, some math is involved, but just the behavior of current at high frequencies is an interesting topic in itself.

For reasons already stated, I avoided surface-mount components—but you can still go into this area yourself for a relatively small investment, if you like the idea of creating fascinatingly tiny devices. This may be the future of hobby electronics, so if you stick with it, you'll probably end up in the world of surface-mount.

Vacuum tubes were not mentioned, because at this point, they are mainly of historical interest. But there's something very special and beautiful about tubes, especially if you can enclose them in fancy cabinetwork. In the hands of a skilled craftsperson, tube amplifiers and radios become art objects.

I didn't show you how to etch your own printed circuit boards. This is a task that appeals to only certain people, and the preparation for it requires you to make very neat drawings or use computer software for that purpose. If you happen to have those resources, you might want to do your own etching. It could be a first step toward mass-producing your own devices.

I didn't cover static electricity at all. High-voltage sparks don't have any practical applications, and they entail some safety issues—but they are stunningly impressive, and you can easily obtain the necessary information to build the equipment. Maybe you should try.

Other Controllers

If you want something more powerful, a BASIC Stamp is the logical next step after a PICAXE. the BASIC Stamp is so called because it originally looked like a postage stamp. The BASIC Stamp has a larger vocabulary of commands and a bigger range of add-on devices (including displays with graphical capability, and a little keyboard that is specifically designed for use with the controller). The BASIC Stamp is shown in Figure 5-149.

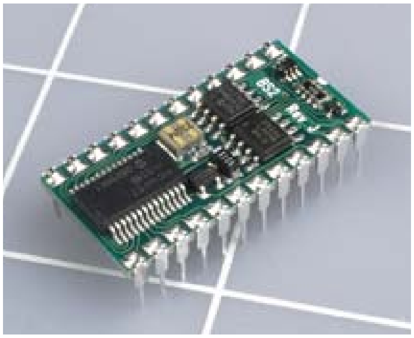


Figure 5-149. *The BASIC Stamp controller consists of surface-mounted components on a platform that has pins spaced at 1/10-inch intervals, for insertion in a breadboard or perforated board. This component uses a version of BASIC that is similar to the programming language of the PICAXE, but has many more extensions. The BASIC Stamp is available for use with a wide range of peripheral devices, including many alphanumeric dot-matrix displays.*

On the downside, you'll find that everything associated with the BASIC Stamp is a bit more expensive than in the PICAXE world, and the download procedure isn't quite as simple.

One of the more recent developments in the world of MCUs is the Arduino, which is both sophisticated and powerful. It does require programming in the C language. This language is a little more difficult to understand, and has only the vaguest similarity to the syntax that is used in the PICAXE and BASIC Stamp. On the other hand, because C dominates the larger world of computing, learning it might not be such a bad idea—and the Arduino offers some truly amazing capabilities. Because it is so popular, there are also many software tools, documentation, user forums, and many enthusatic hobbyists to help you. Two other Make: Books titles that I mentioned previously, *Getting Started with Arduino* and *Making Things Talk*, provide a great introduction.

In Closing

I believe that the purpose of an introductory book is to give you a taste of a wide range of possibilities, leaving you to decide for yourself what you want to explore next. Electronics is ideal for those of us who like to do things ourselves, because almost any application—from robotics, to radio-controlled aircraft, to telecommunications, to computing hardware—allows opportunities that we can explore at home, with limited resources.

As you delve deeper into the areas of electronics that interest you most, I trust you'll have a satisfying learning experience. But most of all, I hope you have lots of fun along the way.

Online Retail Sources and Manufacturers

Acknowledgments

My association with MAKE magazine began when its editor, Mark Frauenfelder, asked me to write for it. I have always been very grateful to Mark for his support of my work. Through him I became acquainted with the exceptionally capable and motivated production staff at MAKE. Gareth Branwyn eventually suggested that I might like to write an introductory guide to electronics, so I am indebted to Gareth for initiating this project and supervising it as my editor. After I wrote an outline in which I described my idea for "Learning by Discovery" and the associated concept that cutting open components or burning them up can be an educational activity, MAKE's publisher, Dale Dougherty, uttered the memorable phrase, "I want this book!" Therefore I offer special thanks to Dale for his belief in my abilities. Dan Woods, the associate publisher, was also extremely supportive.

The production process was swift, competent, and painless. For this I thank my editor at O'Reilly, Brian Jepson; senior production editor Rachel Monaghan; copyeditor Nancy Kotary; proofreader Nancy Reinhardt; indexer Julie Hawks; designer Ron Bilodeau; and Robert Romano, who tweaked my illustrations. Most of all I am indebted to Bunnie Huang, my technical advisor, who reviewed the text in detail and knows a bunch of stuff that I don't know. Any residual errors are still my fault, even though I would prefer to blame them on Bunnie.

Thanks also to Matt Mets, Becky Stern, Collin Cunningham, Marc de Vinck, Phillip Torrone, Limor Fried, John Edgar Park, John Baichtal, and Jonathan Wolfe for helping out with some last-minute project testing.

Lastly I have to mention the genius of John Warnock and Charles Geschke, founders of Adobe Systems and creators of the very beautiful PostScript language, which revolutionized all of publishing. The horror of attempting to create this book using graphic-arts tools from…some other company…is almost unimaginable. In fact, without Illustrator, Photoshop, Acrobat, and InDesign, I doubt I would have attempted the task. I am also indebted to the Canon 1Ds with 100mm macro lens, which took many of the pictures in this book.

No free samples or other favors were received from any of the vendors mentioned herein, with the exception of two sample books from MAKE, which I read to ensure that I was not duplicating anything that had already been published.

About the Author

Charles Platt became interested in computers when he acquired an Ohio Scientific C4P in 1979. After writing and selling software by mail order, he taught classes in BASIC programming, MS-DOS, and subsequently Adobe Illustrator and Photoshop. He wrote five computer books during the 1980s.

He has also written science-fiction novels such as *The Silicon Man* (published originally by Bantam and later by Wired Books) and *Protektor* (from Avon Books). He stopped writing science fiction when he started contributing to *Wired* in 1993, and became one of its three senior writers a couple of years later.

Charles began contributing to MAKE magazine in its third issue and is currently a contributing editor. *Make: Electronics* is his first title for Make Books. Currently he is designing and building prototypes of medical equipment in his workshop in the northern Arizona wilderness.

Radio Mathematics

Understanding radio and electronics beyond an intuitive or verbal level requires the use of some mathematics. None of the math is more advanced than trigonometry or advanced algebra, but if you don't use math regularly, it's quite easy to forget what you learned during your education. In fact, depending on your age and education, you may not have encountered some of these topics at all.

It is well beyond the scope of this book to be a math textbook, but this section touches some of topics that most need explanation for amateurs. For introductory-level tutorials and explanations of advanced topics, a list of on-line, no-cost tutorials is presented in the sidebar, "Online Math Resources". You can browse these tutorials whenever you need them in support of the information in this reference text.

Online Math Resources

The following Web links are a compilation of on-line resources organized by topic. Other resources are available online at **www.arrl.org/tech-prep-resource-library**. Look for the Math Tutorials section.

Many of the tutorials listed below are part of the *Interactive Mathematics* Web site (**www.intmath.com**), a free, online system of tutorials. The system begins with basic number concepts and progresses all the way through introductory calculus. The lessons referenced here are those of most use to a student of radio electronics.

Working With Decibels

The *decibel* (*dB*) is a way of expressing a ratio *logarithmically*, meaning as a power of some *base* number, such as 10 or the base for *natural logarithms*, the number $e \approx 2.71828$. A decibel, using the metric prefix "deci" (d) for one-tenth, is one-tenth of a *Bel* (B), a unit used in acoustics representing a ratio of 10, and named for the telephone's inventor, Alexander Graham Bell. As it turns out, the Bel was too large a ratio for common use and the deci-Bel, or decibel, became the standard unit.

In radio, the logarithmic ratio is used, but it compares signal strengths — power, voltage, or current. The decibel is more useful than a *linear* ratio because it can represent a wider scale of ratios. The numeric values encountered in radio span a very wide range and so the dB is more suited to discuss large ratios. For example, a typical receiver encounters signals that have powers differing by a factor of 100,000,000,000,000 (10^{14} or 100 trillion!). Expressed in dB, that range is 140, which is a lot easier to work with than the preceding number, even in scientific notation!

The formula for computing the decibel equivalent of a power ratio is

$$\text{dB} = 10 \log (\text{power ratio}) = 10 \log (P1/P2) \tag{1}$$

or if voltage is used

$$\text{dB} = 20 \log (\text{voltage ratio}) = 20 \log (V1/V2) \tag{2}$$

For equations 1 and 2 to produce equivalent results, both of the voltages must be measured across equivalent impedances. Otherwise, impedance must be accounted for according to $P = V^2 / Z$.

Positive values of dB mean the ratio is greater than 1 and negative values of dB indicate a ratio of less than 1. For example, if an amplifier turns a 5 W signal into a 25 W signal, that's a gain of 10 log (25 / 5) = 10 log (5) = 7 dB. On the other hand, if by adjusting a receiver's volume control the audio output signal voltage is reduced from 2 V to 0.1 V, that's a loss: 20 log (0.1 / 2) = 20 log (0.05) = –26 dB.

If you are comparing a measured power or voltage (P_M or V_M) to some reference power (P_{REF} or V_{REF}) the formulas are:

$$\text{dB} = 10 \log (P_M / P_{REF})$$

$$dB = 20 \log (V_M / V_{REF})$$

There are several commonly-used reference powers and voltages, such as 1 V or 1 mW. When a dB value uses one of them as the references, dB is followed with a letter. Here are the most common:

- dBV means dB with respect to 1 V (V_{REF} = 1 V)
- dBμV means dB with respect to 1 μV (V_{REF} = 1 μV)
- dBm means dB with respect to 1 mW (P_{REF} = 1 mW)

If you are given a ratio in dB and asked to calculate the power or voltage ratio, use the following formulas:

$$\text{Power ratio} = \text{antilog}\ (dB / 10) \qquad (3)$$

$$\text{Voltage ratio} = \text{antilog}\ (dB / 20) \qquad (4)$$

Example: A power ratio of –9 dB = antilog –(9 / 10) = antilog (–0.9) = ⅛ = 0.125

Example: A voltage ratio of 32 dB = antilog (32 / 20) = antilog (1.6) = 40

Antilog is also written as $\log^{-1}$ and may be labeled that way on calculators.

CONVERTING BETWEEN DB AND PERCENTAGE

You may also have to convert back and forth between decibels and percentages. Here are the required formulas:

$$dB = 10 \log\ (\text{percentage power} / 100\%) \qquad (5)$$

$$dB = 20 \log\ (\text{percentage voltage} / 100\%) \qquad (6)$$

$$\text{Percentage power} = 100\% \times \text{antilog}\ (dB / 10) \qquad (7)$$

$$\text{Percentage voltage} = 100\% \times \text{antilog}\ (dB / 20) \qquad (8)$$

Example: A power ratio of 20% = 10 log (20% / 100%) = 10 log (0.2) = –7 dB

Example: A voltage ratio of 150% = 20 log (150% / 100%) = 20 log (1.5) = 3.52 dB

Example: –1 dB represents a percentage power = 100% × antilog (–1 / 10) = 79%

Example: 4 dB represents a percentage voltage = 100% × antilog (4 / 20) = 158%

Rectangular and Polar Coordinates

Graphs are drawings of what equations describe with symbols — they're both saying the same thing. Graphs are used to present a visual representation of what an equation expresses. The way in which mathematical quantities are positioned on the graph is called the *coordinate system*. *Coordinate* is another name for the numeric scales that divide the graph into regular units. The location of every point on the graph is described by a pair of *coordinates*.

The two most common coordinate systems used in radio are the *rectangular-coordinate* system shown in **Figure 1** (sometimes called *Cartesian coordinates*) and the *polar-coordinate* system shown in **Figure 2**.

The line that runs horizontally through the

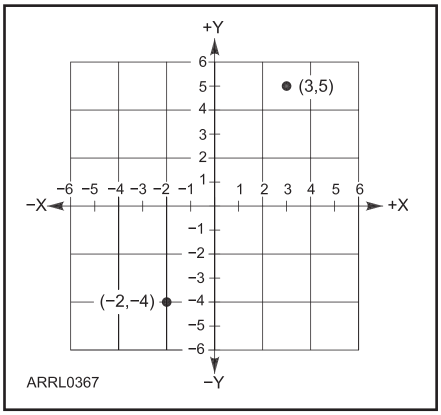

Figure 1 — Rectangular-coordinate graphs use a pair of axes at right angles to each other; each calibrate in numeric units. Any point on the resulting grid can be expressed in terms of its horizontal (X) and vertical (Y) values, called coordinates.

Computer Software and Calculators

Every version of the *Windows* operating system comes with a calculator program located in the Accessories program group and a number of free calculators are available on-line. Enter "online" and "calculator" into the search window of an Internet search engine for a list. If you can express your calculation as a mathematical expression, such as sin(45) or 10log(17.5), it can be entered directly into the search window at **www.google.com** and the Google calculator will attempt to solve for the answer.

Microsoft *Excel* (and similar spreadsheet programs) also make excellent calculators. If you are unfamiliar with the use of spreadsheets, here are some online tutorials and help programs:

homepage.cs.uri.edu/tutorials/csc101/pc/excel97/excel.html
www.baycongroup.com/el0.htm
www.bcschools.net/staff/ExcelHelp.htm

For assistance in converting units of measurement, the Web site **www.onlineconversion.com** is very useful. The Google online unit converter can also be used by entering the required conversion, such as "12 gauss in tesla", into the Google search window.

Decibels In Your Head

Every time you increase the power by a factor of 2 times, you have a 3-dB increase of power. Every 4 times increase of power is a 6-dB increase of power. When you increase the power by 10 times, you have a power increase of 10 dB. You can also use these same values for a decrease in power. Cut the power in half for a 3-dB loss of power. Reduce the power to ¼ the original value for a 6-dB loss in power. If you reduce the power to 1⁄10 of the original value you will have a 10-dB loss. The power-loss values are often written as negative values: –3, –6 or –10 dB. The following tables show these common decibel values and ratios.

Common dB Values and Power Ratios

P2/P1	*dB*
0.1	–10
0.25	–6
0.5	–3
1	0
2	3
4	6
10	10

Common dB Values and Voltage Ratios

V2/V1	*dB*
0.1	–20
0.25	–12
0.5	–6
0.707	–3
1.0	0
1.414	3
2	6
4	12
10	20

You can also derive all the dB equivalents of integer ratios by adding or subtracting dB values. For example, to calculate the dB for a power ratio of 10/4 (2.5), subtract the dB equivalents for 10 and 4: 10 – 6 = 4 dB. Similarly for a ratio of 10/2 (5), 10 – 3 = 7 dB. The ratio of 5/4 (1.25) is 7 – 6 = 1 dB and so forth. The same trick can be used with the voltage ratios.

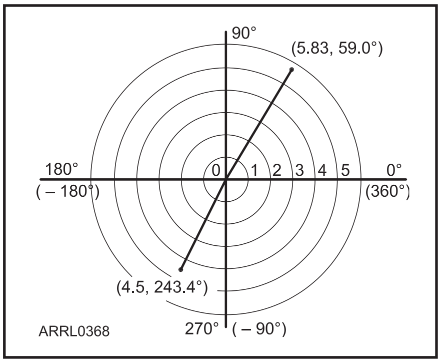

Figure 2 — Polar-coordinate graphs use a radius from the origin and an angle from the 0º axis to specify the location of a point. Thus, the location of any point can be specified in terms of a radius and an angle.

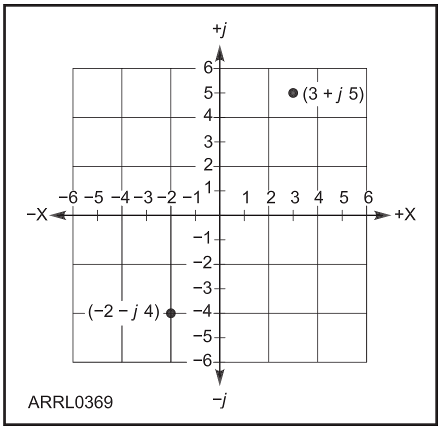

Figure 3 — The Y axis of a complex-coordinate graph represents the imaginary portion of complex numbers. This graph shows the same numbers as in Figure 1, graphed as complex numbers.

center of a rectangular coordinate graph is called the *X axis*. The line that runs vertically through the center of the graph is normally called the *Y axis*. Every point on a rectangular coordinate graph has two coordinates that identify its location, X and Y, also written as (X,Y). Every different pair of coordinate values describes a different point on the graph. The point at which the two axes cross — and where the numeric values on both axes are zero — is called the *origin*, written as (0,0).

In Figure 1, the point with coordinates (3,5) is located 3 units from the origin along the X axis and 5 units from the origin along the Y axis. Another point at (–2,–4) is found 2 units to the left of the origin along the X axis and 4 units below the origin along the Y axis. Do not confuse the X coordinate with the X representing reactance! Reactance is usually plotted on the Y-axis, creating occasional confusion.

In the polar-coordinate system, points on the graph are described by a pair of numeric values called *polar coordinates*. In this case, a length, or *radius*, is measured from the origin, and an *angle* is measured counter-clockwise from the 0º line as shown in Figure 2. The symbol *r* is used for the radius and θ for the angle. A number in polar coordinates is written $r\angle\theta$. So the two points described in the last paragraph could also be written as (5.83, ∠59.0°) and (4.5, ∠243.4°). Unlike geographic maps, 0º is always to the *right* along the X-axis and 90°at the top along the Y-axis!

Angles are specified counterclockwise from the 0º axis. A negative value in front of an angle specifies an angle measured clockwise from the 0º axis. (Angles can also be given with reference to some arbitrary line, as well.) For example, –270º is equivalent to 90º, –90º is equivalent to 270º, 0º and –360º are equivalent, and +180º and –180º are equivalent. With an angle measured clockwise from the 0º axis, the polar coordinates of the second point in Figure 2 would be (4.5, ∠–116.6°).

In some calculations the angle will be specified in *radians* (1 radian = 360 / 2π degrees = 57.3°), but you may assume that all angles are in degrees in this book. Radians are used when *angular frequency* (ω) is used instead of frequency (*f*). Angular frequency is measured in units of 2π radians/sec and so ω = 2πf.

In electronics, it's common to use both the rectangular and polar-coordinate systems when dealing with impedance problems. The examples in the next few sections of this book should help you become familiar with these coordinate systems and the techniques for changing between them.

Complex Numbers

Mathematical equations that describe phases and angles of electrical quantities use the symbol *j* to represent the square root of minus one ($\sqrt{-1}$). (Mathematicians use *i* for the same purpose, but *i* is used to represent current in electronics.) The number *j* and any real number multiplied by *j* are called *imaginary numbers* because no real number is the square root of minus one. For example, 2*j*, 0.1*j*, 7*j*/4, and 457.6*j* are all imaginary numbers. Imaginary numbers are used in electronics to represent reactance, such as *j*13 Ω of inductive reactance or –*j*25 Ω of capacitive reactance.

Real and imaginary numbers can be combined by using addition or subtraction. Adding a real number to an imaginary number creates a hybrid called a *complex number*, such as 1 + *j* or 6 – 7*j*. These numbers come in very handy in radio, describing impedances, relationships between voltage and current, and many other phenomena.

If the complex number is broken up into its real and imaginary parts, those two numbers can also be used as coordinates on a graph using *complex coordinates*. This is a special type of rectangular-coordinate graph that is also referred to as the *complex plane*. By convention, the X axis coordinates represent the real number portion of the complex number and Y axis coordinates the imaginary portion. For example, the complex number 6 – 7*j* would have the same location as the point (6,–7) on a rectangular-coordinate graph. **Figure 3** shows the same points as Figure 1.

The number *j* has a number of interesting properties:

$1/j = -j$

$j^2 = -1$

$j^3 = -j$

$j^4 = 1$

Multiplication by *j* can also represent a phase shift or rotation of +90°. In polar coordinates *j* = 1 ∠90°.

WORKING WITH COMPLEX NUMBERS

Complex numbers representing electrical quantities can be expressed in either rectangular form (a + *j*b) or polar form (r∠θ) as described above. Adding complex numbers is easiest in rectangular form:

$$(a + jb) + (c + jd) = (a+c) + j(b+d) \tag{9}$$

Multiplying and dividing complex numbers is easiest in polar form:

$$a\angle\theta_1 \times b\angle\theta_2 = \left(a \times b\right)\angle\left(\theta_1 + \theta_2\right) \tag{10}$$

and

$$\frac{a\angle\theta_1}{b\angle\theta_2} = \left(\frac{a}{b}\right)\angle\left(\theta_1 - \theta_2\right) \tag{11}$$

Converting from one form to another is useful in some kinds of calculations. For example, to calculate the value of two complex impedances in parallel you use the formula

$$Z = \frac{Z_1 Z_2}{Z_1 + Z_2}$$

To calculate the numerator (Z_1Z_2) you would write the impedances in polar form. To calculate the numerator ($Z_1 + Z_2$) you would write the impedances in rectangular form. So you need to be able to convert back and forth from one form to the other. Here is the procedure:

To convert from rectangular (a + *j*b) to polar form (r ∠ θ):

$$r = \sqrt{a^2 + b^2} \text{ and } \theta = \tan^{-1}(b / a) \quad (12)$$

To convert from polar to rectangular form:

$$a = r \cos\theta \text{ and } b = r \sin\theta \quad (13)$$

Many calculators have polar-rectangular conversion functions built-in and they are worth learning how to use. Be sure that your calculator is set to the correct units for angles, radians or degrees.

Example: Convert 3 ∠ 60° to rectangular form:

$$a = 3 \cos 60° = 3\,(0.5) = 1.5$$

$$b = 3 \sin 60° = 3\,(0.866) = 2.6$$

$$3\angle 60° = 1.5 + j2.6$$

Example: Convert 0.8 + *j*0.6 to polar form:

$$r = \sqrt{0.8^2 + 0.6^2} = 1$$

$$\theta = \tan^{-1}\left(0.6 / 0.8\right) = 36.8°$$

$$0.8 + j0.6 = 1\angle 36.8°$$

Accuracy and Significant Figures

The calculations you have encountered in this chapter and will find throughout this handbook follow the rules for accuracy of calculations. Accuracy is represented by the number of *significant digits* in a number. That is, the number of digits that carry numeric value information beyond order of magnitude. For example, the numbers 0.123, 1.23, 12.3, 123, and 1230 all have three significant digits.

The result of a calculation can only be as accurate as its *least* accurate measurement or known value. This is important because it is rare for measurements to be more accurate than a few percent. This limits the number of useful significant digits to two or three. Here's another example; what is the current through a 12-Ω resistor if 4.6 V is applied? Ohm's Law says I in amperes = 4.6 / 12 = 0.3833333... but because our most accurate numeric information only has two significant digits (12 and 4.6), strictly applying the significant digits calculation rule limits our answer to 0.38. One extra digit is often included, 0.383 in this case, to act as a guide in rounding off the answer.

Quite often a calculator is used, and the result of a calculation fills the numeric window. Just because the calculator shows 9 digits after the decimal point, this does not mean that is a more correct or even useful answer.

Radio-Frequency Electronics

Circuits and Applications

This second, much updated edition of the best-selling *Radio-Frequency Electronics* introduces the basic concepts and key circuits of radio-frequency systems. It covers the fundamental principles applying to all radio devices, from wireless single-chip data transceivers to high-power broadcast transmitters.

New to this edition:

- Extensively revised and expanded throughout, including new chapters on radar, digital modulation, GPS navigation, and *S*-parameter circuit analysis.
- New worked examples and end-of-chapter problems aid and test understanding of the topics covered.
- Numerous extra figures provide a visual aid to learning, with over 400 illustrations throughout the book.

Key topics covered include filters, amplifiers, oscillators, modulators, low-noise amplifiers, phase lock loops, transformers, waveguides, and antennas. Assuming no prior knowledge of radio electronics, this is a perfect introduction to the subject. It is an ideal textbook for junior or senior courses in electrical engineering, as well as an invaluable reference for professional engineers in this area.

Praise for the first edition:
This book is wonderfully informative, and refreshingly different from the usual rehash of standard engineering topics. Hagen has put his unique insights, gleaned from a lifetime of engineering and radio science, into this volume and it shows. There's an insight per page, at least for me, that makes it truly enjoyable reading, even for those of us who think we know something about the field! *Paul Horowitz, Harvard University*

Jon B. Hagen was awarded his Ph.D. from Cornell University in 1972, where he went on to gain 30 years' experience as an electronic design engineer, as well as establishing and teaching a Cornell electrical engineering course on RF electronics. Now retired, he has held positions as Principal Engineer at Raytheon, Electronics Department Head at the Arecibo Observatory in Puerto Rico, and Director of the NAIC Support Laboratory at Cornell.

Preface *page* xiii

1 Introduction 1
1.1 RF circuits 2
1.2 Narrowband nature of RF signals 3
1.3 AC circuit analysis – a brief review 3
1.4 Impedance and admittance 4
1.5 Series resonance 4
1.6 Parallel resonance 5
1.7 Nonlinear circuits 5
Problems 5

2 Impedance matching 10
2.1 Transformer matching 11
2.2 L-networks 12
2.3 Higher Q – pi and T-networks 14
2.4 Lower Q – the double L-network 15
2.5 Equivalent series and parallel circuits 16
2.6 Lossy components and efficiency of matching networks 16
Problems 17

3 Linear power amplifiers 19
3.1 Single-loop amplifier 19
3.2 Drive circuitry: common-collector, common-emitter, and common-base 20
3.3 Shunt amplifier topology 22
3.4 Dual-polarity amplifiers 22
3.5 Push–pull amplifiers 23
3.6 Efficiency calculations 25
3.7 AC amplifiers 26

3.8 RF amplifiers 29
3.9 Matching a power amplifier to its load 31
Problems 31

4 Basic filters 34
4.1 Prototype lowpass filter designs 35
4.2 A lowpass filter example 36
4.3 Lowpass-to-bandpass conversion 38
Appendix 4.1 Component values for normalized lowpass filters 41
Problems 43

Preface

This book was written to help the reader to understand, analyze, and design RF circuits. Developed as a textbook for an RF engineering course at Cornell University, it can also be used for self-study and as a reference for practising engineers. The scope of topics is wide and the level of analysis ranges from introductory to advanced. In each chapter, I have tried to convey an intuitive "how things work" understanding from which the mathematical analysis follows. The initial chapters present the amplifiers, filters, modulators, and demodulators, which are the basic building blocks of radio systems, from AM and FM to the latest digital radio systems. Later chapters alternate between systems, such as television, and radio astronomy, and theoretical topics, such as noise analysis and radio spectrometry. The book provides the RF vocabulary that carries over into microwave engineering, and one chapter is devoted to waveguides and other microwave components.

In this second edition, many chapters have been expanded. Others have been rearranged and consolidated . New chapters have been added to cover radar, the GPS navigation system, digital modulation, information transmission, and *S*-parameter circuit analysis.

The reader is assumed to have a working knowledge of basic engineering mathematics and electronic circuit theory, particularly linear circuit analysis. Many students will have had only one course in electronics, so I have included some fundamental material on amplifier topologies, transformers, and power supplies. The reader is encouraged to augment reading with problem-solving and lab work, making use of mathematical spreadsheet and circuit simulation programs, which are excellent learning aids and confidence builders. Some references are provided for further reading, but whole trails of reference can be found using the internet.

For helpful comments, suggestions, and proofreading, I am grateful to many students and colleagues, especially Wesley Swartz, Dana Whitlow, Bill Sisk, Suman Ganguly, Paul Horowitz, Michael Davis, and Mario Ierkic.

CHAPTER

1

Introduction

Consider the magic of radio. Portable, even hand-held, short-wave transmitters can reach thousands of miles beyond the horizon. Tiny microwave transmitters riding on spacecraft return data from across the solar system. And all at the speed of light. Yet, before the late 1800s, there was nothing to suggest that telegraphy through empty space would be possible even with mighty dynamos, much less with insignificantly small and inexpensive devices. The Victorians could extrapolate from experience to imagine flight aboard a steam-powered mechanical bird or space travel in a scaled-up Chinese skyrocket. But what experience would have even hinted at *wireless* communication? The key to radio came from theoretical physics. Maxwell consolidated the known laws of electricity and magnetism and added the famous displacement current term, $\partial D/\partial t$. By virtue of this term, a changing electric field produces a magnetic field, just as Faraday had discovered that a changing magnetic field produces an electric field. Maxwell's equations predicted that *electromagnetic waves* can break away from the electric currents that generate them and propagate independently through empty space with the electric and magnetic field components of the wave constantly regenerating each other.

Maxwell's equations predict the velocity of these waves to be $1/\sqrt{\varepsilon_0 \mu_0}$ where the constants, ε_0 and μ_0, can be determined by simple measurements of the forces between static electric charges and between current-carrying wires. The dramatic result is, of course, the experimentally-known speed of light, 3×10^8 m/sec. The electromagnetic nature of light is revealed. Hertz conducted a series of brilliant experiments in the 1880s in which he generated and detected electromagnetic waves with wavelengths very long compared to light. The utilization of Hertzian waves (electromagnetic waves) to transmit information developed hand-in-hand with the new science of electronics.

Where is radio today? AM radio, the pioneer broadcast service, still exists, along with FM, television and two-way communication. But radio now also includes digital broadcasting formats, radar, surveillance, navigation and broadcast satellites, cellular telephones, remote control devices, and wireless data communications. Applications of radio frequency (RF) technology outside

Figure 1.1. The radio spectrum.

radio include microwave heaters, medical imaging systems, and cable television. Radio occupies about eight decades of the electromagnetic spectrum, as shown in Figure 1.1.

1.1 RF circuits

The circuits discussed in this book generate, amplify, modulate, filter, demodulate, detect, and measure ac voltages and currents at radio frequencies. They are the blocks from which RF systems are designed. They scale up and down in both power and frequency. A six-section bandpass filter with a given passband shape, for example, might be large and water-cooled in one application but subminiature in another. Depending on the frequency, this filter might be made of sheet metal boxes and pipes, of solenoidal coils and capacitors, or of piezoelectric mechanical resonators, yet the underlying circuit design remains the same. A class-C amplifier circuit might be a small section of an integrated circuit for a wireless data link or the largest part of a multi-megawatt broadcast transmitter. Again, the design principles are the same.

1.2 Narrowband nature of RF signals

Note that most frequency allocations have small fractional bandwidths, i.e., the bandwidths are small compared to the center frequencies. The fractional bandwidth of the signal from any given transmitter is less than 10 percent – usually much less. It follows that the RF voltages throughout a radio system are very nearly sinusoidal. An otherwise purely sinusoidal RF "carrier" voltage[1] must be *modulated* (varied in some way) to transmit information. Every type of modulation (audio, video, pulse, digital coding, etc.) works by varying the amplitude and/or the phase of the sinusoidal RF wave, called the "carrier" wave. An unmodulated carrier has only infinitesimal bandwidth; it is a pure spectral line. Modulation always broadens the line into a spectral band, but the energy clusters around the carrier frequency. Oscilloscope traces of the RF voltages in a transmitter or on a transmission line or antenna are therefore nearly sinusoidal. When modulation is present, the amplitude and/or phase of the sinusoid changes but only over many cycles. Because of this narrowband characteristic, elementary sine wave ac circuit analysis serves for most RF work.

1.3 AC circuit analysis – a brief review

The standard method for ac circuit analysis that treats voltages and currents in linear networks is based on the linearity of the circuit elements: inductors, capacitors, resistors, etc. When a sinusoidal voltage or current generator drives a circuit made of linear elements, the resulting steady-state voltages and currents will all be perfectly sinusoidal and will have the same frequency as the generator. Normally we find the response (voltage and current amplitudes and phases) of driven ac circuits by a mathematical artifice. We replace the given sinusoidal generator by a hypothetical generator whose time dependence is $e^{j\omega t}$ rather than $\cos(\omega t)$ or $\sin(\omega t)$. This source function has both a real and an imaginary part since $e^{j\omega t} = \cos(\omega t) + j\sin(\omega t)$. Such a nonphysical (because it is complex) source leads to a nonphysical (complex) solution. But the real and imaginary parts of the solution are separately good physical solutions that correspond respectively to the real and imaginary parts of the complex source. The value of this seemingly indirect method of solution is that the substitution of the complex source converts the set of linear *differential* equations into a set of easily solved linear *algebraic* equations. When the circuit has a simple topology, as is often the case, it can be reduced to a single loop by combining obvious series and parallel branches. Many computer programs are available to find the currents and voltages in complicated ac circuits. Most versions of SPICE will do this steady-state ac analysis (which is much simpler than the transient analysis which is their primary function). Special linear ac analysis programs for RF and microwave work such as Agilent's ADS and MMICAD include circuit models for strip lines, waveguides, and other RF components. You can write your own program to analyze ladder networks (see Problem 1.3) and to analyze most filters and matching networks.

---

[1] There is no low-frequency limit for radio waves but the wavelengths corresponding to audio frequencies, hundreds to thousands of kilometers, make it inefficient to connect an audio amplifier directly to an antenna of reasonable size. Instead, the information is impressed on a carrier wave whose wavelength is compatible with practical antennas.

1.4 Impedance and admittance

The coefficients in the algebraic circuit equations are functions of the complex *impedances* (V/I), or *admittances* (I/V), of the RLC elements. The voltage across an inductor is $L\mathrm{d}I/\mathrm{d}t$. If the current is $I_0\mathrm{e}^{\mathrm{j}\omega t}$, then the voltage is $(\mathrm{j}\omega L)I_0\mathrm{e}^{\mathrm{j}\omega t}$. The impedance and admittance of an inductor are therefore respectively $\mathrm{j}\omega L$ and $1/(\mathrm{j}\omega L)$. The current into a capacitor is $C\mathrm{d}V/\mathrm{d}t$, so its impedance and admittance are $1/(\mathrm{j}\omega C)$ and $\mathrm{j}\omega C$. The impedance and admittance of a resistor are just R and $1/R$. Elements in series have the same current so their total impedance is the sum of their separate impedances. Elements in parallel have the same voltage so their total admittance is the sum of their separate admittances. The real and imaginary parts of impedance are called *resistance* and *reactance* while the real and imaginary parts of admittance (the reciprocal of impedance) are called *conductance* and *susceptance*.

1.5 Series resonance

A capacitor and inductor in series have an impedance $Z_\mathrm{s} = \mathrm{j}\omega L+1/(\mathrm{j}\omega C)$. This can be written as $Z_\mathrm{s} = \mathrm{j}(L/\omega)(\omega^2 - 1/[LC])$, so the impedance is zero when the (angular) frequency is $1/\sqrt{LC}$. At this *resonant frequency*, the series LC circuit is a perfect *short circuit* (Figure 1.2). Equal voltages are developed across the inductor and capacitor but they have opposite signs and the net voltage drop is zero.

At resonance and in the steady state there is no transfer of energy in or out of this combination. (Since the overall voltage is always zero, the power, IV, is always zero.) However, the circuit does contain *stored* energy which simply sloshes back and forth between the inductor and the capacitor. Note that this circuit, by itself, is a simple bandpass filter.

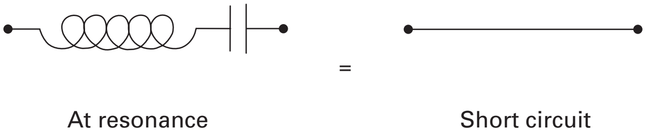

Figure 1.2. Series-resonant LC circuit.

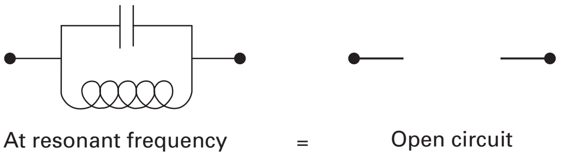
1.6 Parallel resonance

A capacitor and an inductor in parallel have an admittance $Y_p = j\omega C + 1/(j\omega L)$ which is zero when the (angular) frequency is $1/\sqrt{LC}$. At this resonant frequency, the parallel *LC* circuit is a perfect *open circuit* (Figure 1.3) – a simple bandstop filter.

Like the series *LC* circuit, the parallel *LC* circuit stores a fixed quantity of energy for a given applied voltage. These two simple combinations are important building blocks in RF engineering.

Figure 1.3. Parallel-resonant *LC* circuit.



1.7 Nonlinear circuits

Many important RF circuits, including mixers, modulators, and detectors, are based on nonlinear circuit elements such as diodes and saturated transistors used as switches. Here we cannot use the linear $e^{j\omega t}$ analysis but must use time-domain analysis. Usually the nonlinear elements can be replaced by simple models to explain the circuit operation. Full computer modeling can be used for accurate circuit simulations.

Problems

Problem 1.1. A generator has a source resistance r_S and an open circuit rms voltage V_0. Show that the maximum power available from the generator is given by $P_{max} = V_0^2/(4r_S)$ and that this maximum power will be delivered when the load resistance, R_L, is equal to the source resistance, r_S.

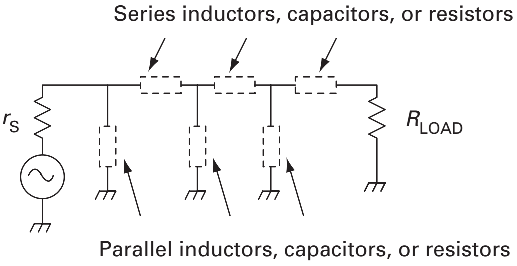
Problem 1.2. A passive network, for example a circuit composed of resistors, inductors, and capacitors, is placed between a generator with source resistance r_S and a load resistor, R_L. The *power response* of the network (with respect to these resistances) is defined as the fraction of the generator's maximum available power that reaches the load. If the network is *lossless*, that is, contains no resistors or other dissipative elements, its power response function can be found in terms of the impedance, $Z_{in}(\omega) = R(\omega) + jX(\omega)$, seen looking into the network with the load connected. Show that the expression for the power response of the lossless network is given by

$$P(\omega) = \frac{4r_S R(\omega)}{(R(\omega) + r_S)^2 + X(\omega)^2}$$

where $R = \text{Re}(Z_{in})$ and $X = \text{Im}(Z_{in})$.

Problem 1.3. Most filters and matching networks take the form of the ladder network shown below.

Ladder network topology.



Series inductors, capacitors, or resistors
r_S
R_{LOAD}
Parallel inductors, capacitors, or resistors

Write a program whose input data is the series and shunt circuit elements and whose output is the power response as defined in Problem 1.2.

Hints: One approach is to begin from the load resistor and calculate the input impedance as the elements are added, one by one. When all the elements are in place, the formula in Problem 1.2 gives the power response – as long as the load resistor is the only resistor. The process is repeated for every desired frequency.

A better approach, which is no more complicated and which allows resistors, is the following: Assume a current of 1 + j0 ampere is flowing into the load resistor. The voltage at this point is therefore $R_L + j0$ volts. Move to the left one element. If this is a series element, the current is unchanged but the voltage is higher by IZ where Z is the impedance of the series element. If the element is a shunt element, the voltage remains the same but the input current is increased by VY where Y is the admittance of the shunt element. Continue adding elements, one at a time, updating the current and voltage. When all the elements are accounted for, you have the input voltage and current and could calculate the total input impedance of the network terminated by the load resistor. Instead, however, take one more step and treat the source resistance, r_S, as just another series impedance. This gives you the voltage of the source generator, from which you can calculate the maximum power available from the source. Since you already know the power delivered to the load, $(1)^2 R_L$, you can find the power response. Repeat this process for every desired frequency.

The ladder elements (and, optionally, the start frequency, stop frequency, frequency increment, and source and load resistances) can be treated as data, that is, they can be located together in a block of program statements or in a file so they can be changed easily. For now, the program only needs to deal with six element types: series and parallel inductors, capacitors, and resistors. Each element in the circuit file must therefore have an identifier such as “PL”, “SL”, “PC”, “SC”, “PR”, and “SR” or 1, 2, 3, 4, 5, 6, or whatever, plus the value of the component in henrys, farads, or ohms. Organize the circuit file so that it begins with the element closest to R_L and ends with some identifier such as “EOF” (for “End Of File”) or some distinctive number.

An example program, which produces both tabular and graphical output, is shown below, written in MATLAB, which produces particularly compact and readable code. The input data (included as program statements) is for the circuit shown below, of an LC network designed to connect a 50-ohm load to a 1000-ohm source. You will find this, or your own equivalent program, to be a useful tool when designing matching networks and filters. In the problems for Chapters 4, 10, 14, and 17, the program will be enhanced to plot phase response and to handle transmission lines, transformers, and transistors, making it a powerful design tool.

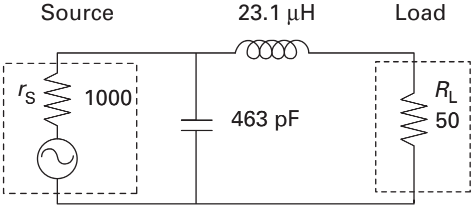
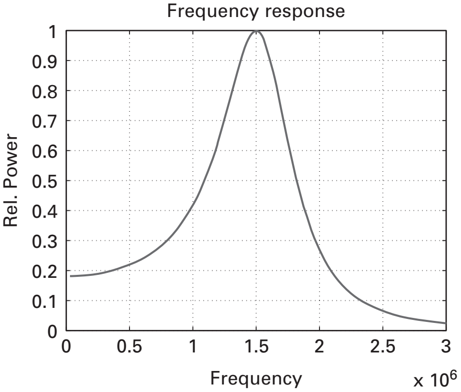
The circuit corresponding to the input data statements in the example program above is shown below, together with the analysis results produced by the program.

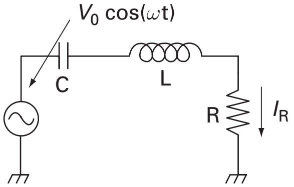
Example circuit.



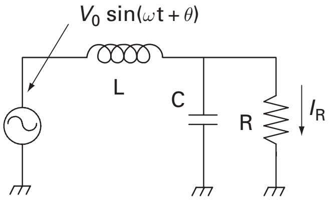
Analysis results.



Problem 1.4. (AC circuit analysis review problem.) For the circuit in the figure, derive an expression for $I_R(t)$. Use a complex source voltage, $V_0e^{j\omega t}$, the real part of which is $V_0\cos(\omega t)$. The impedances of C, L, and R are $(j\omega C)^{-1}, j\omega L$, and R, respectively. Find the complex current through the resistor. $I_R(t)$ will be the real part of this complex current.



Problem 1.5. (More AC circuit analysis review.) For the circuit in the figure, derive an expression for $I_R(t)$. Note that the source voltage, $V_0 \sin(\omega t + \theta)$, is equal to the *imaginary* part of $V_0 e^{j(\omega t+\theta)}$. Therefore, if we take the complex voltage to be $V_0 e^{j(\omega t+\theta)}$, $I_R(t)$ will be the imaginary part of the complex current through R. Alternatively, you can let the complex voltage source have the value $-jV_0 e^{j(\omega t+\theta)}$, the real part of which is $V_0 \sin(\omega t)$. With this source, $I_R(t)$ is the real part of the complex current through R.



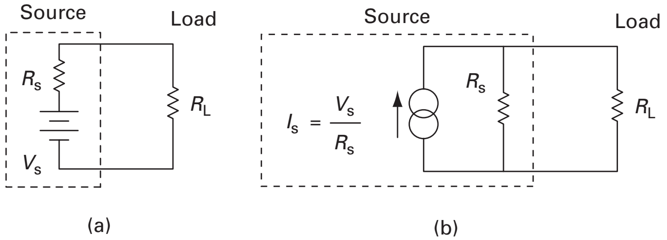
CHAPTER

2

Impedance matching

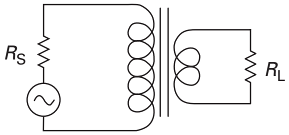
Matching normally means the use of a lossless (nonresistive) network between a signal source and a load in order to maximize the power transferred to the load. This presupposes that the source is not capable of supplying infinite power, i.e., that the source is not just an ideal voltage generator or an ideal current generator. Rather, the source is assumed to be an ideal voltage generator in series with a source impedance, i.e., a Thévenin equivalent circuit, or an ideal current generator in parallel with a source admittance, a Norton equivalent circuit. Note that these equivalent circuits are themselves equivalent; each can be converted into the form of the other. An antenna that is feeding a receiver is an example of an ac signal source connected to a load. Figure 2.1 shows the simplest situation, a dc generator driving a resistive load. The generator is represented in Thévenin style (a) and in Norton style (b).

Figure 2.1. DC generator driving a resistive load, Equivalent circuits.



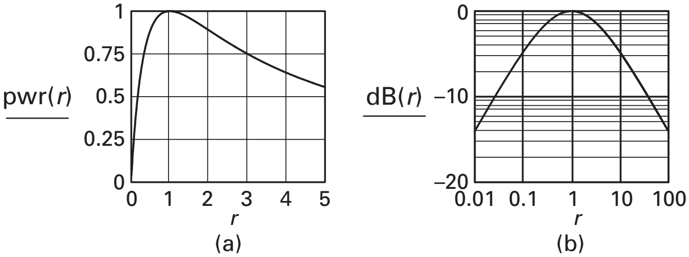
You can see the equivalence by inspection: the generators have the same open-circuit voltage and the same short-circuit current. Maximum power is transferred when the load resistance is made equal to the source resistance. You can show this by differentiating the expression for the power, $P_{\text{load}} = [V_S\, R_L/(R_L{+}R_S)]^2/R_L$. Figure 2.2 plots the relative transferred power (Pwr/MaxPwr) as a function of the normalized load resistance ($r = R_L/R_S$). In (a) the scales are linear and in (b) the scales are logarithmic so the relative power is expressed in dB. Note that R_L can differ by a factor of 10 from R_S and the power transferred is still 33% of the maximum value.

Figure 2.3. Transformer converts R_L to R_S for maximum power transfer.



2.1 Transformer matching

Figure 2.2. Relative power transfer as a function of R_L/R_S, (=r)



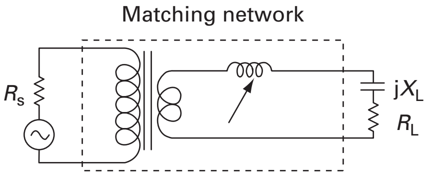
(a)

(b)

In the case of an ac source, a transformer can make the load resistance match (equal) the source resistance (and vice versa) as shown in Figure 2.3. The impedance is transformed by the square of the turns ratio.[1]

The ac situation often has a complication: the source and/or the load may be reactive, i.e., have an unavoidable built-in reactance. An example of a reactive load is an antenna; most antennas are purely resistive at only one frequency. Above this resonant frequency they usually look like a resistance in series with an inductor and below the resonant frequency they look like a resistance in series with a capacitor. An obvious way to deal with this is first to cancel the reactance to make the load and/or source impedance purely resistive and then use a transformer to match the resistances. In the circuit of Figure 2.4, an inductor cancels

Figure 2.4. A series reactor makes the load a pure resistance.



---

[1] Let the secondary winding be the load side. Then $V_{sec} = V_{pri}\, N_{sec}/N_{pri}$. For energy to be conserved, $V_{pri}I_{pri} = V_{sec}I_{sec}$. Therefore $I_{sec} = I_{pri}\, N_{pri}/N_{sec}$ and $V_{pri}/I_{pri} = (V_{sec}/I_{sec})\,(N_{pri}/N_{sec})^2$ or $Z_{pri} = Z_{sec}(N_{pri}/N_{sec})^2$.

the reactance of a capacitive (but not purely capacitive) load. If we are working at 60 Hz, we would say the inductor corrects the load's power factor.

From the standpoint of the load, the matching network converts the source impedance, $R_S + j0$, into the complex conjugate of the load impedance. When a matching network is used between two devices, each device will look into an impedance that is the complex conjugate of its own impedance. As a result, the reactances cancel and the resistances are equal. Whenever the source and/or load have a reactive component, the match will be frequency dependent, i.e., away from the design frequency the match will not be perfect. In fact, with reactive sources and/or reactive loads, *any* lossless matching circuit will be frequency dependent – a filter of some kind – whether we like it or not.

2.2 L-networks

More often than not, matching circuits use no transformers (i.e., no coupled inductors). Figure 2.5 shows a two-element L-network (in this figure, a rotated letter L) that will match a source to a load resistor whose resistance is smaller than the source resistance. The trick is to put a reactor, X_P, in *parallel* with the *larger* resistance. Consider a specific example: $R_S = 1000$ and $R_L = 50$.

The impedance of the left-hand side is given by

$$Z_{\text{left}} = R_{\text{left}} + jX_{\text{left}} = \frac{1000\,jX_P}{1000 + jX_P} = \frac{(1000jX_P)(1000 - jX_P)}{(1000 + jX_P)(1000 - jX_P)}$$

$$= \frac{1000^2 jX_P + 1000X_P^2}{1000^2 + X_P^2}. \tag{2.1}$$

We can pick the value of X_P so that the real part of Z_{left} will be 50 ohms, i.e., equal to the load resistance. Using Equation (2.1), we find that $X^2_P = 52\,628$ so we can pick either $X_P = 229$ (an inductor) or $X_P = -229$ (a capacitor). The left-hand side now has the correct equivalent series resistance, 50 ohms, but it is accompanied by an equivalent series reactance, X_{left}, given by the imaginary part of Equation (2.1). We can cancel X_{left} by inserting a series reactor, X_S, equal to $-X_{\text{left}}$. Figure 2.6 shows the matching circuits that result when X_P is an inductor and when X_P is a capacitor.

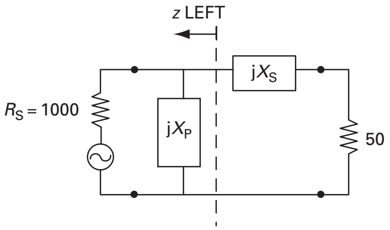


Figure 2.5. Two reactors in an L-network match R_L to R_S.

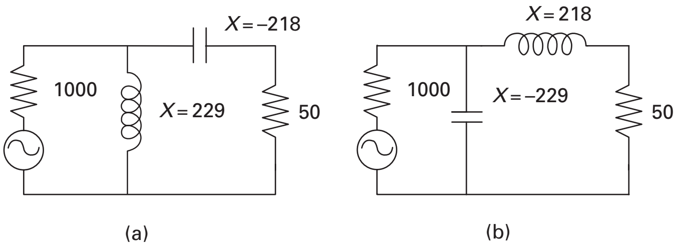

Figure 2.6. The two realizations for the L-network of Figure 2.5.

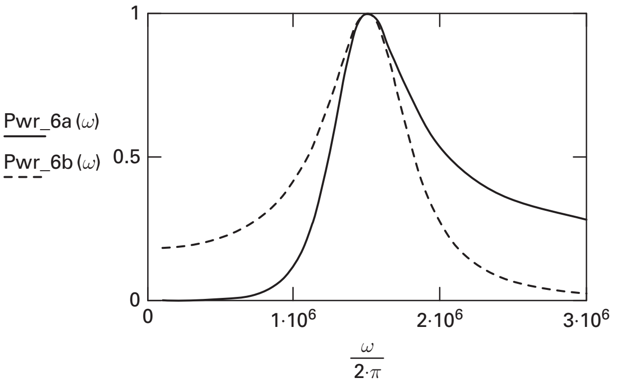

Figure 2.7. Frequency response (power vs. frequency) for the L-networks of Figure 2.6.

The final step is to find the values of L and C that produce the specified reactances at the given frequency. For the circuit of Figure 2.6(b), $\omega L = 218$. Suppose the design frequency is 1.5 MHz ($\omega = 2\pi \cdot 1.5 \cdot 10^6$), near the top of the AM broadcast band. Then $L = 23.1\ \mu\text{H}$ and $C = 462\ \text{pF}$. Note that the values of the two reactors are completely determined by the source and load resistances. Except for the choice of which element is to be an inductor and which is to be a capacitor, there are no free parameters in this two-element matching circuit. The match is perfect at the design frequency but, away from that frequency, we must accept the resulting frequency response. The frequency responses (fractional power reaching the load vs. frequency) for the two circuits of Figure 2.6 are plotted in Figure 2.7. Note that around the design frequency, i.e., around the resonant peak, the curves are virtually identical. Otherwise, the complete cutoff at very low frequencies of Figure 2.6a and the complete cutoff at very high frequencies of Figure 2.6b can be predicted from inspection of the circuits.

Quick design procedure for L-networks

If you remember only that the parallel reactance goes across the larger resistance you will be able to repeat the steps used above and design L-networks. But if you are doing these things often it may be worth memorizing the following "Q factor" for L-network design:

$$Q_{\mathrm{EL}} = \sqrt{\frac{R_{\mathrm{high}}}{R_{\mathrm{low}}} - 1}. \tag{2.2}$$

You can verify (Problem 2.6) that the ratios $R_{\mathrm{high}}/X_{\mathrm{parallel}}$ and $X_{\mathrm{series}}/R_{\mathrm{low}}$ are both equal to this factor, Q_{EL}. Remember the definition of Q_{EL} and these ratios immediately give you the L-network reactance values. You can also verify that, when Q_{EL} is large, the two elements in an L-network have nearly equal and opposite reactances, i.e., together they resonate at the design frequency. In this case the magnitude of the reactances is given by the geometric mean of R_{high} and R_{low} (especially easy to remember).

When the ratio of the source resistance to the load resistance is much different from unity, an L-network produces a narrowband match, i.e., the match will be good only very close to the design frequency. Conversely, when the impedance ratio is close to unity, the match is wide. The width of any resonance phenomenon is described by a factor, *the effective Q* (or *circuit Q* or just *Q*), which is equal to the center frequency divided by the two-sided 3-dB bandwidth (the difference between the half-power points). Equivalently, Q_{eff} is the reciprocal of the fractional bandwidth. When an ideal voltage generator drives a simple *RLC* series circuit, Q_{eff} is given by X/R where X is either X_L or X_C at the center frequency (since they are equal). The L-network matching circuit is equivalent to a simple series *RLC* circuit, but Q_{EL} is twice Q_{eff} because the nonzero source resistance is also in series; the matching circuit makes the effective source resistance equal to the load resistance so the loop's total series resistance is twice the load resistance. As a result, the fractional bandwidth is given by $1/Q_{\mathrm{eff}} = 2/Q_{\mathrm{EL}}$. In many applications the bandwidth of the match is important and the match provided by the L-network (which is completely determined by the source and load resistances) may be too narrow or too wide. When matching an antenna to a receiver, for example, one wants a narrow bandwidth so that signals from strong nearby stations won't overload the receiver. In another situation the signal produced by a modulated transmitter might have more bandwidth than the L-network would pass. Networks described below solve these problems.

2.3 Higher *Q* – pi and T-networks

Higher *Q* can be obtained with back-to-back L-networks, each one transforming down to a center impedance that is lower than either the generator or the source resistance. The resulting pi-network is shown in Figure 2.8.

With the simple L-networks we had $Q_{\mathrm{EL}} = \sqrt{19} = 4.4$. In this pi-network both the 1000-ohm source and the 50-ohm load are matched down to a center impedance of 10 ohms (a free parameter). The bandwidth is equivalent to that of an L-network with $Q_{\mathrm{EL}} = 11.95$. When $R_{\mathrm{HIGH}} \gg R_{\mathrm{LOW}}$, the pi-network has a bandwidth equivalent to that of an L-network with $Q_{\mathrm{EL}} = \sqrt{R_{\mathrm{HIGH}}/R_{\mathrm{CENTER}}}$. Again, the fractional bandwidth is given by $1/Q_{\mathrm{eff}} = 2/Q_{\mathrm{EL}}$.

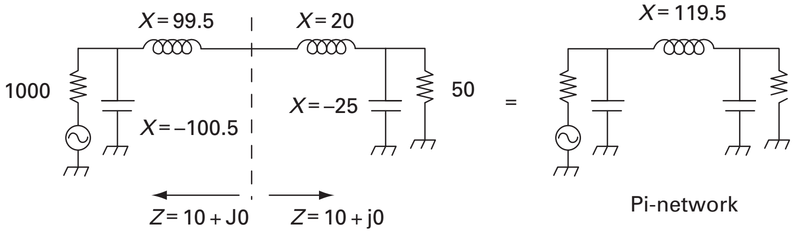

Figure 2.8. Pi-network (back-to-back L-networks) provides higher *Q*.

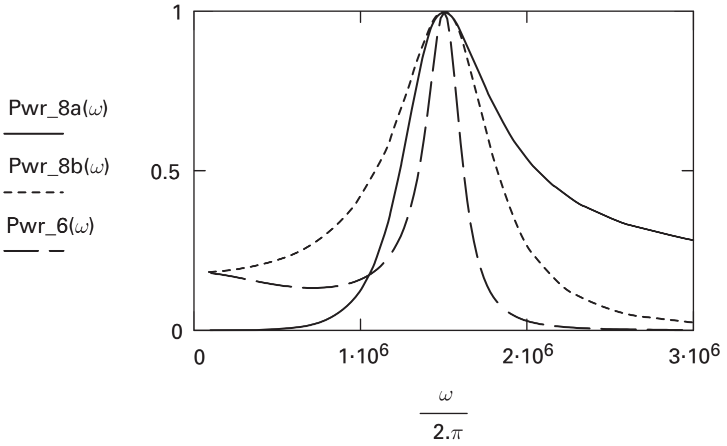

Figure 2.9. Response of the pi-network of Figure 2.8 compared with the L-networks of Figure 2.6.

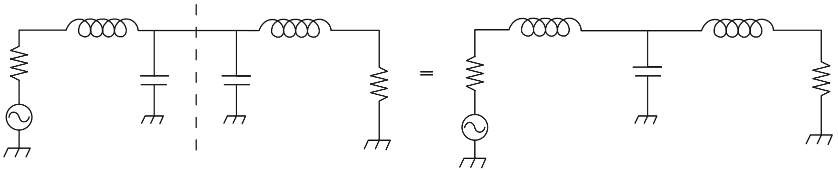

Figure 2.10. The T-network, like the pi-network, provides higher *Q*.

The response of this pi-network is shown in Figure 2.9 together with the responses of the L-networks of Figure 2.6.

You can guess that we could just as well have used "front-to-front" L-networks, each one transforming up to a center impedance that is higher than both the source and load impedances. This produces the T-network of Figure 2.10. Note that both the pi-network and the T-network have a free parameter (the center impedance) which gives us some control over the frequency response while still providing a perfect match at the center or design frequency.

2.4 Lower *Q* – the double L-network

In a double L-network (Figure 2.11) the first stage transforms to an impedance value between the source and load impedances. The second stage takes it the

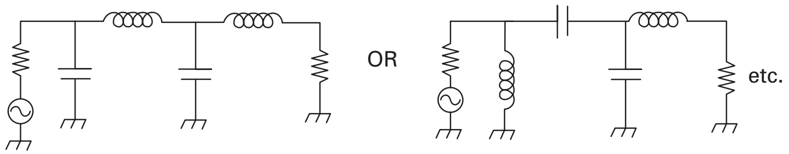

Figure 2.11. Double L-network for lower Q (wider bandwidth).

rest of the way. The process can, of course, be done in smaller steps with any number of cascaded networks. A long chain of L-networks forms an artificial transmission line that tapers in impedance to produce a frequency-independent match. Real transmission lines (i.e., lines with distributed L and C) are sometimes physically tapered to provide this kind of impedance transformation. A tapered transmission line is sometimes called a transformer, since, like the transformer in Figure 2.3, it provides frequency-independent matching.

2.5 Equivalent series and parallel circuits

To design the L-network we used the fact that a two-element parallel XR circuit, where $1/Z = 1/R_{\text{parallel}} + 1/\mathrm{j}X_{\text{parallel}}$, has an equivalent series circuit, where $Z = R_{\text{series}} + \mathrm{j}X_{\text{series}}$. Conversion between equivalent series and parallel representations is used so often it is worth a few more words. If you are given, for example, an antenna or a black box with two terminals and you make measurements at a *single frequency* you can only determine whether the box is "capacitive," i.e., equivalent to an RC combination, or is "inductive," i.e., equivalent to an RL combination. Suppose it is capacitive. Then you can represent it equally well as a series circuit where $Z = R_{\text{series}} + 1/\mathrm{j}\omega C_{\text{series}}$ or as a parallel circuit where $1/Z = 1/R_{\text{parallel}} + \mathrm{j}\omega C_{\text{parallel}}$. As long as you're working only at (or never very far from) the single frequency, either representation is equally valid, even if the box contains a complicated circuit with discrete resistors, capacitors, inductors, transmission lines, metallic and resistive structures, etc. If you measure the impedance at more than one frequency you might determine that the box does indeed contain a simple parallel RC or series RC circuit or that its impedance variation at least resembles that of a simple parallel circuit more than it resembles that of a simple series circuit.

2.6 Lossy components and efficiency of matching networks

So far we have considered networks made of ideal inductors and capacitors. Real components, however, are lossy due to the finite conductivity of metals, lossy dielectrics or magnetic materials, and even radiation. Power dissipated in nonideal components is power that does not reach the load so, with lossy components, we must consider a matching network's efficiency. As explained above, a lossy reactor can be modeled as an ideal L or C together with either a series or parallel resistor. Normally we can make the approximation that the values of L or C and the value of the associated resistor are constant throughout the band of interest. Let us consider the efficiency of the L-network that uses a series inductor and a parallel capacitor. We shall assume that the loss in the capacitor is negligible compared to the loss in the inductor. (This is very often the case with lumped components.) We shall model the lossy inductor as an ideal inductor in series with a resistor of value r_S. The ratio of the inductive reactance, X_L, to this resistance value is the *quality factor*, Q_U, where the subscript denotes "*unloaded Q*" or *component Q*. (Less series resistance certainly implies a higher quality component.) Note that this resistance, like the inductor, is in series with the load resistor so the same current, I, flows through both. The power delivered to the load is I^2R_L and the power dissipated in r_S is I^2r_S. Using the relations $X_S = Q_{EL}R_{load}$ and $Q_U = X_S/r_S$, we find the efficiency of the match is given by

$$\eta = \text{Efficiency} = \frac{\text{Power Out}}{\text{Power In}} = \frac{I^2R_L}{I^2R_L + I^2r_S} = \frac{1}{1 + Q_{EL}/Q_U}. \tag{2.3}$$

Efficiency is maximized by maximizing the ratio Q_U/Q_{EL}, i.e., the ratio of unloaded Q to loaded Q. If we model the lossy inductor as a parallel LR circuit and define the unloaded Q as r_P/X we would get the same expression for efficiency (Problem 2.7). Likewise, if the loss occurs in the capacitor we will also get this expression, as long as we define the unloaded Q of the capacitor again as parallel resistance over parallel reactance or as series reactance over series resistance. When the load resistance is very different from the source resistance, the effective Q of an L-network will be high so, for high efficiency, the unloaded Q of the components must be very high. The double L-network, with its lower loaded Q's, can be used to provide higher efficiency.

Q factor summary

Loaded Q, the Q factor associated with *circuits*, can be either high or low depending on the application. Narrowband filters have high loaded Q. Wideband matching circuits have low loaded Q. Loaded Q is therefore not a measure of quality. Unloaded Q, however, which specifies the losses in *components*, is indeed a measure of quality since lowering component losses always increases circuit efficiency.

Problems

Problem 2.1. A nominal 47-ohm, $\frac{1}{4}$-watt carbon resistor with 1.5 inch wire leads is measured at 100 MHz to have an impedance of 48+j39 ohms. Find the component values for (a) an equivalent series RL circuit, and (b) an equivalent parallel RL circuit.

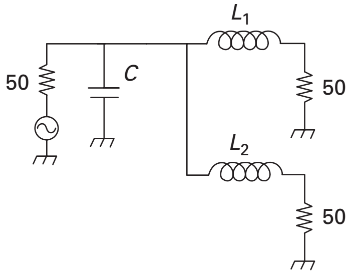
Problem 2.2. (a) Design an L-network to match a 50-ohm generator to a 100-ohm load at a frequency of 1.5 MHz. Let the parallel element be an inductor. Use your circuit analysis program (Problem 1.3) to find the frequency response of this circuit from 1 MHz to 2 MHz in steps of 50 kHz.

(b) Same as (a), but let the parallel element be a capacitor.

Problem 2.3. Design a double L matching network for the generator, source, and frequency of Problem 2.2(a). For maximum bandwidth, let the intermediate impedance be the geometric mean of the source impedance and the load impedance, i.e., $\sqrt{50 \cdot 100}$. Use your circuit analysis program (Problem 1.3) to find the response as in Problem 2.2.

Problem 2.4. Suppose the only inductors available for building the networks of Problems 2.2(a) and 2.3 have a Q_U (unloaded Q) of 100 at 1.5 MHz. Assume the capacitors have no loss. Calculate the efficiencies of the matching networks at 1.5 MHz. Check your results using your circuit analysis program.

Problem 2.5. The diagram below shows a network that allows a 50-ohm generator to feed two loads (which might be antennas). The network divides the power such that the top load receives twice as much power as the bottom load. The generator is matched, i.e., it sees 50 ohms. Find the values of X_{L1} , X_{L2} and X_C. Hint: transform each load first with an L-section network and then combine the two networks into the circuit shown.



Problem 2.6. Verify the prescription given for calculating the values of an L-network: $X_P = \pm R/Q$ and $X_S = \mp rQ$ where $R > r$ and $Q = \sqrt{R/r - 1}$.

Problem 2.7. At a single frequency, a lossy inductor can be modeled as a lossless inductor in series with a resistance or as a lossless inductor in parallel with a resistance. Convert the series combination r_S, L_S to its equivalent parallel combination r_P, L_P and show that Q_U defined as X_S/r_S is equal to Q_U defined as r_P/X_P.

CHAPTER

3

Linear power amplifiers

An amplifier is a circuit designed to impose a specified voltage waveform, $V(t)$, or, sometimes, a specified current waveform, $I(t)$, upon the terminals of a device known as the "load." The specified waveform is often supplied in the form of an analog "input signal" such as the millivolt-level signal from a dynamic microphone. In a public address system, an audio amplifier produces a scaled-up copy of the microphone voltage (the input signal) and this amplified voltage (the output signal) is connected to a loudspeaker (the load). An audio amplifier generally supplies more than a watt to the loudspeaker. The microphone cannot supply more than milliwatts, so the audio amplifier is a power amplifier as well as a voltage amplifier. The ability to amplify power is really the defining characteristic of an amplifier. Of course energy must be conserved; amplifiers contain or are connected to power supplies, usually batteries or power line-driven ac-to-dc converter circuits, originally known as "battery eliminators" but long since simply called "power supplies" (see Chapter 29). The amplifiers discussed in this chapter are the basic "resistance-controlled"[1] circuits in which transistors (or vacuum tubes) are used as electronically variable resistors to control the current through the load. Such circuits span the range from monolithic op-amps to the output amplifiers in high-power microwave transmitters.

3.1 Single-loop amplifier

Figure 3.1 shows the simplest resistance-controlled amplifier. This circuit is just a resistive voltage divider. The manually variable resistor (rheostat) in (a) represents the electronically variable resistor (transistor) in (b). Remember that the main current path through the transistor is between the emitter and the

---

[1] Resistance-controlled amplifier are also called *linear* amplifiers, to distinguish them from *switching* amplifiers, which are discussed in Chapters 9 and 29. Note, however, that *linear amplifier* is also used to denote amplifiers whose output waveform is a faithful (linearly proportional) copy of the input.

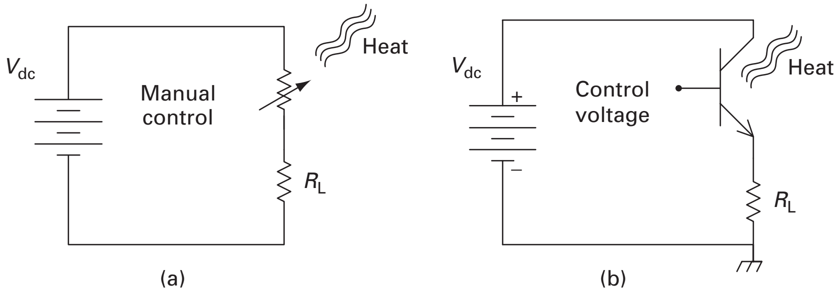


Figure 3.1. Basic single-loop amplifier.

collector; the current through the control terminal, the base, is typically less than 1% of the emitter-collector current. The base voltage can vary the transistor's resistance from infinity to almost zero so any arbitrary current waveform (within the range of zero to V_{dc}/R_L) can be obtained by using an appropriate corresponding control voltage waveform. The load, represented as a resistor, R_L, could be, for example a heating element, a loudspeaker, a servomotor, or a transmitting antenna.

3.2 Drive circuitry: common-collector, common-emitter, and common-base

We will concentrate on the topologies of the output circuit or "business end" of amplifiers, i.e., the high-current paths between the load and the power supply(s). But let us briefly discuss the drive circuitry that controls the resistance of the transistor(s). The discussion is illustrated with circuits using bipolar transistors, but the basic concepts apply also to FETs and tubes.

In Figure 3.1(b), only one terminal is shown for the control voltage (drive signal) input. When the return connection for the drive signal is made at the bottom of the load resistor, we get the amplifier shown in Figure 3.2. This circuit is called a *common-collector* amplifier because the collector, in common with the drive signal return, is a ground point with respect to *ac* signals, even though it does have a dc voltage.

This circuit is also called an *emitter follower*. The transistor will adjust its current flow to make the instantaneous emitter voltage almost equal to the instantaneous base voltage. Here "almost identical" means a small dc offset (the emitter voltage will be about 0.7 volts less than the base voltage) along with a one or two percent reduction in signal amplitude. The reason the emitter voltage closely follows the base voltage is that the emitter current is a rapidly increasing (exponential) function of the base-to-emitter voltage.

Figure 3.3 shows the *common-emitter* drive arrangement, in which the return for the drive signal is connected to the transistor's emitter. It is common to rearrange the circuit as in (b), so that the return connection for the drive signal and the negative terminal of the supply are at the same point (ground).

Figure 3.2. The emitter follower.

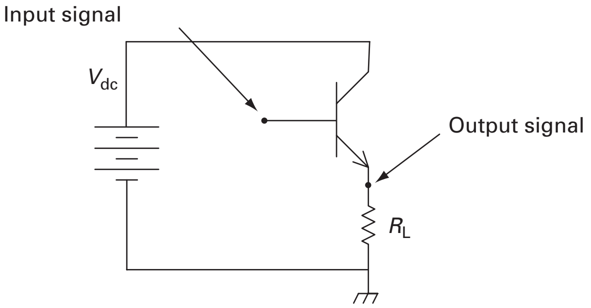

Figure 3.3. Common-emitter amplifier.

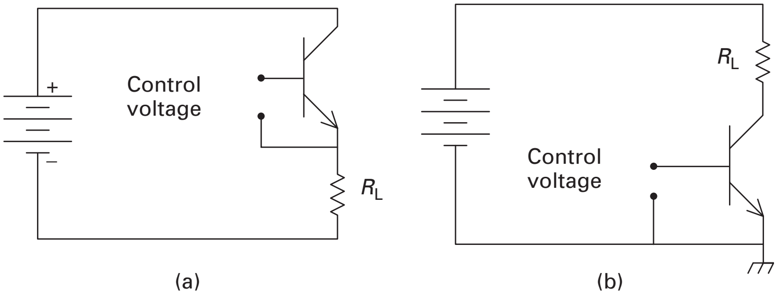

Figure 3.4. Common-base amplifier.

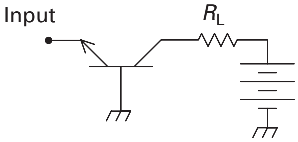


With the drive voltage placed directly across the base-emitter junction, the transistor current is a nonlinear (exponential) function of the drive voltage, and the output voltage (voltage across the load) will not be an accurate scaled version of the drive voltage. A special driver circuit can be used to generate an inverse exponential (logarithmic) drive signal to linearize the amplifier. This happens automatically if the base drive is a current waveform; the output current (and hence the voltage across the load) will have the same waveform shape as the base current. It is also common to use a negative feedback correction loop to force the output signal to follow the input signal. The common-emitter amplifier can supply voltage amplification as well as power amplification.

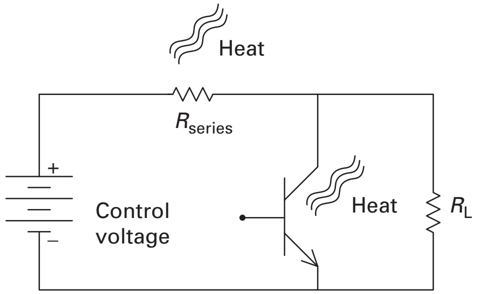
The third and final base drive arrangement, common-base, is shown in Figure 3.4. In this circuit the drive current flows through the main loop. Gain is obtained because, while the driver and load have essentially the same current (the base current might be only one percent as large as the collector-emitter current), the voltage swing at the collector, determined by the supply voltage, is much greater than the voltage swing at the emitter, determined by the near short-circuit base-emitter junction.

Note that, as in the common-emitter amplifier, the drive signal is applied across the transistor's base-to-emitter junction, so the signal developed across the load resistor will be a nonlinear function of the input voltage. But if the drive voltage is applied to the emitter through a series resistor, the drive current and, hence, the output current, will be essentially proportional to the drive voltage.

3.3 Shunt amplifier topology

In the amplifiers discussed above, the load current is controlled by a transistor in series with the load and the power supply. Another way to vary the current in the load is to divert current around it, as in the shunt circuit amplifier shown in Figure 3.5, where the supply and a series resistor form a (nonideal) current source.

Figure 3.5. Shunt amplifier.

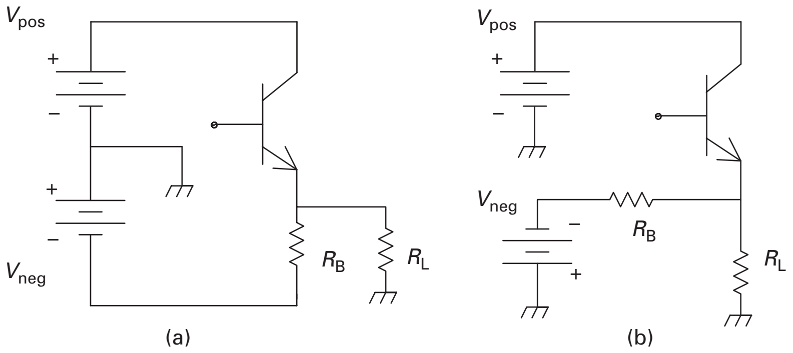


This shunt circuit appears inferior to the series circuit; power will be wasted in the series resistor and the full supply voltage is not available to the load. We will see later, however, that shunt circuits can be used to advantage in *ac* amplifiers which, unlike the general-purpose amplifiers above, are amplifiers designed for signals whose average dc value is zero, e.g., audio and RF signals.

3.4 Dual-polarity amplifiers

If the amplifier must supply output voltages of either polarity and also must handle arbitrary waveforms (as opposed to ac waveforms, whose average dc value is zero) it will require a circuit with two power supplies (or a single "floating" power supply, as we shall see later). The two-loop circuit shown in Figure 3.6 still uses only one transistor.

Here R_B pulls the output toward the negative supply as much as the transistor allows. The voltage on the load is determined by a tug of war between R_B and the transistor. Note that this circuit is a combination of the series and shunt amplifier arrangements. If we make $V_{NEG} = -2\ V_{POS}$ and $R_B = R_L$, you can see



(a) (b)

Figure 3.6. A dual-supply, single-transistor amplifier (drawn in two ways).

that the maximum negative swing will be equal to the maximum positive swing. A constant *bias* current is maintained in the transistor to set the output voltage at zero when the input signal is zero. The maximum efficiency is calculated in the next section, and is only $\frac{1}{12}$. Biased amplifiers (this one and everything discussed so far), which draw current from the supply(s) even when the input signal is zero, are known as *class-A* amplifiers. They are commonly used where their low efficiency is not a problem.

3.5 Push–pull amplifiers

The two-transistor *push–pull* configuration shown in Figure 3.7 provides output voltage of both polarities and has high efficiency compared to the single-transistor amplifiers. (Note: non-push–pull amplifiers are often called “single-ended” amplifiers.)

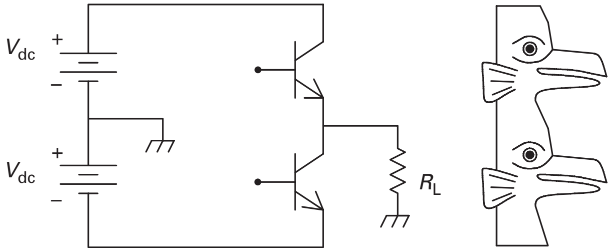


Figure 3.7. Totem pole push–pull amplifier.

The top transistor allows the top supply to “push” current into the load. The lower transistor lets the lower supply “pull” current from the load. The push–pull circuit is the circuit of choice for arbitrary waveforms. The efficiency, calculated in the next section, is $\pi/4$ (78%) for a sine wave of maximum amplitude. Since there are no series resistors, both positive and negative load currents are limited only by the size of the transistors and power supplies. By contrast, the single-transistor circuit of Figure 3.6 can deliver high positive

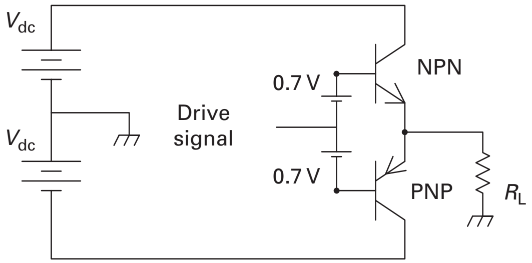

Figure 3.8. Complementary (PNP/NPN) push–pull amplifier.

current but the maximum negative current is limited by R_B.[2] Push–pull amplifiers are normally set up to run as *class-B* amplifiers, which means that, when the input voltage is zero, both transistors are just turned off and there is no power drawn from the supply(s). For low distortion, it is important that the crossover at $I = 0$ be continuous, so sometimes push–pull amplifiers are run class-AB which means that each transistor is given some bias current. Note that the amplifier of Figure 3.7 uses two NPN transistors, placed one above the other like faces on a totem pole. The top transistor acts as an emitter follower; when it is conducting, the output voltage will be almost equal to that transistor's base voltage. The bottom transistor, however, is driven in the common-emitter mode. The two transistors need drive signals of opposite polarities and present different drive impedances, requiring separate and different drive circuits. This unappealing asymmetry is eliminated in the complementary push–pull amplifier shown in Figure 3.8.

The complementary push–pull amplifier uses an NPN and a complementary (identical, except for polarity) PNP transistor. Both operate as emitter followers. Except for the 0.7 V offsets, their bases could be tied together. This can be taken care of, as shown in the figure, by using a pair of 0.7 V batteries. (In practice, this is done with some diode circuitry, rather than batteries.) There is no vacuum tube analog to this circuit, because there are no PNP tubes.[3] For completeness, we note that a third type of push–pull amplifier is obtained by interchanging the transistors in the complementary push–pull amplifier. This circuit, in which both transistors are driven in the common-emitter mode, is found in some switching (one transistor full-on while the other is full-off) servo amplifiers.

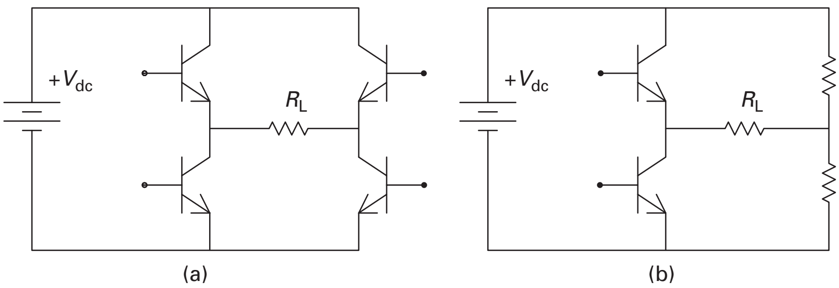
So-called bridge amplifiers are shown in Figure 3.9(a). They use a single power supply, but can supply the load with either polarity.

---

[2] As long as the load is a pure resistor, the pull-down resistor, R_B, is not a problem; any waveform not exceeding the power supply voltage limits can be faithfully amplified. But if the load contains an unavoidable capacitance C_L in parallel with R_L, the amplifier must be able to deliver current $V_{out}/R_L + C_L\, d/dt\, (V_{out})$. See Problem 3.6.

[3] The charge carriers in semiconductors are both electrons (negative) and "holes" (positive). Vacuum tubes use only electrons as charge carriers, although unwanted positive ions are sometimes produced by electron impact.

Figure 3.9. Bridge amplifiers: (a) full bridge (b) half bridge.



These circuits have no direct connection between the power supply and the load; either the supply or the load must “float,” i.e., have no ground connection. In the circuit of Figure 3.9(a), the top pair or bottom pair of transistors can operate as on–off switches (fully conducting or fully turned off). This circuit is a true push–pull amplifier, while the half bridge of Figure 3.9(b) is equivalent to a push-pull amplifier that has resistors in series with the power supples. This reduces the maximum voltage swing as well as the efficiency.

3.6 Efficiency calculations

As we are assuming that the drive power is small compared to the output power, we will calculate efficiency as the ratio of the average output power to the dc input power. Depending on the devices used, this ratio is known as the *collector efficiency*, *drain efficiency*, or *plate efficiency*. Most often, we want to compute the efficiency for the situation in which the amplifier is producing a sinusoidal output at full power (the condition for which the efficiency is usually a maximum).

When calculating efficiency, it is important to remember that average power is the time average of instantaneous power, i.e., the time average of voltage × current. Consider, for example, a power supply of voltage V_{dc} that is furnishing a current $I = I_0 + I_1\cos(\omega t)$. The average power is $\langle V_{dc}(I_0 + I_1\cos(\omega t))\rangle$, where the brackets $\langle\ldots\rangle$ indicate averaging. Since the average of a sum is equal to the sum of the averages, we can expand this expression.

$$\langle V_{dc}(I_0 + I_1\cos(\omega t))\rangle = \langle V_{dc}I_0\rangle + \langle V_{dc}I_1\cos(\omega t)\rangle = V_{dc}I_0, \tag{3.1}$$

since the average value of $\cos(\omega t)$ is zero. When a sine wave $V_0\sin(\omega t)$ is applied to a resistor, the instantaneous power is $VI = [V_0\sin(\omega t)]^2/R$ and the average power is $V_0^2\langle\sin^2(\omega t)\rangle/R = V_0^2/(2R)$.[4] It is also useful to remember that $\langle\sin(\theta)\cos(\theta)\rangle = 0$ and that the average value of $\sin(\theta)$ or $\cos(\theta)$ over one positive loop is equal to $2/\pi$.

---

[4] To see that $\langle\sin^2(\theta)\rangle = 1$, note that $\langle\sin^2(\theta)\rangle = \langle\cos^2(\theta)\rangle$, since the waveforms are identical, and use the identity $\sin^2(\theta) + \cos^2(\theta) = 1$.

We will first calculate the efficiency of the amplifier of Figure 3.6, under the conditions that $R_B = R_L$, $V_{pos} = V_{dc}$, and $V_{neg} = -2V_{dc}$. Let I_L denote the current downward into the load; I_B, the bias current leftward into R_B; and I_E, the current downward from the emitter. Note that $I_E = I_L + I_B$. Assume the maximum signal condition: $V_L = V_{dc} \cos(\omega t)$. This lets us write $I_B = (V_{dc} \cos(\omega t) + 2V_{dc})/R_B$. The power from the negative supply is therefore $P_{neg} = \langle I_B\ 2V_{dc} \rangle = 4V_{dc}^2/R_B$. The current into the load is just $I_L = V_{dc} \cos(\omega t)/R_L$. Adding I_L and I_B, we have $I_E = V_{dc} \cos(\omega t)/R_L + (V_{dc} \cos(\omega t) + 2V_{dc})/R_B$. Since this is the same as the current supplied by the positive supply (ignoring the transistor's small base current), we find that the power from the positive supply is given by $P_{pos} = 2V_{dc}^2/R_B$. The total dc power, P_{dc}, is the sum of P_{pos} and P_{neg}: $P_{dc} = 6V_{dc}^2/R_B$. The power into the load is $V_0^2/(2R_L)$, so the efficiency is given by

$$\eta = \frac{V_{dc}^2/(2R_L)}{6V_{dc}^2/R_B} \tag{3.2}$$

which reduces to $\eta = \frac{1}{12}$ when $R_B = R_L$.

Next we will find the efficiency of the push–pull amplifiers of Figures 3.7 and 3.8. Again, we assume the maximum signal condition, $V_L = V_{dc} \cos(\omega t)$. Consider the top transistor, which conducts during the positive half of the cycle. Assuming negligible base current, the current through this transistor will be the same as the current in the load, $I = (V_{dc} \cos(\omega t))/R_L$. During the positive half-cycle, the positive supply furnishes an average power given by $\langle V_{dc} \times (V_{dc}/R_L) \cos(\omega t) \rangle = (V_{dc}^2/R_L)\, 2/\pi$, since here the average is just over the positive loop. The negative supply, during its half-cycle, furnishes the same average power, since the circuit is symmetric. Thus, the efficiency is given by

$$\eta = \frac{V_{dc}^2/(2R_L)}{(V_{dc}^2/R_L)2/\pi} = \frac{\pi}{4} = 78\%. \tag{3.3}$$

3.7 AC amplifiers

All the amplifiers discussed above are known as *dc amplifiers* because they can handle signals of arbitrarily low frequency. (They might well be called universal amplifiers since they have no high-frequency limitations except those set by the transistors.) Audio and RF signals, however, are pure ac signals: their average value, i.e., their dc component, is zero. For these signals, special *ac amplifier* circuits provide simplicity and efficiency.

The circuit in Figure 3.10(a) is an ac version of the class-A amplifier of Figure 3.6. The drive signal at the base is given a positive offset (bias) which will create the same bias voltage at the emitter and a bias current through the pull-down resistor, R_E. The coupling capacitor (*dc blocking capacitor*) eliminates the dc bias from the load, and the output signal swings both positive and

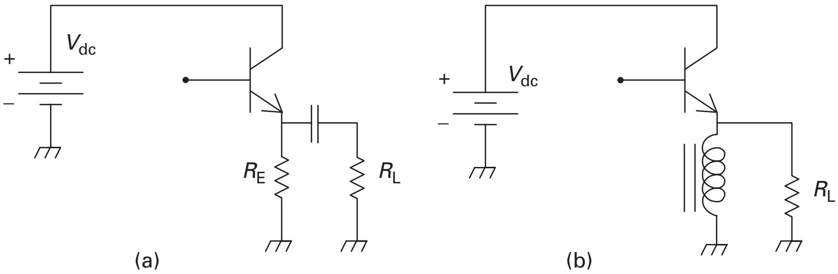


Figure 3.10. Common-collector single-ended ac amplifiers.

negative. The capacitance is chosen to be high enough that the full ac signal at the emitter will appear at the load. Only one power supply is required for this ac version. If $R_E = R_L$, the maximum peak-to-peak output swing is 2/3 V_{dc} and efficiency is again only $\frac{1}{12}$.

A major improvement is to replace the power-dissipating pull-down resistor with an inductor (ac *choke*) as shown in Figure 3.10(b). The inductor allows the output to go negative as well as positive[5] and makes possible a maximum output swing from $-V_{dc}$ to $+V_{dc}$. The inductance is chosen to be high enough to eliminate currents at the signal frequencies. No capacitor is needed; assuming the choke has negligible dc resistance, the average dc on the load will be zero. There must be sufficient bias current through the inductor to keep the transistor always on for the continuous control needed in linear operation. You can calculate (Problem 3.1) that the maximum efficiency of this circuit is 50%; the inductor improves the efficiency by a factor of 6 and the output swing by a factor of 3.

It might seem that the maximum efficiency of the class-B amplifier (78%) is only slightly better than the maximum efficiency of this class-A amplifier (50%). But these maximum efficiencies apply only when the amplifier is delivering a sine wave of maximum amplitude. For speech and music, the average power is much less than the maximum power. The class-B amplifier has little dissipation when the signal is low but a class-A amplifier, with its constant bias current, draws constant power equal to twice the maximum output power. A class-A audio amplifier rated for 25 watts output would consume a continuous 50 watts from its supply while a class-B amplifier of equal power rating would consume, on average, only a few watts, since the average power of audio signals is much lower than the peak power.

Common-emitter versions of this class-A amplifier are shown in Figure 3.11. The circuit of Figure 13.11(b) uses the shunt amplifier topology of Figure 3.5. Here, the inductor provides a wideband constant current source. (If the signal has a narrow bandwidth (RF), a parallel-resonant *LC* circuit will serve the same

---

[5] The bias current flowing downward in the inductor is essentially constant since the inductance is large. At the part(s) of the cycle when the current through the transistor becomes less than the inductor current, the inductor maintains its constant current by "sucking" current out of the load resistor and thus producing the negative output voltage.

Figure 3.11. Common-emitter single-ended ac amplifiers.

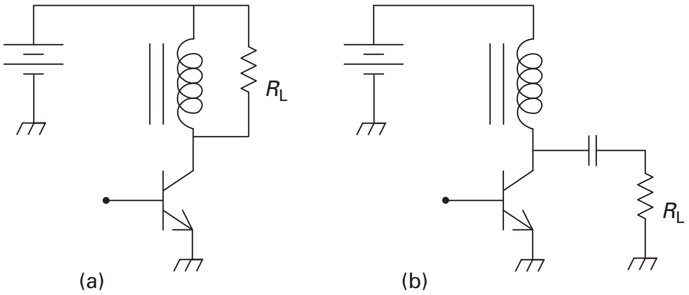

Figure 3.12. Transformer-coupled single-ended ac amplifier.

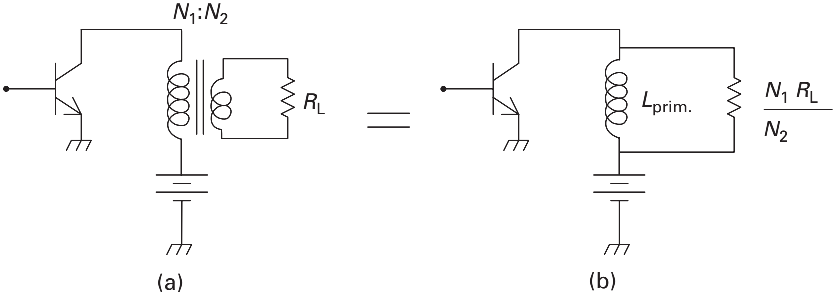

purpose.) A blocking capacitor allows one end of the load to be grounded, which is often a convenience. As we have seen, current drive is called for to achieve linearity if the emitter is tied directly to ground. At the expense of some efficiency, however, the emitter can be tied to ground through a resistor to allow the emitter voltage to follow the drive (base) voltage. Then the emitter current, collector current, and output voltage will all be linearly proportional to the input voltage. This technique of linearizing a common-emitter amplifier is known as "emitter degeneration" or "series feedback." To its credit, the common-emitter arrangement requires only a small and always positive drive signal, whereas the circuit of Figure 3.10(b) requires a drive voltage identical to the output signal, swinging both positive and negative.

Often the resistance of a given load is unsuitable for obtaining the desired power with the given power supply voltage. In this case, the choke and blocking capacitor can be replaced by a transformer as shown below in Figure 3.12.

This circuit is equivalent to that of Figure 13.11(a). The equivalence is shown in (b). Note how the load resistor is R_L, multiplied by the square of the transformer turns ratio. The transformer's primary winding provides the inductor. Again, these choke-coupled and transformer-coupled class-A amplifiers can provide a peak-to-peak collector swing of twice V_{dc}. Note that if we used only the simple "ideal transformer" model to replace the load resistor by its transformed value, we would have no inductance and would predict a maximum

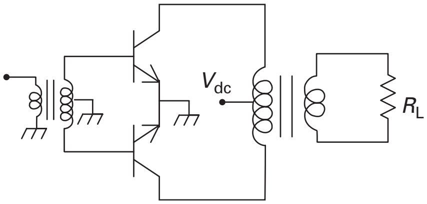

Figure 3.13. Symmetric transformer-coupled push–pull ac amplifier.

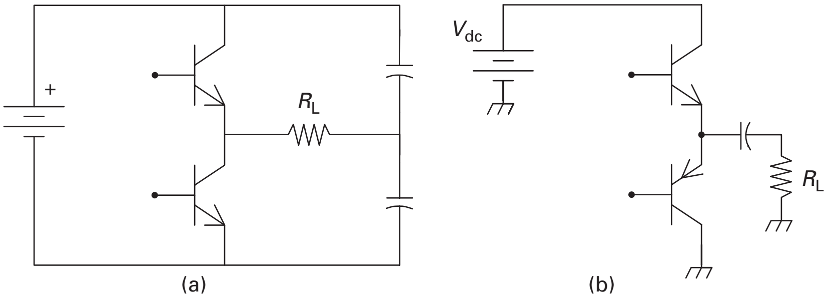

Figure 3.14. Half-bridge ac amplifier (a) and an equivalent version (b).

peak-to-peak swing of only V_{dc} (see Chapter 14). A center-tapped transformer can be used to make the symmetric push–pull amplifier shown in Figure 3.13.

This push–pull circuit, like the transformerless push–pull circuits, can be operated class B for high efficiency. Some high-power tube-type audio and RF amplifiers use this symmetric transformer circuit. Note the use of a center-tapped driver transformer – one way to supply the bases with the required opposite polarity signals.

Transistor audio amplifiers are usually push–pull and transformerless. They can be built with a single power supply by using capacitor coupling, as in the half-bridge circuit shown below in Figure 3.14(a). The circuit of Figure 3.14(b) is equivalent and uses only a single capacitor. The transistors can be in either the totem pole arrangement (a), or in the complementary NPN/PNP arrangement (b).

Since an audio or RF waveform has no dc component, the capacitors each charge to half the supply voltage and are equivalent to batteries. The capacitors thus form an artificial center tap for the power supply so this is an efficient push–pull amplifier, unlike the resistive half-bridge circuit of Figure 3.9(b).

3.8 RF amplifiers

RF amplifiers form a subset of ac amplifiers. RF signals are narrowband ac signals. Besides having no dc component, they have an almost constant waveform; while the amplitude and phase can vary, the shape remains sinusoidal.

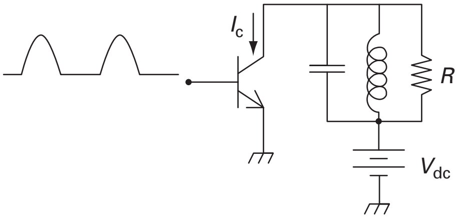

Figure 3.15. Single-ended class-B RF amplifier.

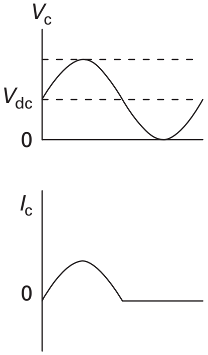

Figure 3.16. Collector voltage and current in the single-ended class-B RF amplifier.

This makes it possible to build a class-B RF amplifier with only a single transistor. The circuit (which looks no different from a class-A amplifier, except for the input waveform) is shown in Figure 3.15.

Here the transistor "pulls" current from the load, but there is no pusher transistor. Instead, a parallel resonant *LC* circuit provides a flywheel (energy storage) effect which maintains the sinusoidal waveform during the half-cycle in which the transistor is not conducting. The drive waveform consists only of positive loops. Between these loops, the transistor is nonconducting. This amplifier has the same 78% maximum efficiency of a push–pull class-B amplifier and also the class-B virtue of drawing no power when the signal level is zero. Let us analyze this circuit. Assume that, during the active half-cycle, the transistor current is $I_0 \sin(\theta)$, where $\theta = \omega t$ and I_0 is to be determined. Assume the resonant circuit provides enough energy storage (high enough Q) that the output voltage (the voltage across the load resistor) can be written as $A \sin(\theta)$. The output power is therefore $A^2/(2R)$. These voltage and current waveforms are shown in Figure 3.16.

During the active half-cycle, the power (*IV* product) into the *RCL* parallel circuit is $I_0 \sin(\theta) A \sin(\theta)$. Over a cycle, this averages to $I_0 A/4$, where one factor of $\frac{1}{2}$ is the time average of $\sin^2(\theta)$ and the other factor of $\frac{1}{2}$ comes from the transistor being turned off during half of every cycle. The power delivered to the parallel circuit must be equal to the power delivered to the load:

$$\frac{I_0 A}{4} = \frac{{V_{dc}}^2}{2R}. \tag{3.4}$$

From this we find $I_0 = 2A/R$. We can calculate the power delivered by the supply by noting that over the half-cycle, the instantaneous power is $V_{dc} I_0 \sin(\theta)$. The average over the half-cycle is $V_{dc}\, I_0\, 2/\pi$ and the average over the entire cycle is again half of this or $V_{dc}\, I_0/\pi = V_{dc}\, 2A/(\pi R)$. The efficiency, power out divided by power supplied by the supply, is therefore

$$\eta = \frac{A^2/(2R)}{V_{dc} 2A/(\pi R)} = \frac{A}{V_{dc}} \frac{\pi}{4}. \tag{3.5}$$

At the maximum output, where $A = V_{dc}$, the efficiency of this "single-ended" class-B amplifier is $\pi/4$, the same as the maximum efficiency for a push–pull class-B amplifier.

The circuit of Figure 3.15, if made to conduct throughout the complete cycle, would be a class-A amplifier. The *LC* would not be needed as a flywheel, but it does act as a bandpass filter. Moreover, the inductance, or part of it, serves to cancel out the unavoidable collector-to-emitter parasitic capacitance inherent in the transistor.

3.9 Matching a power amplifier to its load

In Chapter 2 we saw that, for maximum power transfer, a load should have the same impedance as the source that drives it. However, the power amplifiers discussed in this chapter all have essentially zero output impedances. Their Thévenin equivalent circuits are almost perfect voltage generators. Do we therefore try to make the load resistances as low as possible? No. The amplifiers are designed to deliver a specified power to a specified load. This determines the power supply voltages and current capacities and the required current-handling capacity of the transistor(s). Therefore, power amplifiers are deliberately mismatched to their loads. But a power amplifier does still have some very small output impedance. Won't it therefore supply the most power to a load of that impedance? The answer is yes, as long as the amplitude is kept very low. If the amplitude is turned up, such a load will simply "short out" the amplifier.

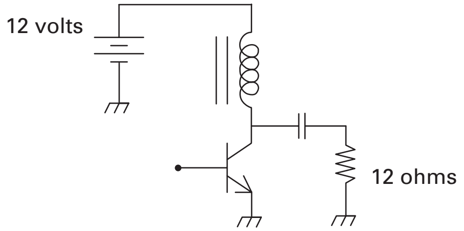
The output amplifier in a transmitter usually includes an impedance transforming network, often called an *antenna tuner*. The purpose of this network is *not* to make the antenna impedance equal to the amplifier's very low output impedance. Rather, the network transforms the antenna impedance to the impedance needed for the amplifier to produce its rated power.

Problems

Problem 3.1. Calculate efficiency of the class-A amplifier of Figure 3.10(b). Assume the output is a sine wave whose peak-to-peak amplitude is $2V_{\rm dc}$, symmetric about $V=0$.

Assume that the dc bias current in the inductor is just enough to allow the amplifier to produce the maximum signal.

Problem 3.2. The class-A amplifier shown below is operating at maximum power, applying a 24-volt peak-to-peak sine wave to the load resistor.



Assume the choke has zero dc resistance and enough inductance to block any ac current and that the capacitor has enough susceptance to prevent any ac voltage drop.

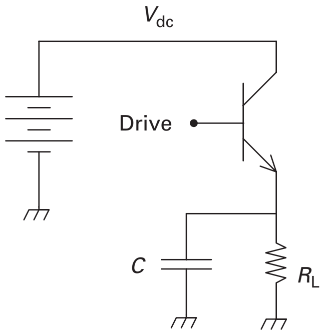
(a) Draw the waveform of the collector voltage. Hint: Remember that there can be no dc voltage drop across the choke.
(b) Draw the waveform of the collector current. Hint: Remember that there is no ac current through the choke.
(c) What power is drawn from the supply under the maximum signal sine wave condition?
(d) Show that the efficiency under this maximum signal sine wave condition is 50%.
(e) What power is drawn from the supply if the signal is zero?

Problem 3.3. An ideal push–pull amplifier does not have the current limitation of the emitter follower, so it can drive capacitive loads at high frequencies. But what about inductive loads? Suppose a load has an unavoidable series inductance but large voltages at high frequencies must be produced across the resistive part of the load. How does this impact the amplifier design?

Problem 3.4. Justify the statements made about the voltage gain (about 99%) and the offset (about 0.7 volts) of the emitter follower. Use the relation between the emitter current and base-to-emitter voltage of a (bipolar) transistor, $I \approx I_{\text{sat}} \exp([V_b - V_e]/0.026)$. To get a value for I_{sat}, assume that $I = 10$ ma when $V_b - V_e = 0.7$ volts. Remember that in the emitter follower, $V_e = I_e R$. Assume a reasonable value for R such as 1000 ohms and find V_e for several values of V_b.

Problem 3.5. Find the power gain of an emitter follower, i.e., the ratio of output signal power to input signal power. Use the fact that the input current (base current) is less than the emitter current by a factor $1/(\beta+1)$ where β is the transistor's current gain (typically on the order of 100). Remember that the output voltage is essentially the same (follows) the input voltage.

Problem 3.6. The emitter follower amplifier shown below has a load which includes an unavoidable parallel capacitance.



(a) What is the maximum peak-to-peak voltage that can be delivered to the load at low frequencies (where the capacitor can be neglected)?
(b) At what frequency will a sine-wave output signal of half the maximum amplitude become distorted? Hint: Express the emitter current as the sum of the resistor current

and capacitor current and note that distortion will occur if this current should ever be negative (the transistor can only supply positive current). Answer: $\omega = \sqrt{3(RC)}$.

Problem 3.7. Consider the push–pull amplifier of Figure 3.8 when it is being driven by a sine-wave signal, $V(t) = V_0\sin(\omega t)$, and is connected to a load that is an inductor, L, rather than a resistor. Draw a graph showing the current flowing into the inductor and the individual emitter currents flowing in the direction of the load. Based on your graph, would you agree with the statement: The top transistor applies positive voltage to the load and the bottom transistor applies negative voltage to the load?

Problem 3.8. The maximum efficiency (the efficiency when the signal is a maximum-amplitude sine wave) of the amplifier in Figure 3.6 is $\frac{1}{12}$ when $R_B = R_L$ and $V_{NEG} = -2V_{POS}$.

(a) Calculate the maximum efficiency when $R_B = \sqrt{2}R_L$ and $V_{NEG} - (1 + \sqrt{2})\ V_{POS}$.

(b) Show that this combination of R_B and V_{NEG} yields the greatest maximum efficiency.

Problem 3.9. Draw a circuit for a "double push–pull" amplifier with four transistors. Two of the transistors connect the load to supply voltages $V_{dc}/2$ and $-V_{dc}/2$. The other two transistors connect the load to a second pair of supplies with voltages V_{dc} and $-V_{dc}$. The transistors connecting the smaller power supplies are turned off (nonconducting) when $|V_{out}| > V_{dc}/2$ and the transistors connecting the larger power supplies are turned off when $|V_{out}| < V_{dc}/2$. Calculate the efficiency when the output is a sine wave swinging from $-V_{dc}$ to $+V_{dc}$. This circuit is sometimes called a class-K amplifier.

CHAPTER

4 Basic filters

Bandpass filters are key elements in radio circuits, for example, in radio receivers, to select the desired station. Here we will discuss lumped-element filters made of inductors and capacitors. We will first look at lowpass filters, and then see how they serve as prototypes for conversion to bandpass filters. We begin with the well-established lowpass filter prototypes – Butterworth, Chebyshev, Bessel, etc. These lowpass prototypes are simple *LC* ladder networks with series inductors and shunt capacitors, as shown in Figure 4.1.

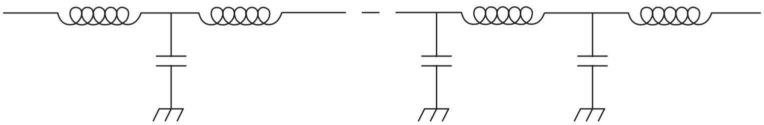


Figure 4.1. Lowpass ladder network.

An n-section lowpass filter has n components (capacitors plus inductors). The end components can be either series inductors, as shown above, or shunt capacitors, or one of each. Since they contain no (intentional) resistance, these filters are *reflective filters*; outside the passband, it is mismatch that keeps power from reaching the load. The ladder network can be redrawn as a cascade of voltage dividers as in Figure 4.2.

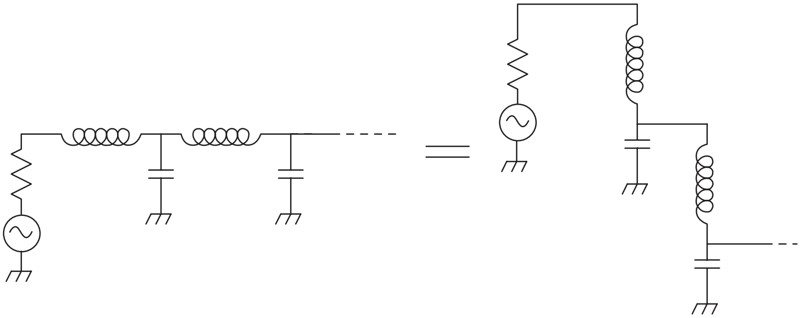

Figure 4.2. Ladder network as a cascade of voltage dividers.

At high frequencies the division ratio increases so the load is increasingly isolated from the source. For frequencies well above cutoff, each circuit element contributes 6 dB of attenuation per octave (20 dB per decade). Within the passband, an ideal lowpass filter provides a perfect match between the load and the source. Filters with many sections approach this ideal. When the source and load impedances have no reactance (either built-in or parasitic) it is theoretically possible to have a perfect match across a wide band.

4.1 Prototype lowpass filter designs

The Butterworth filter is maximally flat, that is, it is designed so that at zero frequency the first $2n-1$ derivatives with respect to frequency of the power transfer function are zero. The final condition (needed to determine the values of n elements) is the specification of the cutoff frequency, f_0, often specified as the 3-dB or half-power frequency. The frequency response of the Butterworth filter turns out to be

$$\left|\frac{V_\text{out}}{V_\text{in}}\right|^2 = \frac{1}{1+(f/f_0)^{2n}}. \tag{4.1}$$

While it is the flattest filter, the Butterworth filter does not have skirts as sharp as those of the Chebyshev filter. The trade-off is that the Chebyshev filters have some passband ripple. The design criterion for the Chebyshev filter is that these ripples all have equal depth. The response is given by

$$\left|\frac{V_\text{out}}{V_\text{in}}\right|^2 = \frac{1}{1+(V_\text{r}^{-2}-1)\cosh^2\left(n\cosh^{-1}(f/f_0)\right)}, \tag{4.2}$$

where V_r is the height above zero of the ripple valley (in voltage) relative to the height of the peaks.

You will find tables of filter element values in many handbooks and textbooks. Two tables from Matthaei, Young and Jones [2] are given in Appendix 4.1 at the end of this chapter. These tables are for normalized filters, i.e., the cutoff frequency[1] is 1 radian/sec ($1/2\pi$ Hz). The value of the n-th component is g_n farads or henrys, depending on whether the filter begins with a capacitor or with an inductor. The proper source impedance is $1+j0$ ohms. This is also the proper load impedance except for the even-order Chebyshev filters, where it is $1/g_{n+1}+j0$ ohms. Figure 4.3 shows plotted power responses of a Butterworth filter and several Chebyshev filters.

---

[1] The cutoff frequency for the Butterworth filters is the half-power (3 db) point. For an n-dB Chebyshev filter it is the highest frequency for which the response is down by n dB (see Figure 4.3).

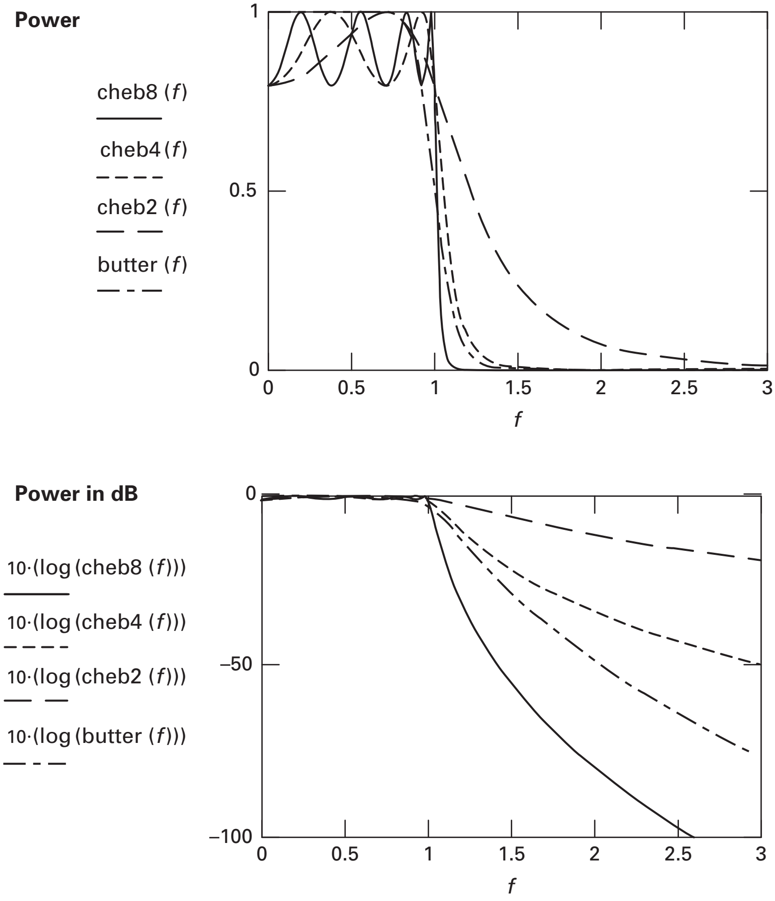

Figure 4.3. Butterworth and Chebyshev responses.

4.2 A lowpass filter example

As an example, we will look at the three-section Butterworth lowpass filter. From the table, the filter has values of 1 H, 2 F, and 1 H (Figure 4.4a) or 1F, 2H, and 1F (Figure 4.4b). The (identical) responses for these two filters are given in Table 4.1 and plotted in Figure 4.5. Note that they work as advertised; the 3-dB point is at 0.159 Hz.

Suppose we need a three-section Butterworth that is 5 kHz wide and works between a 50-ohm generator and a 50-ohm load. We can easily find the element values by scaling the prototype. The values of the inductors are just multiplied by 50 (we need 50 times the reactance) and divided by $2\pi \cdot 5000$ (we need to reach that reactance at 5 kHz, not 1 radian/sec). Similarly, the capacitor values are divided by 50 and divided by $2\pi \cdot 5000$. Figure 4.6 shows the circuit resulting from scaling the values of Figure 4.4b.

The response of the scaled filter is shown below in Table 4.2 and Figure 4.7.

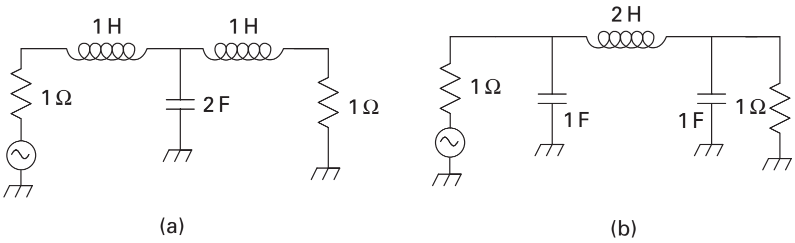

Figure 4.4. Equivalent three-section Butterworth lowpass filters.

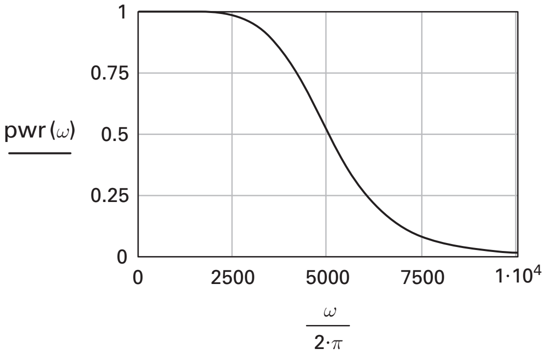

Figure 4.7. Plotted response of the scaled lowpass filter of Figure 4.6.

4.3 Lowpass-to-bandpass conversion

Here we will see how to convert lowpass filters into bandpass filters. Remember how the lowpass filters work: as frequency increases, the series arms (inductors), which are short circuits at dc, begin to pick up reactance. Likewise, the shunt arms (capacitors), which are open circuits at dc, begin to pick up susceptance. Both effects impede the signal transmission, as we have seen. To convert these lowpass filters in the most direct way to bandpass filters, we can replace the inductors by series *LC* combinations and the capacitors by parallel *LC* combinations. The series combinations are made to resonate (have zero impedance) at the center frequency of the desired bandpass filter, just as the inductors had zero impedance at dc, the "center frequency" of the prototype lowpass filter. It is important to note that as we move away from resonance, a series LC arm picks up reactance at twice the rate of the inductor alone. This is easy to see: The reactance of the series arm is given by

$$X_{\text{series}} = \omega L - \frac{1}{\omega C}. \tag{4.3}$$

Differentiating with respect to ω, we find

$$\frac{\mathrm{d}X}{\mathrm{d}\omega} = L + \frac{1}{\omega^2 C}. \tag{4.4}$$

At $\omega = \omega_0$,

$$\frac{\mathrm{d}X}{\mathrm{d}\omega} = L + \frac{1}{{\omega_0}^2 C} = 2L. \tag{4.5}$$

As we move off resonance, the inductor and the capacitor provide equal contributions to the reactance. Likewise, the parallel LC circuits, which replace the capacitors in the prototype lowpass filter, pick up susceptance at twice the rate of their capacitors. With this in mind, let us convert our 5-kHz lowpass filter into a bandpass filter. Suppose we want the center frequency to be 500 kHz and the bandwidth to be 10 kHz. As we move up from the center frequency, the series arms must pick up a reactance at the same rate the inductors picked up a reactance in the prototype lowpass filter. Similarly, the shunt arms must pick up susceptance at the same rate the capacitors picked up susceptance in the prototype. This will cause the bandpass filter to have the same shape above the center frequency as the prototype had above dc. If the 3-dB point of the prototype filter was 5 kHz, the upper 3-dB point of the bandpass filter will be at 5 kHz above the center frequency. The bandpass filter, however, will have a mirror-image response as we go below the center frequency. (Below center frequency the reactances and susceptances change sign but the response remains the same.)

Let us calculate the component values. As we leave center frequency, the series circuits will get equal amounts of reactance from the L and the C, as explained above. Therefore the series inductor values should be exactly half what they were in the low pass prototype. Note: no matter how high we make the center frequency, the values of the inductors are reduced only by a factor of 2 from the those of the scaled lowpass filter. The series capacitors are chosen to resonate at the center frequency with the new (half-value) series inductors. The values of the parallel arms are determined similarly; the parallel capacitors must have half the value they had in the prototype lowpass filter. Finally, the parallel inductors are chosen to resonate with the new (half-value) parallel capacitors. These simple conversions yield the bandpass filter shown in Figure 4.8.

The response of this bandpass filter is given below in Table 4.3 and Figure 4.9.

While this theoretical filter works perfectly (since its components are lossless), the component values are impractical; typical real components with these values would be too lossy to achieve the calculated filter shape. When a bandpass filter is

Figure 4.8. Bandpass filter.

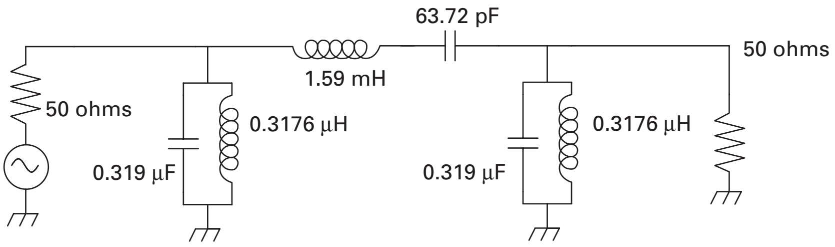

Table 4.3 Response of the bandpass filter of Figure 4.8.

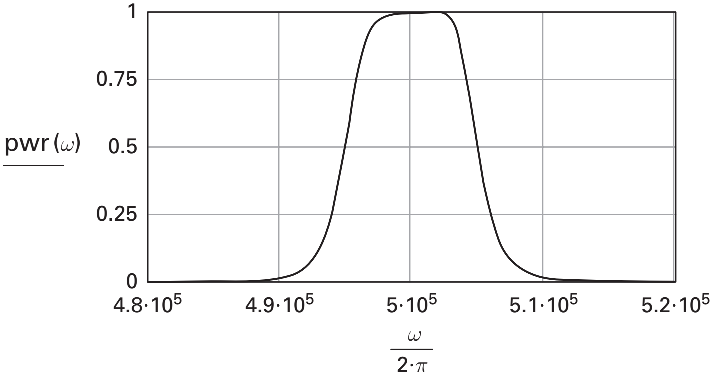
Figure 4.9. Plotted response for Table 4.3.



to have a large fractional bandwidth (bandwidth divided by center frequency) this direct conversion from lowpass to bandpass can be altogether satisfactory. It is when the fractional bandwidth is small, as in this example, that the direct conversion gets into trouble.[2] We will see later that the problem is solved by transforming the prototype lowpass filters into somewhat more complicated bandpass circuits known as *coupled resonator filters*. Those filters retain the desired shape (Butterworth, Chebyshev, etc.) and can serve, in turn, as prototypes for filters made from quartz or ceramic resonators and for filters made with resonant irises (thin aperture plates that partially block a waveguide).

---

[2] The component problem with the straightforward lowpass-to-bandpass conversion is that the values of the series inductors are very different from the values of the parallel inductors. (The same is true of the capacitors, but high-Q capacitors can usually be found.) In the above example, the inductors differ by a factor of about 5000 and it is normally impossible to find high-Q components over this range. (Low-Q inductors, of course, make the filter lossy and, if not accounted for, distort the bandpass

Appendix 4.1. Component values for normalized lowpass filters[3]

shape.) The inductors in coupled-resonator filters are all of about the same value. If a high-Q inductor can be found, the coupled resonator filter is designed for whatever impedance calls for that value of inductor and then transformers or matching sections are used at each end to convert to the desired impedance.

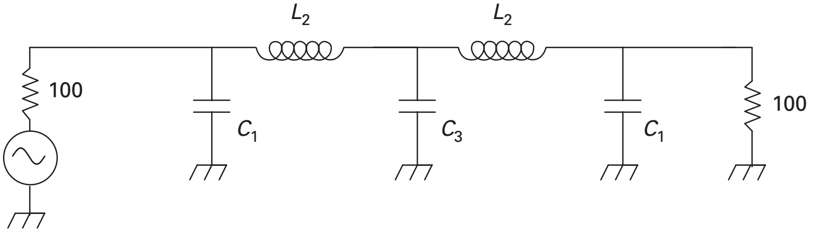
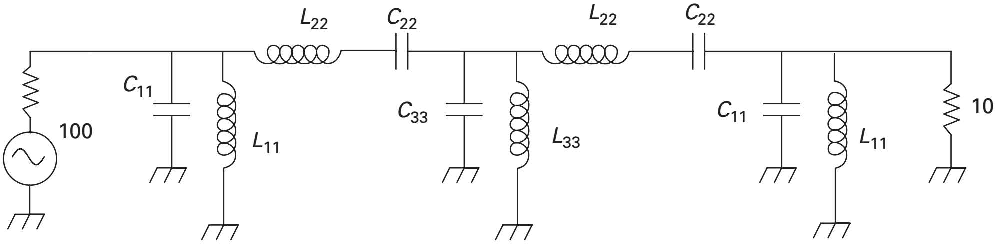
Problems

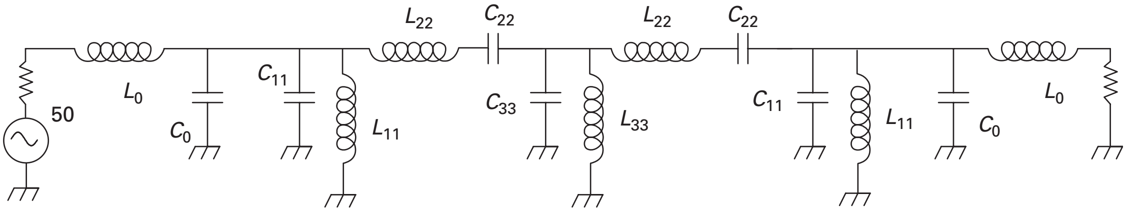
Problem 4.1. Design a five-element lowpass filter with a Chebyshev 0.5-dB ripple shape. Let the input and output impedances be 100 ohms. Use parallel capacitors at the ends. The bandwidth (from dc to the last 0.5-dB point) is to be 100 kHz. Use Table A4.2 to find the values of the prototype 1 ohm, 1 rad/sec filter and then alter these values for 100 ohms and 100 kHz.



Problem 4.2. Use the results of Problem 4.1 to design a five-element bandpass filter with a Chebyshev 0.5-dB ripple shape. Let the input and output impedances remain at 100 ohms. The center frequency is to be 5 MHz and the total bandwidth (between outside 0.5-dB points) is to be 200 kHz.



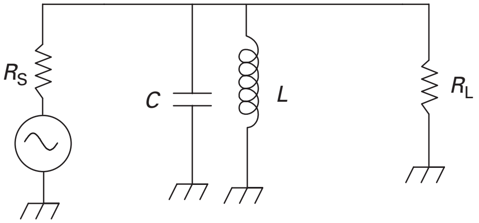
Problem 4.3. Convert the filter of Problem 4.2 to operate at 50 ohms by adding an L-section matching network at each end. Test the filter design using your ladder network analysis program, sweeping from 4.5 to 5.5 MHz in steps of 20 KHz.



Problem 4.4. The one-section bandpass filter shown below uses a single parallel resonator. In its prototype lowpass filter, the resonator is a single shunt capacitor. Show that the frequency response of this filter is given by

$$\frac{P}{P_{\max}} = \frac{1}{1 + Q^2(f/f_0 - f_0/f)^2}$$

where f_0 is the resonant frequency of the LC combination and Q is defined as $R/(\omega_0 L)$, where R is the parallel combination of R_S and R_L.



Problem 4.5. Highpass filters are derived from lowpass filters by changing inductors to capacitors and vice versa and replacing the component values in the prototype lowpass

tables by their reciprocals. (A 2-F capacitor, for example, would become a 0.5-H inductor.) The prototype highpass response at ω will be equal to the prototype lowpass response at 1/ω. Convert the lowpass filter of Figure 4.4(b) into a highpass filter. (Answer: 1 H, 0.5 F, 1 H.) Next, scale it to have a cutoff frequency of 5 kHz and to operate at 50 ohms. Finally, convert the scaled filter into a bandstop filter with a stopband 10 kHz wide, centered at 500 kHz.

Problem 4.6. Enhance your ladder network analysis program (Problem 1.3) to display not just the amplitude response of a network, but also the phase response (phase angle of the output voltage minus phase angle of the input voltage). Calculate the phase response of the Butterworth filter in Figure 4.4(a). Note: ladder networks belong to a class of networks ("minimum phase networks") for which the amplitude response uniquely determines the phase response and vice versa. In Chapter 12 we will encounter "allpass" filters which are not in this class; phase varies with frequency while amplitude remains constant.

Example answer: For the MATLAB program listing in Problem 1.3, simply insert the following two lines ahead of the last two lines in the original program.

```
figure(3);plot(-180/pi*angle(Vgen));
grid; xlabel('Frequency');ylabel('degrees');title('Phase response');
```

CHAPTER

5

Frequency converters

A common operation in RF electronics is frequency translation, whereby all the signals in a given frequency band are shifted to a higher frequency band or to a lower frequency band. Every spectral component is shifted by the same amount. Cable television boxes, for example, shift the selected cable channel to a low VHF channel (normally channel 3 or 4). Nearly every receiver (radio, television, radar, cell phone, …) uses the *superheterodyne* principle, in which the desired channel is first shifted to an intermediate frequency or "IF" band. Most of the amplification and bandpass filtering is then done in the fixed IF band, with the advantage that nothing in this major portion of the receiver needs to be retuned when a different station or channel is selected. The same principle can be used in frequency-agile transmitters; it is often easier to shift an already modulated signal than to generate it from scratch at an arbitrary frequency. Frequency translation is also called *conversion* and is even more commonly called *mixing*.[1]

5.1 Voltage multiplier as a mixer

A mixer takes the input signal or band of signals (segment of spectrum), which is to be shifted, and combines it with a reference signal whose frequency is equal to the desired shift in frequency. In a radio receiver, the reference or "L.O." signal is a sine-wave, generated within the receiver by a *local oscillator*.[2] Mixers, in order to produce new frequencies, must necessarily be nonlinear since linear circuits can change only the amplitudes and phases of a set of superposed sine waves. Multiplication is the nonlinear operation used in mixers

---

[1] In audio work "mixing" means addition, a linear superposition that produces no new frequencies. In RF work, however, mixing means multiplication; an RF mixer either directly or indirectly forms the product of the input signal voltage and a sinusoidal "local oscillator" (L.O.) voltage. Multiplication produces new frequencies.

[2] The earliest radio receivers employed no frequency conversion, so they had no "local" oscillator; the only oscillator was remote – at the transmitter location.

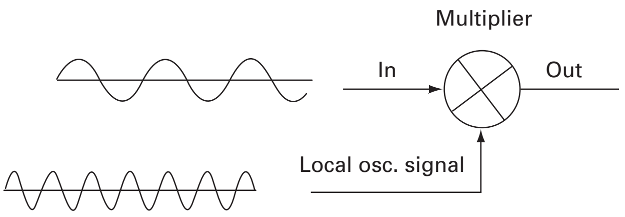

Figure 5.1. A voltage multiplier used as a frequency converter (mixer).

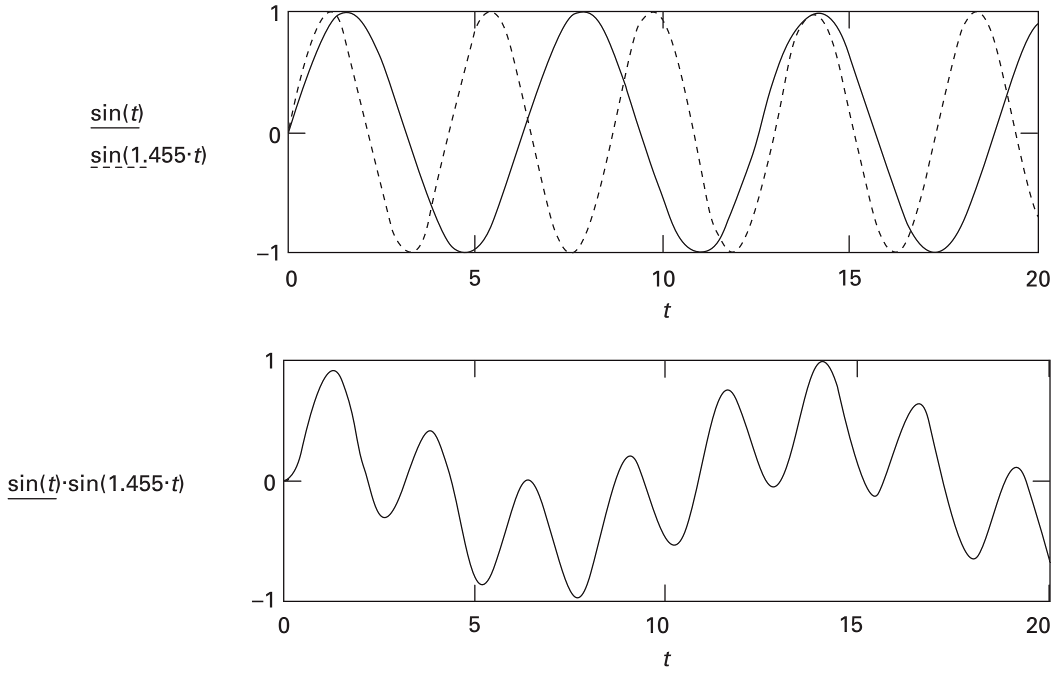

Figure 5.2. Multiplier input and output waveforms.

to produce new signals at the shifted frequencies. Figure 5.1 shows a voltage multiplier with its signal and L.O. inputs. A circumscribed *X* is the standard symbol for a mixer. The input signal port of the mixer is usually labeled "RF," while the other two ports are labeled "LO" and "OUT" (or "IF").

The output voltage from the multiplier is the product (or proportional to the product) of the two input voltages. In Figure 5.2 a sine-wave input signal is multiplied by an L.O. that is 1.455 times higher in frequency. These multiplicands are shown in the top graph. The bottom graph shows their product which can be seen to contain frequencies both higher and lower than the original frequencies.

The familiar "sin(*a*)sin(*b*)" trigonometric identity shows that, in this simple case, the multiplier output consists of just two frequencies: an up-shifted signal at $\omega_L + \omega_R$ and a down-shifted signal at $\omega_L - \omega_R$:

$$\sin(\omega_R t)\sin(\omega_L t) = {}^1\!/_2[\cos(\omega_R - \omega_L)t - \cos(\omega_R + \omega_L)t]. \qquad (5.1)$$

If we replace the single RF signal by $V_1\sin(\omega_{R1}t)+V_2\sin(\omega_{R2}t)$, a signal with two spectral components, you can confirm that the output will be

$$\begin{aligned}&{}^1\!/_2V_1\cos([\omega_{R1}-\omega_L]t)+{}^1\!/_2V_2\cos([\omega_{R2}-\omega_L]t)\\&-{}^1\!/_2V_1\cos([\omega_{R1}+\omega_L]t)-{}^1\!/_2V_2\cos([\omega_{R2}+\omega_L]t).\end{aligned}\tag{5.2}$$

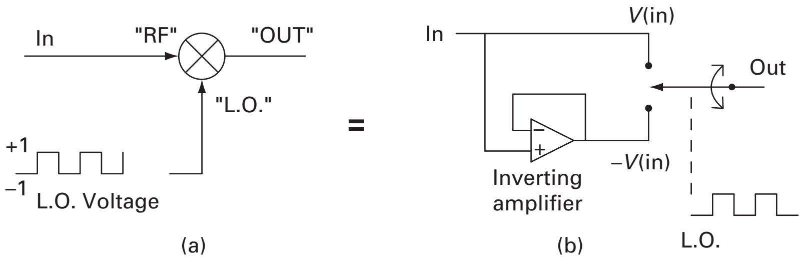
Just as this linear combination of two signals is faithfully copied into both an up-shifted band and a down-shifted band, any linear combination, i.e., any spectral distribution of signals, will be faithfully copied into these shifted output bands. With respect to signals applied to the RF port, you can see that the mixer is a linear device; all the components are translated (both up and down) in frequency, but their relative amplitudes are left unchanged and there is no interaction between them. Usually one wants only the up-shifted band or only the down-shifted band; the other is eliminated with an appropriate bandpass filter. Ideal analog (or digital) multipliers are being used more commonly as mixers in RF electronics as their speeds increase with improving technology.

5.2 Switching mixers

If the L.O. waveform is square, rather than a sinusoidal, the mixer output will contain not only the fundamental up-shifted and down-shifted outputs but also components at offsets corresponding to the third, fifth, and all other odd harmonics of the L.O. frequency, i.e., at offsets corresponding to all the frequencies in the Fourier decomposition of the square wave. You can confirm this by simply multiplying the Fourier series for the square-wave L.O. by the superposition of signals in the input at the RF port. These new components are usually very easy to filter out so there is no disadvantage in using a square-wave L.O. In fact, there is an advantage. Consider an L.O. signal that is a square wave with values ±1. In this case, since the multiplier multiplies the input signal only by either +1 or − 1, it can be replaced by an electronic SPDT switch that connects the output alternately to the input signal and the negative of the input signal. This equivalence is shown in Figure 5.3.

The phase inversion needed for the bottom side of the switch can easily be done with a center-tapped transformer and the switching can be done with two

Figure 5.3. Switching mixer operation.



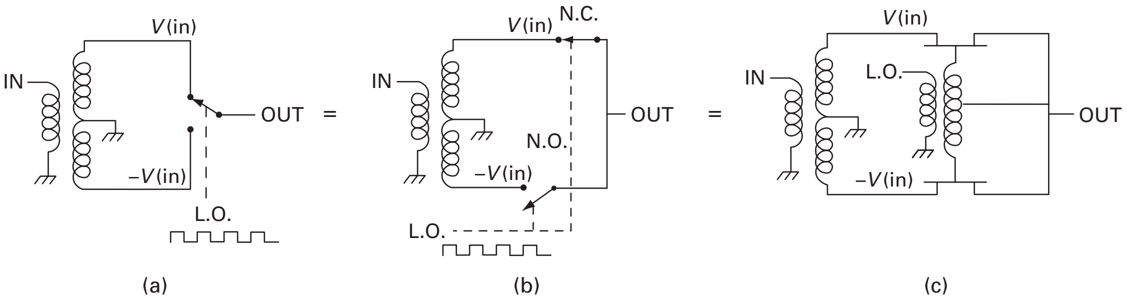


Figure 5.4. Active switching mixer using transistors.

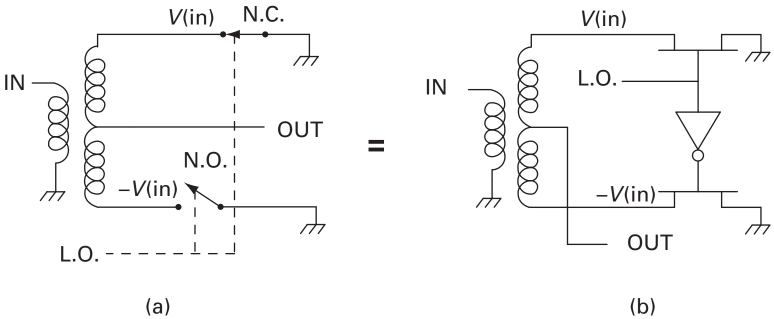

Figure 5.5. Alternate active switching mixer.

transistors, one for the high side and one for the low side. In the circuit of Figure 5.4 the switches are FETs. (Mixers based on transistors are called *active mixers*.) A second center-tapped transformer provides the L.O. phase inversion so that one FET is turned on while the other is turned off.

We could just as well have taken the signal from the center tap and used the FETs to ground one end of the secondary and then the other. With this arrangement, shown in Figure 5.5, it is easier to provide the drive signals to the transistors, since they are not floating.

Diodes are commonly used as the switching elements for the arrangement shown in Figure 5.5. This results in the *passive* switching mixer circuit shown in Figure 5.6.

Voltage from the L.O. transformer alternately drives the top diode pair and the bottom pair into conduction. The L.O. signal is made large enough that the conducting diodes have very low impedance (small depletion region) and the nonconducting diodes have a very large impedance (wide depletion region). The end of the input transformer connected between the turned-on diode pair is effectively connected to ground through the secondary of the L.O. transformer. Note that current uses both sides of the L.O. transformer on the way to ground, so no net flux is created in that transformer and it has zero impedance for this current. This circuit is usually drawn in the form shown in Figure 5.6(b) and is referred to as a *diode ring mixer*.

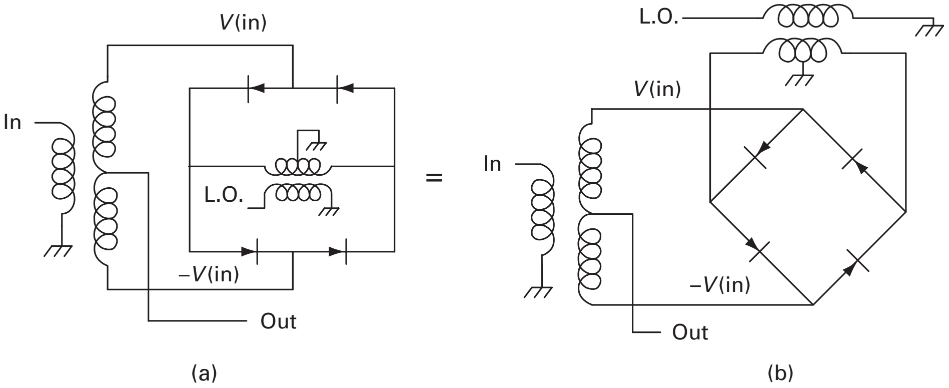

Figure 5.6. Diode ring mixer.

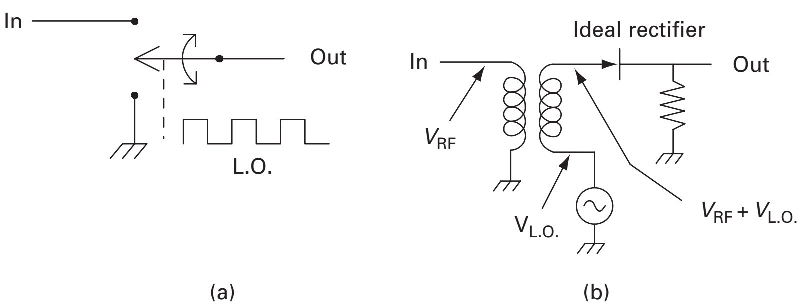
Figure 5.7. Unbalanced switching mixers.



All the switching mixers shown above are "double-balanced" which means that no L.O. frequency energy appears at the RF or IF ports and no RF, except for the mixing products, appears at the OUT port. A balanced mixer is desirable, for example, when it is the first element in a receiver. An unbalanced mixer would allow L.O. energy to feed back into the antenna and the radiation could cause interference to other receivers (and could also reveal the position of the receiver). An unbalanced switching mixer is shown in Figure 5.7(a). It multiplies the signal by a square wave that goes from +1 to 0 (rather than +1 to − 1) which is just a $+\frac{1}{2}$ to $-\frac{1}{2}$ square wave together with a bias of $\frac{1}{2}$. The square-wave term produces the up-shifted and down-shifted bands as before, but the bias term allows one-quarter of the RF input power to get through, unshifted in frequency, to the output.

A simple version of this mixer, using an ideal rectifier, is shown in Figure 5.7 (b). The L.O. and RF voltages are added here, by means of a transformer, and their sum is rectified. The voltage at the output is equal to the sum voltage when the sum is positive and is equal to zero when the sum is negative. If the L.O. voltage is large compared to the RF voltage, the rectifier effectively conducts when the L.O. voltage is positive and disconnects when the L.O. voltage is negative, allowing the resistor to pull down the output voltage to zero. Thus, the RF signal is switched to the output at the L.O. rate. Note, however, that this mixer is totally unbalanced; both the L.O. and RF signals appear at the mixer, together with the sum and difference frequencies.

Switching mixer loss

Let us consider the loss in the switching mixers in Figures 5.4, 5.5, and 5.6. Refer to Figure 5.4(a) and assume that the OUT port is terminated by a load resistor R_L whose value equals R_S, the source impedance of a sine-wave signal source connected to the IN port. Note that the source has no way of knowing that the load resistor is being reversed on half of every cycle of the L.O. The source just sees a matched load and therefore delivers its maximum power. Some of the power on the load is at the desired sum or difference frequency. The ratio of this desired power to the power available from the source is known as the conversion gain. For the diode ring mixer, the ratio is less than unity, i.e., a conversion loss. We can easily calculate this loss. The reversing switch presents the load with a voltage that is half the source voltage (since R_S and R_L form a voltage divider), multiplied by a dimensionless ±1 square wave. Fourier analysis shows that the square wave is made of a sine wave at the square-wave frequency plus a sine wave at every odd multiple of this frequency. The amplitude of the fundamental sine wave is $4/\pi$. The amplitudes of the higher harmonics fall off as $1/n$. Evaluating the product of this square wave and the source voltage we have

$$\begin{aligned} V_{\mathrm{OUT}} &= \tfrac{1}{2}V_S\cos(\omega_R t)\cdot[4/\pi)(\cos(\omega_L t)+3^{-1}\cos(3\omega_L t)+5^{-1}\cos(5\omega_L t)+\ldots] \\ &= \tfrac{1}{2}V_S(4/\pi)\cos(\omega_R t)\cos(\omega_L t)+\ldots \\ &= \tfrac{1}{2}V_S(4/\pi)[(1/2)\cos(\omega_R-\omega_L)t+(1/2)\cos(\omega_R+\omega_L)t]+\ldots \end{aligned} \tag{5.3}$$

We see that the amplitude of the desired sum or difference frequency component is $\tfrac{1}{2}V_S(4/\pi)\cdot(1/2)$. The amplitude available from the source is $\tfrac{1}{2}V_S$, so the conversion gain is the ratio of the squares of these amplitudes:

$$\text{Conversion gain} = \left(\frac{1}{2}\frac{4}{\pi}\frac{1}{2}\right)^2 \Bigg/ \left(\left(\frac{1}{2}\frac{4}{\pi}\frac{1}{2}\right)^2\left(\frac{1}{2}\right)\left(\frac{1}{2}\right)\right)^2 = \left(\frac{4}{\pi}\frac{1}{2}\right)^2 = 0.4052 \tag{5.4}$$

or, in dB, 10 log (0.4052) = −3.92 dB. In practice, the loss is typically greater than this by a dB or so, due to loss in the diodes and in the transformers.

5.3 A simple nonlinear device as a mixer

Finally, let us consider a mixer that uses a single nonlinear device, but not as a switch. Figure 5.8 shows a single-diode mixer. The first op-amp is used to sum the RF and L.O. voltages. The sum is applied to the diode. The input of the second op-amp is a virtual ground so the full sum voltage is applied across the

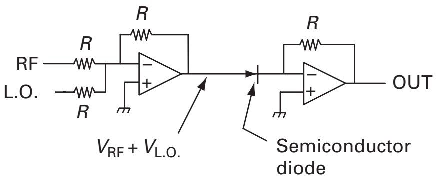


Figure 5.8. Hypothetical single-diode mixer circuit.

diode. With its feedback resistor, the second op-amp acts as a current-to-voltage converter; it produces a voltage proportional to the current in the diode. The current, a nonlinear (exponential) function of the applied voltage, will contain mixing products at frequencies $N\omega_{\mathrm{RF}} \pm M\omega_{\mathrm{L.O.}}$ where N and M are simple integers. Note that this circuit is essentially the same as that of Figure 5.7(b), except that here we are considering low-level signals, where the diode cannot be treated as an ideal rectifier.

This op-amp circuit is intended to emphasize that the diode's nonlinearity operates on the *sum* of the RF and L.O. Commonly used circuits use passive components and the summing is not always obvious. Diodes are exponential devices; the current vs. applied voltage is given by

$$I = I_{\mathrm{s}}(\exp(V/V_{\mathrm{th}}) - 1), \tag{5.5}$$

where $V_{\mathrm{th}} = V_{\mathrm{thermal}} = kT/e$ (Boltzmann's constant × absolute temperature / electron charge) $= 26\,\mathrm{mV}$. The term I_{s} is a temperature-dependent "saturation current." In a small-signal situation, i.e., when $V \ll 26\,\mathrm{mV}$, we can expand the exponential to find the output of the above mixer:

$$V_{\mathrm{out}} = I_{\mathrm{s}}R[V/V_{\mathrm{th}} + (V/V_{\mathrm{th}})^2/2! + (V/V_{\mathrm{th}})^3/3! + \ldots \tag{5.6}$$

Since $V = V_{\mathrm{RF}} + V_{\mathrm{L.O.}}$, the first term will give feedthrough (no balance) at both the RF and L.O. frequencies. The second term (the square law term) will produce the desired up-shifted and down-shifted sidebands since the square of $V_{\mathrm{L.O.}} + V_{\mathrm{RF}}$ contains the cross-product, $2V_{\mathrm{RF}}\, V_{\mathrm{L.O.}}$. This term also produces bias terms and double frequency components. The third-order term will give outputs at the third harmonics of the RF and L.O. frequencies and at $2\omega_{\mathrm{RF}}+\omega_{\mathrm{L.O.}}$, $2\omega_{\mathrm{RF}}-\omega_{\mathrm{L.O.}}$, $2\omega_{\mathrm{L.O.}}+\omega_{\mathrm{RF}}$, and $2\omega_{\mathrm{L.O.}}-\omega_{\mathrm{RF}}$. Normally these products are far removed from the desired output band and can be filtered out. If the input voltage is small enough, we do not have to continue the expansion. For larger signals, however, the next term (fourth-order) gives undesirable products within the desired output band. To see how this happens, consider an input signal with two components, $A_1\cos(\omega_1 \mathrm{t})$ and $A_2\cos(\omega_2 \mathrm{t})$. One of the fourth-order output terms will be, except for a constant,

$$\cos(\omega_{\mathrm{L}}t)[\mathrm{A}_1 \cos(\omega_1 t) + \mathrm{A}_2 \cos(\omega_2 t)]^3. \tag{5.7}$$

You can expand this expression to show that it contains components with frequencies $\omega_{\mathrm{L}}+2\omega_1+\omega_2$ and $\omega_{\mathrm{L}}-2\omega_1-\omega_2$. When ω_1 and ω_2 are close to each other, $2\omega_1+\omega_2$ and $2\omega_1-\omega_2$ are nearby and can lie within the desired output band. In a radio receiver, this means that two strong signals will create an objectionable mixing product at a nearby, i.e., inband, frequency which will impede the reception of a weak signal at that frequency.

Simple mixers can also be made with a transistor. A bipolar transistor, if driven by the sum of the RF and L.O. voltages, will have a collector current containing the same set of frequency components as the diode mixer discussed above. Sometimes a dual-gate FET is used as a mixer; the L.O. voltage is applied to one gate and the RF voltage is applied to the other. This provides some isolation between L.O. and RF (which is provided automatically in a balanced mixer such as the diode ring mixer).

We will see later that multiplication, the basis of mixing, is also the operation needed to modulate the amplitude of a *carrier* sine wave, i.e., to produce amplitude modulation (AM). Multiplication, mixing, and AM modulation are all the same basic operation.

Problems

Problem 5.1. Sometimes two multipliers, two phase shifters, and an adder are used to build a mixer that has only one output band (a so-called single-sideband mixer). The design for an *upper* sideband mixer, for example, follows directly from the identity:

$$\cos([\omega_{\mathrm{RF}}+\omega_{\mathrm{L.O.}}]t)=\cos(\omega_{\mathrm{RF}}t)\cos(\omega_{\mathrm{L.O.}}t)-\sin(\omega_{\mathrm{RF}}t)\sin(\omega_{\mathrm{L.O.}}t).$$

Draw a block diagram for a circuit that carries out this operation.

Problem 5.2. The diode ring switching mixer also works when the L.O. and RF ports are interchanged. Explain the operation in this case.

Problem 5.3. Show that the diode ring switching mixer will work if the L.O. frequency is one-third of the nominal L.O. frequency. This is sometimes done for convenience if this $\frac{1}{3}\omega_{\mathrm{L.O.}}$ frequency is readily available. Find the conversion gain (loss) for this situation. Why would this scheme not work if the L.O. frequency is half the nominal L.O. frequency?

Problem 5.4. Consider a situation where two signals of the same frequency but with a phase difference, θ, are separately mixed to a new frequency. Suppose identical mixers are used and that they are driven with the same L.O. signal. Show that the phase difference of the shifted signals is still θ.

Problem 5.5. In RF engineering, considerable use is made of the trigonometry identities $\cos(a+b)=\cos(a)\cos(b)-\sin(a)\sin(b)$ and $\sin(a+b)=\sin(a)\cos(b)+\cos(a)\sin(b)$. Prove these identities, either using geometric constructions or using the identity $e^{jx}=\cos(x)+j\sin(x)$.

CHAPTER

6

Amplitude and frequency modulation

Modulation means *variation* of the amplitude or the phase (or both) of an otherwise constant sinusoidal RF *carrier wave* in order that the signal carry information: digital data or analog waveforms such as audio or video. In this chapter we look at pure amplitude modulation (AM) and pure frequency modulation (FM). Historically, these were the first methods to be used for communications and broadcasting. While still used extensively, they are giving way to modulation schemes, mostly digital, some of which amount to simultaneous AM and FM.

The simplest form of AM is *on/off keying*. This binary digital AM (full on is a data “1” and full off is a data “0”) can be produced with a simple switch, originally a telegraph key in series with the power source or the antenna. The first voice transmissions used a carbon microphone as a variable resistor in series with the antenna to provide a continuous range of amplitudes. With AM, the frequency of the carrier wave is constant, so the zero crossings of the RF signal are equally spaced, just as they are for an unmodulated carrier. The simplest FM uses just two frequencies; the carrier has frequency f_0 for data “zero” and $f_0 + \Delta f$ for data “one.” FM is usually generated by a VCO (voltage-controlled oscillator). For binary FSK (frequency shift keying), the control voltage has only two values: one produces f_0 and the other produces $f_0 + \Delta f$. FM broadcasting uses a continuous range of frequencies; the instantaneous frequency is determined by the amplitude of the audio signal. With FM, the amplitude of the carrier wave signal is constant. Figure 6.1 shows an unmodulated carrier wave, an AM-modulated wave, an FM-modulated wave, and a wave with simultaneous AM and FM modulation.

Phase modulation is a type of frequency modulation, since frequency is the time derivative of phase.

Amplitude and frequency (or phase) exhaust the list of carrier wave properties that can be modulated. The fractional bandwidth of RF signals is low enough that if one zooms in on a stretch of several cycles, the waveform is essentially sinusoidal and can be described by just its amplitude and frequency. Schemes such as single-sideband suppressed carrier (SSBSC), double-sideband

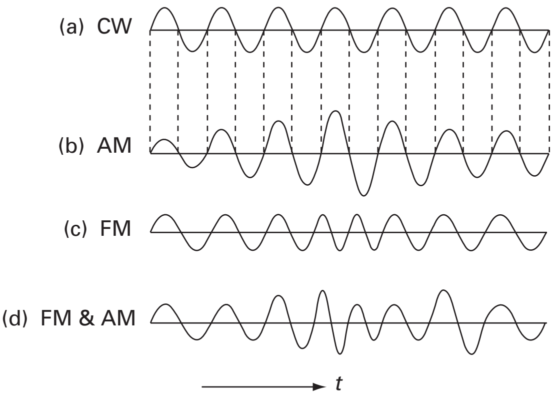

Figure 6.1. (a) Unmodulated wave; (b) with AM modulation; (c) with FM modulation; (d) with simultaneous AM and FM.

suppressed carrier AM (DSBSC), quadrature amplitude modulation (QAM), and others, produce simultaneous amplitude and frequency modulation. A sine-wave generator with provisions for both amplitude and phase modulation can, in principle, produce a radio signal with *any* specified type of modulation, for example, the comb of 52 individually modulated subcarriers used in Wi-Fi data links. Note: the term *digital modulation* means that the modulation uses a finite number of modulation states (often just two) rather than a continuum of states and that the time spent in any state is an integral multiple of a fundamental symbol time (baud).

6.1 Amplitude modulation

Amplitude modulation, the first scheme used for radio broadcasting, is still used in the long-wave, middle-wave, and short-wave broadcast bands.[1] Let us examine AM, first in the time domain and then in the frequency domain.

6.1.1 AM in the time domain

Without modulation (when the speech or music is silent) the voltage applied to the antenna is a pure sine wave at the carrier frequency. The power of a radio

---

[1] The long-wave (LW) band, used only outside the Western Hemisphere, extends from 153 to 179 kHz. The middle-wave (MW) band extends from 520 to 1700 kHz. Short-wave bands are usually identified by wavelength: 75 m, 60 m, 49 m, 41 m, 31 m, 25 m, 19 m, 16 m, 13 m and 11 m. The spacing between LW frequency assignments is 9 kHz. MW spacings are 10 kHz in the Western Hemisphere and 9 kHz elsewhere. Short-wave frequency assignments are less coordinated but almost all short-wave stations operate on frequencies which are an integral number of kHz.

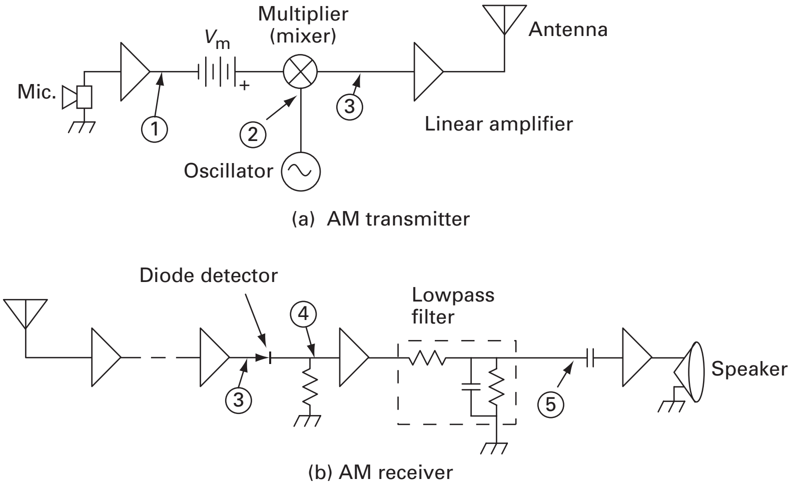

Figure 6.2. Hypothetical AM transmitter and receiver.

station is defined as the transmitter output power when the modulation is zero. The presence of an audio signal changes the amplitude of the carrier. Figure 6.2 shows a hypothetical AM transmitter and receiver.

The audio signal (amplified microphone voltage) has positive and negative excursions but its average value is zero. Suppose the audio voltage is bounded by $+V_m$ and $-V_m$. A dc bias voltage of V_m volts is added to the audio voltage. The sum, $V_m + V_{audio}$, is always positive and is used to multiply the carrier wave, $\sin(\omega_c t)$. The resulting product is the AM signal; the amplitude of the RF sine wave is proportional to the biased audio signal. The simulation in Figure 6.3 shows the various waveforms in the transmitter and receiver of Figure 6.2 corresponding to a random segment of an audio waveform. The biased audio waveform is called the *modulation envelope*. Note that at full modulation where $V_{audio} = +V_m$, the carrier is multiplied by $2V_m$ whereas, at zero modulation, the carrier is multiplied by V_m (bias only). This factor of 2 in amplitude means the fully (100%) modulated signal has four times the power of the unmodulated signal (the carrier wave alone). It follows that the antenna system for a 50 000 W AM transmitter must be capable of handling 200 000 W peaks without breakdown. The average power of the modulated signal is determined by the average square of the modulation envelope. For example, in the case of 100% modulation by a single audio tone, the average power of the modulated signal is greater than the carrier by a factor of $\langle(1+\cos\theta)^2\rangle = \langle 1+2\cos(\theta) + \cos(\theta)^2\rangle = 1 + \langle\cos(\theta)^2\rangle = 3/2$.

Figure 6.2 also shows how the receiver demodulates the signal, i.e., how it recovers the modulation envelope from the carrier wave. The detector is just an ideal rectifier, which eliminates the negative cycles of the modulated RF signal. A simple lowpass filter then produces the average voltage of the positive loops. (Usually this is a simple *RC* filter, but the lowpass filter used in Figure 6.3 is a

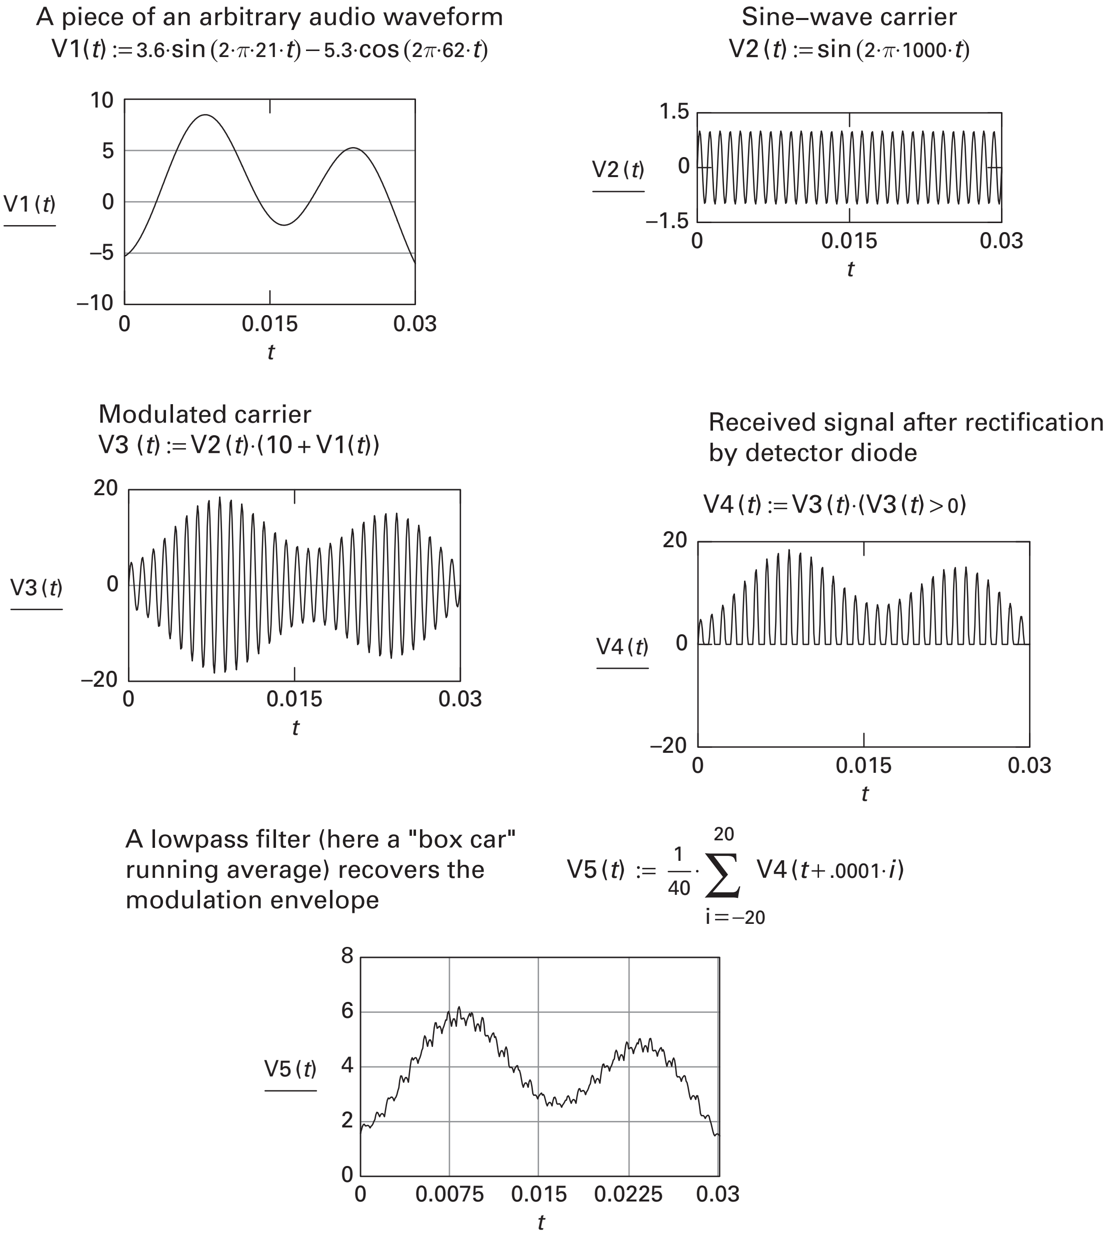

Figure 6.3. Waveforms in the AM system of Figure 6.2.

"boxcar" integrator that forms a running average.) Finally, ac coupling removes the bias, leaving an audio signal identical to the signal from the microphone.

6.1.2 AM in the frequency domain

Let us look at the spectrum of the AM signal to see how the power is distributed in frequency. This is easy when the audio signal is a simple sine wave, say V_a sin

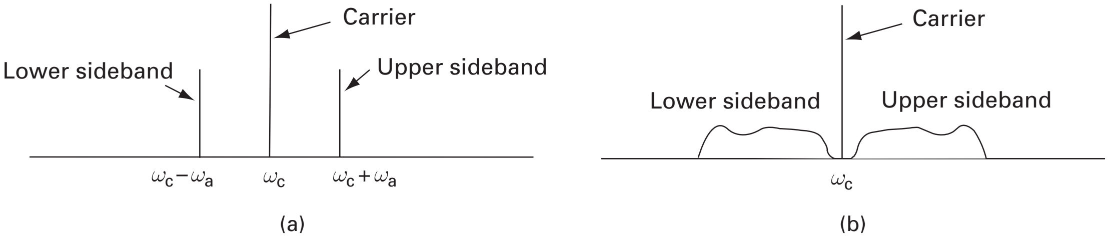

Figure 6.4. Spectrum of an AM power spectrum: (a) modulation by a single-tone modulation; (b) modulation by an audio spectrum.

$(\omega_a t)$. The voltage at point 3 in Figure 6.2 is then $\sin(\omega_c t)(V_m + V_a \sin(\omega_a t)) = V_m \sin(\omega_c t) + 1/2\ V_a \cos([\omega_c - \omega_a]t) - 1/2\ V_a \cos([\omega_c + \omega_a]t)$. These three terms correspond to the *carrier* at ω_c with power $V_m^2/2$, a *lower sideband* at $\omega_c - \omega_a$ with power $V_a^2/8$, and an *upper sideband* at $\omega_c + \omega_a$, also with power $V_a^2/8$. This spectrum is shown in Figure 6.4(a).

Note that the carrier, the component at ω_c, is always present and that its amplitude is independent of the modulation level. At 100% sine-wave modulation $V_a = V_m$ and the average power in each sideband is $\frac{1}{4}$ of the carrier power. The maximum average power is therefore $\frac{3}{2}$ times the carrier power, as we saw earlier from the time domain description. The sidebands, which carry all the information, account here for only $\frac{1}{3}$ of the total power transmitted. With speech waveforms the sidebands may contain even less power.

If, instead of a single sine wave, the audio signal is a superposition of sine waves with different frequencies (and amplitudes), the above analysis is readily extended to show that the upper and lower sidebands become continuous bands of frequency components straddling the carrier symmetrically, as shown in Figure 6.4(b). As the audio signal changes, the shape and size of the sidebands change. A typical audio signal has components at frequencies as high as 10 KHz. AM broadcast stations restrict their audio to not exceed 10 KHz but this still produces a 20 KHz-wide spectrum. The spacing between frequency assignments in the AM broadcast band is only 10 KHz. To prevent overlap, no two stations in a given listening area are assigned the same frequency or adjacent frequencies.

6.2 Frequency and phase modulation

In frequency modulation (FM) and phase modulation (PM) the audio voltage controls the phase angle of the sinusoidal carrier wave while the amplitude remains constant. Since frequency is the time derivative of phase, the two quantities cannot be varied independently; FM and PM are only slightly different methods of *angle modulation*. The advantage of FM (or PM) broadcasting over AM broadcasting is that, under strong signal conditions, the audio signal-to-noise ratio at the output of the receiver can be much higher for FM than for AM. The only price paid for this improvement is increased bandwidth (this topic is discussed in detail in Chapter 23).

6.2.1 FM in the time domain

A simple unmodulated carrier wave is given by $V(t)=\cos(\omega_c t+\phi_0)$ where ω_c and ϕ_0 are constants. The phase, $\phi(t)=(\omega_c t+\phi_0)$, of this cw signal increases linearly with time at a rate ω_c radians per second. In FM, the instantaneous frequency is made to shift away from ω_c by an amount proportional to the modulating audio voltage, i.e., $\omega(t)=\omega_0+k_{osc}V_a(t)$. A linear voltage-controlled oscillator (VCO) driven by the audio signal, as shown in Figure 6.5a, makes an FM modulator.

The excursion from the center frequency, $k_{osc}V_a$, is known as the (radian/s) *deviation*. In FM broadcasting the maximum deviation, defined as 100% modulation, is 75 kHz, i.e., $k_{osc}V_{a_{max}}/2\pi=75\cdot10^3$. Consider the case of modulation by a single audio tone, $V_a(t)=A\cos(\omega_a t)$. The instantaneous frequency of the VCO is then $\omega(t)=\omega_c+k_{osc}A\cos(\omega_a t)$. And, since the instantaneous frequency is the time derivative of phase, the phase is given by the integral

$$\phi(t)=\int\omega(t)\mathrm{d}t=\int(\omega_c+k_{osc}A\cos(\omega_a t))\mathrm{d}t=\omega_c t+\frac{k_{osc}A}{\omega_a}\sin(\omega_a t)+\phi_0. \tag{6.1}$$

From Equation (6.1), we see that, in addition to the linearly increasing phase, $\omega_c t$, of the unmodulated carrier, there is a phase term that varies sinusoidally at the audio frequency. The amplitude of this sinusoidal phase term is $k_{osc}A/\omega_a$. This maximum phase excursion is known as the *modulation index*. The inverse dependence on the modulation frequency, ω_a, results from phase being the integral of frequency. Phase modulation (PM) differs from FM only in that it does not have this ω_a denominator; it could be produced by a fixed-frequency oscillator followed by a voltage-controlled phase shifter. An indirect way to produce a PM signal is to use a standard FM modulator (i.e., a VCO), after first passing the audio signal through a differentiator. The differentiator produces a factor, ω_a, which cancels the ω_a denominator produced by the VCO. This scheme is shown in Figure 6.6.

Similarly, a PM transmitter can be adapted to produce FM. A possible receiver for PM would be the receiver of Figure 6.5(b) with an integrator after

the diode detector to undo the differentiation done in the transmitter of Figure 6.6. (See Chapter 18 for more FM and PM detectors.) In the simple FM receiver of Figure 6.5(b), a bandpass filter converts FM into AM because the carrier frequency is placed on the slope of the filter. When the carrier frequency increases, the filter response decreases the amplitude. After this filter, the rest of the receiver is an AM receiver. A limiting amplifier ahead of the filter is a refinement to eliminate amplitude noise, as well as to make the audio volume independent of signal strength. More refined AM and FM detectors are presented in Chapter 18.

6.2.2 Frequency spectrum of FM

Using the expression for phase from Equation (6.1) (neglecting ϕ_0) and using the usual expansion for $\cos(a+b)$, the complete FM signal (VCO output) for single-tone modulation becomes

$$V(t) = \cos(\phi(t)) = \cos(\phi_{\mathrm{m}} \sin(\omega_{\mathrm{a}} t)) \cos(\omega_{\mathrm{c}} t) - \sin(\phi_{\mathrm{m}} \sin(\omega_{\mathrm{a}} t)) \sin(\omega_{\mathrm{c}} t) \tag{6.2}$$

where $\phi_{\mathrm{m}} = k_{\mathrm{osc}} A/\omega_{\mathrm{a}}$ is the modulation index. Let us first consider the case where the modulation index is small.

6.2.3 Narrowband FM or PM

At very low modulation levels, both FM and PM produce a power spectrum similar to AM, i.e., a carrier with an upper sideband ω_{a} above the carrier and a lower sideband ω_{a} below the carrier. To see this, we expand Equation (6.2) for very small ϕ_{m}, obtaining

$$V(t) \approx \left(1 - \frac{\phi_{\mathrm{m}}^2 \sin^2(\omega_{\mathrm{a}} t)}{2}\right) \cos(\omega_{\mathrm{c}} t) - \phi_{\mathrm{m}} \sin(\omega_{\mathrm{a}} t) \sin(\omega_{\mathrm{c}} t). \tag{6.3}$$

The first term is an almost constant amplitude spike at the carrier frequency, much like the carrier of an AM signal. You can verify directly that the amplitude of $V(t)$ remains constant by summing the squares of the coefficients of $\cos(\omega_c t)$ and $\sin(\omega_c t)$. Expanding the right-hand term gives the two sidebands,

$$V(t) \approx \cos(\omega_c t)\left(1 - \frac{\phi_m^2 \sin^2(\omega_a t)}{2}\right) + (\phi_m/2)\cos[(\omega_c + \omega_a)t] - (\phi_m/2)\cos[(\omega_c - \omega_a)t]. \tag{6.4}$$

This differs from an AM signal in that the sidebands are equivalent to having multiplied the audio signal not by $\cos(\omega_c t)$, the carrier, but by $\sin(\omega_c t)$. Note also that, in this limit of small modulation index, the amplitude of the sidebands is small and the width of the spectrum stays fixed at $2\omega_a$, just as with AM.

6.2.4 Wideband FM spectrum

Looking at Equation (6.2), we see that the signal consists of the products of $\cos(\omega_c t)$ and $\sin(\omega_c t)$, multiplied respectively by the baseband signals $\cos[\phi_m \sin(\omega_a t)]$ and $\sin[\phi_m \sin(\omega_a t)]$. When ϕ_m is not small, these products are similar and each consists of upper and lower sidebands around ω_c, with frequency components spaced from the carrier frequency by integral multiples of ω_a. The $\cos(\omega_c t)$ and $\sin(\omega_c t)$ carriers are suppressed and the spectrum has no distinct central carrier spike. An exact analysis uses Fourier analysis of the cos(sin) and sin(sin) terms[2] to find the comb of sidebands, but a simpler argument can give an estimate of the bandwidth of the FM signal. Referring again to Equation (6.2), the baseband modulating signals produce sidebands. In a time equal to one-quarter of an audio cycle, the expression $\phi_m \sin(\omega_a t)$ changes by ϕ_m radians, so the phase of the baseband modulating signals changes by ϕ_m radians. Dividing this phase change by the corresponding time interval, $1/(4f_a) = \pi/(2\omega_a)$, the average sideband frequency is given by $2\phi_m \omega_a/\pi$. Substituting $\phi_m = k_{osc} A/\omega_a$, the average frequency is $2k_{osc}A/\pi = (2/\pi) \times$ deviation. Therefore, the one-sided bandwidth of the FM signal, when the modulation index is large, is roughly equal to the maximum deviation and the full bandwidth is about twice the maximum deviation. If the deviation is reduced, the bandwidth goes down proportionally at first but then, in the narrowband regime, stays constant at twice the audio bandwidth, as shown above.

---

[2] The terms in Equation (6.2) can be expanded into harmonics of the audio frequency by using the Bessel function identities:

$$\cos(\phi \sin(\omega t)) = J_0(\phi) + 2\sum_{n=1}^{n=\infty} J_{2n}(\phi)\cos(2n\omega t)$$

and

$$\sin(\phi \sin(\omega t)) = 2\sum_{n=0}^{n=\infty} J_{2n+1}(\phi)\sin((2n+1)\omega t).$$

6.2.5 Frequency multiplication of an FM signal

When a signal is passed through a times-N frequency multiplier its phase is multiplied by N. A square-law device, for example, can serve as a frequency doubler since $\cos^2(\phi) = 1/2 + 1/2\cos(2\phi)$. So if the phase of an FM signal, ϕ, (the right-hand expression in Equation 6.1), is multiplied by 2 by using a frequency doubler, both ω_c and kA/ω_a are multiplied by 2, i.e., the frequency and the modulation index are doubled. When a given VCO cannot be linearized well enough within the intended operating range, it can be operated with a low deviation and its signal can be frequency-multiplied to increase the deviation. If the resulting center frequency is too high, an ordinary mixer can shift it back down, preserving the increased deviation.

6.3 AM transmitters

The simple AM transmitter shown in Figure 6.2 is entirely practical. (Of course we would fix it up so that a battery would not be needed to supply the bias voltage.) The linear RF power amplifier would be the major part of this transmitter. We saw in Chapter 3 that a class-B linear amplifier has relatively high efficiency, π/4 or 78.5%, but that is for a maximum-amplitude sine wave. Let us find the efficiency for the transmitter of Figure 6.2, assuming the average modulation power is 10% of the peak modulation power. (The "crest" factor for speech is often taken to be 16 (12 dB), but broadcasters normally use dynamic range compression to increase "loudness.") Let the output signal be given by

$$V_{\text{out}} = V_{\text{dc}}\tfrac{1}{2}[1 + V_{\text{m}}(t)]\cos(\omega t) \tag{6.5}$$

where $|V_{\text{m}}(t)| \leq 1$. Note that the maximum output voltage is V_{dc}, the power supply voltage. (Refer to the amplifier circuit of Figures 3.7 or 3.8.) Remembering that $\langle\cos^2\rangle = 1/2$ and assuming that the audio signal is an ac signal, i.e., $\langle V_{\text{m}}(t)\rangle = 0$, we can express the average output power:

$$\begin{aligned} P_{\text{out}} &= \langle V_{\text{out}}{}^2\rangle/R = \tfrac{1}{4}V_{\text{dc}}{}^2\langle[1 + V_{\text{m}}(t)]^2\rangle/(2R) \\ &= \tfrac{1}{4}V_{\text{dc}}{}^2(1 + 0.1)/(2R) = 1.1V_{\text{dc}}{}^2/(8R), \end{aligned} \tag{6.6}$$

where R is the load (antenna) resistance and where we have used the fact that $\langle\cos(\omega t)\rangle = 0$. The average power delivered by the dc supply is given by

$$\begin{aligned} \langle V_{\text{dc}}I_{\text{supply}}\rangle &= V_{\text{dc}}\langle|V_{\text{out}}(t)/R|\rangle \\ &= V_{\text{dc}} \cdot \tfrac{1}{2}V_{\text{dc}}\langle[1 + V_{\text{m}}(t)/R\rangle 2/\pi = V^2_{\text{dc}}/(\pi R), \end{aligned} \tag{6.7}$$

where we have used the fact that the average of a positive loop sin(x) is equal to 2/π. Calculating the efficiency, we find

$$\eta = \frac{\text{power out}}{\text{power in}} = (1.1)/V_{\text{dc}}{}^{2}/(8R) \div V_{\text{dc}}^{2}/\pi = 1.1\pi/8 = 43.2\%. \qquad (6.8)$$

Therefore, when running this AM transmitter, only 43.2% of the prime power gets to the antenna; the rest is dissipated as heat in the class-B amplifier.

Almost all AM transmitters obtain higher efficiency by using class-C, D, or E RF amplifiers. These amplifiers are not linear in the normal sense, that is, the output signal amplitude is not a constant multiple of the input signal amplitude. But, for a fixed input RF amplitude, the output amplitude *is* proportional to the supply voltage. These amplifiers can therefore be used as high-power *multipliers* that form the product of the power supply voltage times a unit sine wave at the RF frequency. Furthermore, the efficiency of these amplifiers, which is high, is essentially independent of the supply voltage. (These amplifiers are discussed in detail in Chapter 9.) Let us look at the overall efficiency of transmitters using these amplifiers.

6.3.1 AM transmitter using a class-C RF amplifier and a class-B modulator

In the traditional AM transmitter, audio voltage developed by a high-power class-B audio amplifier (the modulator) is added to a dc bias and the sum of these voltages powers a class-C RF amplifier. As explained above, a class-C RF amplifier acts as a high-power multiplier. In the traditional tube-type circuit of Figure 6.7, the dc bias is fed through the secondary of the modulation transformer. Audio voltage produced by the modulator appears across the secondary winding and adds to the bias voltage. With no audio present, the class-B audio amplifier consumes negligible power and the bias voltage supply provides power for the carrier. At 100% sine-wave modulation, the modulator must supply audio power equal to half the bias supply power. A 50 000 watt transmitter thus requires a modulator that can supply 25 000 W of audio power. (Again, this result is for a single tone, but is essentially the same for speech or music.)

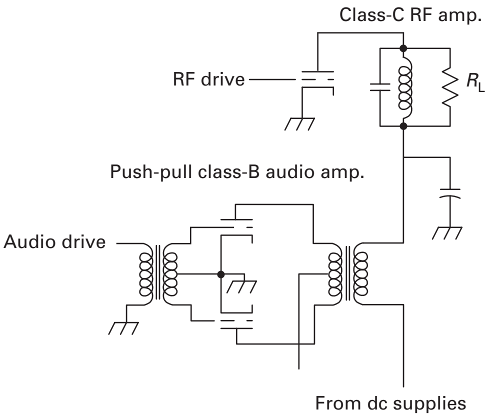

Figure 6.7. Class-B plate-modulated AM transmitter.

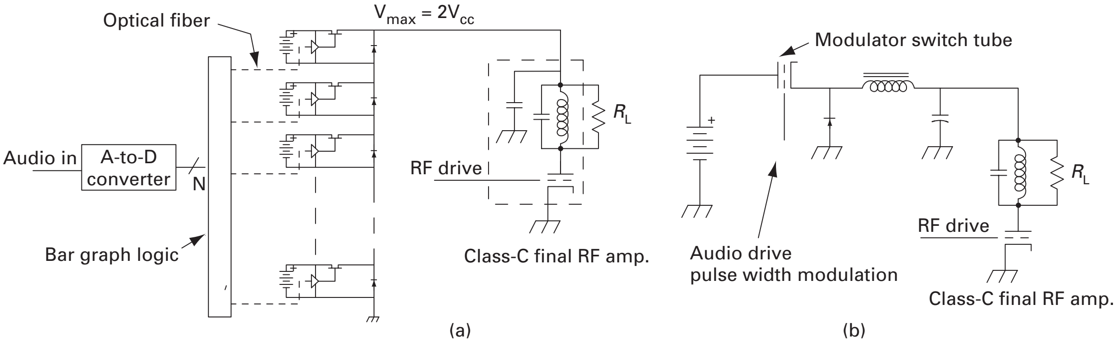
Let us find the efficiency of this transmitter. We will assume the class-C amplifier has an efficiency of 80% and that, as before, the average modulation power is 10% of the maximum possible modulation power. If the normalized output carrier power is 1 W, the dc bias supply must provide 1/0.8 W and the modulator must supply 0.1/0.08 W. To handle peaks, the maximum power from the modulator must be 1/0.08 W. To find the efficiency of the class-B modulator, we must know not only its peak output voltage, but also the mean of the absolute value of its output voltage. (Note that this last piece of information was not needed in the analysis of the class-B RF amplifier transmitter discussed above.) Let us just assume the modulating signal is a single audio sine wave whose power is 0.1/0.8 W. With that assumption, the modulator will have an efficiency of 0.35. The total input power, carrier plus modulation, will therefore be 1/0.8 +(0.1/0.35)/0.8 = 1.61 W. The output power will be 1 + 0.1, so the overall efficiency of this transmitter is 68%, a significant improvement over the transmitter using a linear class-B RF amplifier.

6.3.2 Class-C RF amplifier with a switching modulator

There are several newer methods to produce AM with even higher efficiency. All use switching techniques. The modulator shown in Figure 6.8(a) is just a high-power digital-to-analog converter. It uses solid-state switches to add the voltage of many separate low-voltage power supplies, rather than tubes or transistors to resistively drop the voltage of a single high-voltage supply. Modulators of this type can, in principle, be 100% efficient, since the internal switch transistors are either fully on or fully off. The modulator of Figure 6.8(b) is a pulse rate modulator whose output voltage is equal to the supply voltage multiplied by the duty factor of the switch tube.

This type of circuit, whose efficiency can also approach 100%, is discussed in detail with switching power supplies in Chapter 29. Again specifying an average modulation power of 10%, the combination of an 80% efficient class-C RF amplifier together with a switching modulator, makes an AM transmitter with an overall efficiency of 80%.

Figure 6.8. Class-C RF amplifier with (a) high-power D-to-A modulator and (b) duty cycle switching modulator.



6.3.3 Class-D or E amplifiers with switching modulators

Class D and class-E RF amplifiers can approach 100% efficiency. Like the class-C amplifier, the amplitude of their output sine wave is proportional to the dc supply voltage. When one of these amplifiers is coupled with a switching modulator, the resulting AM transmitters can approach an overall efficiency of 100% for any modulation level.

6.4 FM transmitters

Since FM modulation is generated by a VCO at a low level, and the signal has a constant amplitude, there is no other modulator nor is there any requirement that the final power amplifier have a linear amplitude response. Class-C amplifiers have been used most often, with efficiencies around 80%.

6.5 Current broadcasting practice

Many $\frac{1}{2}$ MW to 2 MW AM stations operate in the long-wave, medium-wave, and short-wave bands. These superpower transmitters use vacuum tubes. Standard AM broadcast band transmitters in the U.S. are limited to 50 kW. For this power and lower powers, new AM transmitters manufactured in the U.S. use transistors. These transmitters combine power from a number of modular amplifiers in the 1 kW range. The advantages of solid state include lower (safer) voltages, indefinite transistor life rather than expensive tube changes every year or two, and better “availability;” a defective module only lowers the power slightly and can be replaced while the transmitter remains on the air. Most FM transmitters over about 10 kW still use vacuum tubes, but solid-state FM transmitters are available up to about 40 kW.

Stereophonic sound was added to FM broadcasting around 1960. Existing monophonic receivers operated as they had, receiving the left + right (L + R) audio signal. Thus the system is (backwardly) *compatible*, just as color television was compatible with existing black and white television receivers. The L − R signal information is in the demodulated signal, but clustered around 38 kHz, above the audible range. The L − R signal uses double-sideband suppressed carrier AM modulation, which is explained in Chapter 8. The demodulator to recover the L-R signal is discussed in Chapter 18. Stereo was added to AM radio broadcasting around 1980. Several systems competed to become the standard, but the public was largely indifferent, having already opted for FM stereo. Compatible digital broadcasting has recently been introduced, with versions for both the AM and FM bands. In this IBOC (In-Band On-Channel) system, a station’s digital simulcast signal (which can contain different program material) shares the same channel with the standard AM or FM signal, mostly using the relatively empty spectral regions near (and somewhat past) the nominal edges of the channel. The digital signal, which can be produced by a separate transmitter and may even use a separate antenna, uses COFDM (Coded Orthogonal Frequency-Division Multiplexing), a modulation system, described in Chapter 22. This system is intended to be a stepping-stone to all-digital radio broadcasting in the traditional AM and FM bands. IBOC broadcasting equipment is equipped to transmit an all-digital mode, to be used if and when the traditional analog broadcasting is discontinued.

Problems

Problem 6.1. An AM transmitter, 100% modulated with an audio sine wave, has sidebands whose total power is equal to half the carrier power. Consider 100% modulation by an audio square wave. What is the ratio of sideband power to carrier power?

Problem 6.2. Suppose you are trying to listen to a distant AM station, but another station on the same frequency is coming in at about the same strength. Will you hear both programs clearly? If not, how will they interfere with each other?

Problem 6.3. During periods where the audio signal level is low, the amplitude of an AM signal varies only slightly from the carrier level. The modulation envelope, which carries all the information, rides on top of the high-power carrier. If the average amplitude could be decreased without decreasing the amplitude of the modulation, power could be saved. Discuss how this might be accomplished at the transmitter and what consequences, if any, it might have at the receiver.

Problem 6.4. Show how a PM transmitter can be used to generate FM.

Problem 6.5. Consider an FM transmitter modulated by a single audio tone. As the modulation level is increased, the spectral line at the carrier frequency decreases. Find the value of the modulation index that makes the carrier disappear completely.

Problem 6.6. One of the methods used for compatible AM stereo was a combined AM/PM system. The left + right (L + R) signal AM-modulated the carrier in the usual way, while the L − R signal was used to phase-modulate the carrier. Draw block diagrams of a transmitter and receiver for this system. Why would PM be preferable to FM for the L − R signal?

CHAPTER

7

Radio receivers

In this chapter we will be mostly concerned with the sections of the receiver that come before the detector, sections that are common to nearly all receivers: AM, FM, television, cell phones, etc. Basic specifications for any kind of radio receiver are *gain, dynamic range, sensitivity* and *selectivity*, i.e., does a weak signal at the selected frequency produce a sufficiently strong and uncorrupted output (audio, video, or data) and does this output remain satisfactory in the presence of strong signals at nearby frequencies?

Sensitivity is determined by the noise power contributed by the receiver itself. Usually this is specified as an equivalent noise power at the antenna terminals. Selectivity is determined by a bandpass-limiting filter and might be specified as “3 dB down at 2 kHz from center frequency and 20 dB down at 10 kHz from center frequency.” (Receiver manufacturers usually do not specify the exact bandpass shape.)

7.1 Amplification

Let us consider how much amplification is needed in ordinary AM receivers. One milliwatt of audio power into a typical earphone produces a sound level some 100 dB above the threshold of hearing. A barely discernable audio signal can therefore be produced by −100 dBm (100 dB below 1 mW or 10^{-13} watts). Let us specify that a receiver, for comfortable earphone listening, must provide 50 dB more than this threshold of hearing, or 10^{-8} watts. You can see that, with efficient circuitry, the batteries in a portable receiver could last a very long time! (Sound power levels are surprisingly small; you radiate only about 1 mW of acoustic power when shouting and about 1 nW when whispering.) How much signal power arrives at a receiver? A simple wire antenna could intercept 10^{-8} watts of RF power at a distance of about 20 000 km from a 10 kW radio station at 1 MHz having an omnidirectional transmitting antenna, so let us first consider “self-powered” receivers.

7.2 Crystal sets

The earliest radios, crystal sets, were self-powered. A crystal diode rectifier recovered the modulation envelope, converting enough of the incoming RF power into audio power to drive the earphone. A simple *LC* tuned circuit served as a bandpass filter to select the desired station and could also serve as an antenna matching network. The basic crystal set receiver is shown in Figure 7.1.

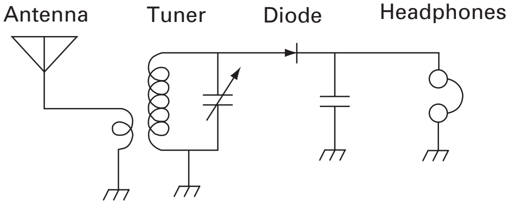


Figure 7.1. Self-powered crystal set receiver.

The considerations given above show that a self-powered receiver can have considerable range. But when the long-wire antenna is replaced by a compact but very inefficient loop antenna and the earphone is replaced by a loudspeaker, amplification is needed. In addition, we will see later that the diode detector, when operated at low signal levels, has a square-law characteristic, which causes the audio to be distorted. For proper envelope detection of an AM signal, the signal applied to a diode detector must have a high level, several milliwatts. The invention of the vacuum tube, followed by the transistor, provided the needed amplification. Receivers normally contain both RF and audio amplifiers. RF amplification provides enough power for proper detector operation, while subsequent audio amplification provides the power to operate loudspeakers.

7.3 TRF receivers

The first vacuum tube radios used a vacuum tube detector instead of a crystal, and added RF preamplification and audio post-amplification, as described above. These *TRF* (Tuned Radio Frequency) sets[1] had individual tuning adjustments for each of several cascaded RF amplifier stages. Changing stations

---

[1] Early radios were called “radio sets” because they were literally a set of parts including one or more tubes and batteries (or maybe just a crystal detector), inductors, “condensers,” resistors, and headphones. Many of these parts were individually mounted on wooden bases, and, together with “hook-up” wires, would spread out over a table top.

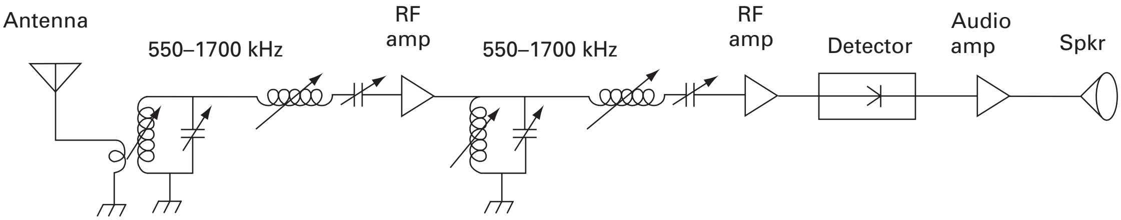

Figure 7.2. TRF receiver.

required the user to adjust several dials (often with the aid of a tuning chart or graph).

Figure 7.2 shows a hypothetical TRF receiver with cascaded amplifiers and bandpass filters.

Note that all the inductors and capacitors should be variable in order to tune the center frequency of the bandpass filters and also maintain the proper bandwidth, which is about 10 kHz for AM. (In a practical circuit, the bandpass filters would use a coupled-resonator design rather than the straightforward lowpass-to-bandpass conversion design shown here.)

7.4 The superheterodyne receiver

The disadvantages of TRF sets were the cost and inconvenience of having many tuning adjustments. Most of these adjustments were eliminated with the invention of the superheterodyne circuit by Edwin H. Armstrong in 1917. Armstrong's circuit consists of a fixed-tuned, i.e., single-frequency, TRF back-end receiver, preceded by a frequency converter front-end (mixer and local oscillator) so that the signal from any desired station can be shifted to the frequency of the TRF back-end. This frequency is known as the intermediate frequency or IF. The superheterodyne is still the circuit used in nearly every radio, television, and radar receiver. Among the few exceptions are some toy walkie-talkies, garage-door openers, microwave receivers used in radar-controlled business place door openers, and highway speed trap radar detectors. Figure 7.3 shows the classic broadcast band "superhet."

Selectivity is provided by fix-tuned bandpass filters in the IF amplifier section. The AM detector here is still a diode, i.e., the basic envelope detector. (In Chapter 18 we will analyze this detector, among others.) All the RF gain can be contained in the fixed-tuned IF amplifier, although we will see later that there are sometimes reasons for having some amplification ahead of the mixer as well. Figure 7.3 also serves as the block diagram for FM broadcast receivers, where the IF frequency is usually 10.7 MHZ, and for television receivers, where the IF center frequency is commonly around 45 MHZ.

Note: There was indeed a *heterodyne* receiver that preceded the superheterodyne. Invented by radio pioneer Reginald Fessenden, the heterodnye receiver

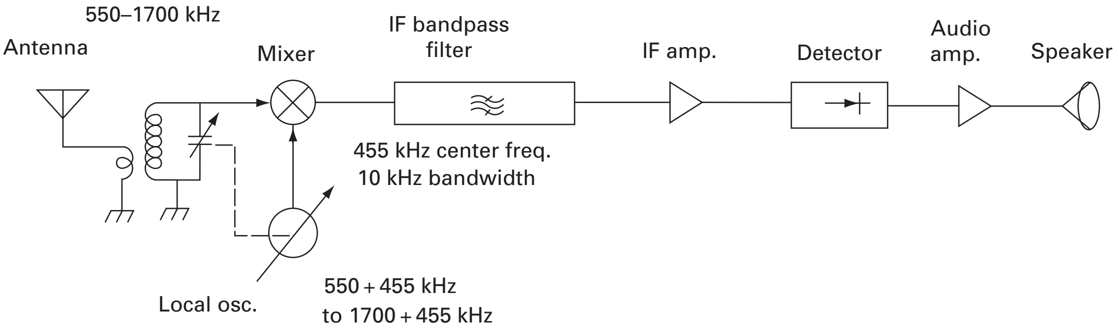

Figure 7.3. Standard superheterodyne receiver for the AM broadcast band.

converted the incoming RF signal directly to audio. This design, known as a "direct-conversion receiver," is disucussed below.

7.4.1 Image rejection

The superhet has some disadvantages of its own. With respect to signals at the input to the mixer, the receiver will simultaneously detect signals at the desired frequency and also any signals present at an undesired frequency known as the *image frequency*. Suppose we have a conventional AM receiver with an IF frequency of 455 kHz and suppose the local oscillator is set at 1015 kHz in order to receive a station broadcasting at $1015 - 455 = 560$ kHz (560 kHz is near the lower edge of the AM broadcast band). All the mixers we have considered will also produce a 455-kHz IF signal from any input signal present at 1470 kHz, i.e., 455 kHz above the local oscillator. If the receiver has no RF filtering before the mixer and if there happens to be a signal at 1470 kHz, it will be detected along with the desired 560 kHz signal. A bandpass filter ahead of the mixer is needed to pass the desired frequency and greatly suppress signals at the image frequency. Note that in this example (the most common AM receiver design), this anti-image bandpass filter must be tunable and, for the receiver to have single-dial tuning, the tuned filter must always "track" 455 kHz below the L.O. frequency. In this example, the tracking requirement is not difficult to satisfy; since the image frequency is more than an octave above the desired frequency, the simple one-section filter shown in Figure 7.2 can be fairly broad and still provide adequate image rejection, maybe 20 dB. (Note, though, that 20 dB is not adequate if a signal at the image frequency is 20 dB stronger than the signal at the desired frequency.)

What if a receiver with the same 455 kHz IF frequency is also to cover the short-wave bands? The worst image situation occurs at the highest frequency, 30 MHz, where the image is only about 3% higher in frequency than the desired frequency. A filter 20 dB down at only 3% from its center frequency will need to have many sections, all of which must be tuned simultaneously with a mechanical multisection variable capacitor or voltage-controlled varicaps. As explained above, the center frequency of the filter must be track with a 455 kHz offset from the L.O. frequency in order that the desired signal fall within the narrow IF passband. Image rejection is not simple when the IF frequency is much lower than the input frequency.

Solving the image problem

A much higher IF frequency can solve the image problem. If the AM broadcast band receiver discussed above were to have an IF of 10 MHz rather than 455 kHz, the L.O. could be tuned to 10.560 MHz to tune in a station at 560 kHz. The image frequency would be 20.560 MHz. As the radio is tuned up to the top end of the AM broadcast band, 1700 kHz, the image frequency increases to 21.700 MHz. In this case, a fixed-tuned bandpass filter, wide enough to cover the entire broadcast band, can be placed ahead of the receiver to render the receiver insensitive to images. This system is shown in Figure 7.4. Only the local oscillator needs to be changed to tune this receiver. Of course, the 10 MHz IF filter must still have a narrow 10 kHz passband to establish the receiver's basic selectivity.

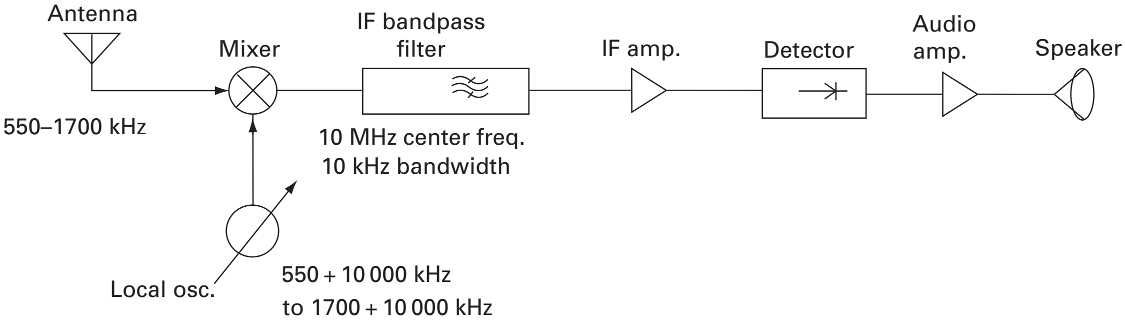

Figure 7.4. Image-free broadcast receiver using a 10 MHz IF.

The circuit of Figure 7.4 is entirely practical although it is more expensive to make the necessary narrowband filters at higher frequencies; quartz crystal resonator elements must be used in place of lumped *LC* elements. If the input band is wider, e.g., 3–30 MHz for a short-wave receiver, the IF frequency would have to be much higher, and narrowband filters become impractical. (Even at 10 MHz, a bandwidth of 10 kHz implies a very narrow fractional bandwidth, 0.1%.) A solution to both the image problem and the narrow fractional bandwidth problem is provided by the *double-conversion superhet*.

Double conversion superhet

Figure 7.5 shows how a second frequency converter takes the first IF signal at 10 MHz and converts it down to 455 kHz, where it can be processed by the standard IF section of the receiver of Figure 7.3. The 10-MHz first IF filter can be wider than the ultimate passband.

Suppose, for example, that the first IF section has a bandwidth of 500 kHz. The second L.O. frequency is at 10.455 MHz, so the second mixer would

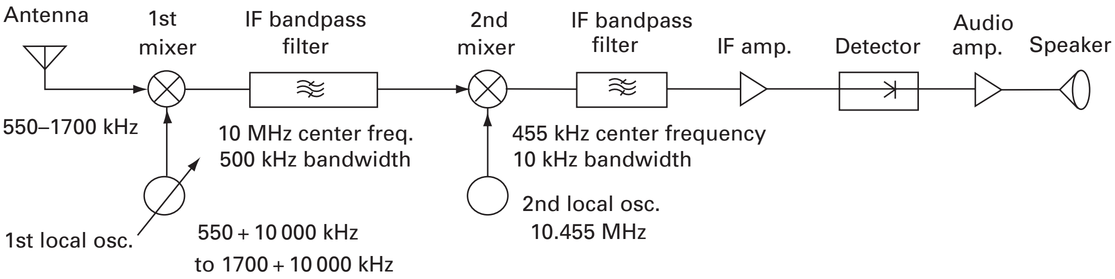

Figure 7.5. Double conversion superhet.

produce an image from a signal at 10.910 MHz. But note that our first IF filter cuts off at 10 MHz + 0.500 MHz /2 = 10.25 MHz, so there will be no signals at 10.910. This system has its own special disadvantages: the receiver usually cannot be used to receive signals in the vicinity of its first IF, since it is difficult to avoid direct feedthrough into the IF amplifier. Multiple conversions require multiple local oscillators and various sum and difference frequency combinations inevitably are produced by nonlinearities and show up as spurious signals known as “birdies.”

Present practice for communications receivers is to use double or triple conversion with a first IF frequency at, say, 40 MHz. The front-end image filter is usually a 30 MHz lowpass filter. In as much as modern crystal filters can have a fairly small bandwidth even at 40 MHz, the output of the first IF section can be mixed down to a second IF with a much lower frequency. Sometimes triple conversion is necessary when the final IF frequency is very low, e.g., 50 kHz. The use of first IF frequencies in the VHF region requires very stable local oscillators but crystal oscillators and frequency synthesizers provide the necessary stability. (Oscillator phase noise was a problem in the first generation of receivers with synthesized local oscillators; the oscillator sideband noise was shifted into the passband by strong signals near the desired signal but outside the nominal passband.)

Image rejection mixer

Another method of solving the image problem is to use an image rejection mixer, such as the circuit shown in Figure 7.6.

This circuit uses two ordinary mixers (multipliers). The lower multiplier forms the product of $\cos(\omega_{\mathrm{L.O}}.t)$ and an input signal, $\cos[(\omega_{\mathrm{L.O}}.\pm\omega_{\mathrm{IF}})\ \mathrm{t}]$, depending on whether the input signal is above or below the L.O. frequency. The upper multiplier has a 90° delay in its connection to the L.O., so it forms the product of $\sin(\omega_{\mathrm{L.O}}.t)$ and $\cos[(\omega_{\mathrm{L.O}}.\pm\omega_{\mathrm{IF}})\mathrm{t}]$. Neglecting the sum frequency terms, the outputs of the upper and lower multipliers are, respectively, $\mp\sin(\omega_{\mathrm{IF}}\mathrm{t})$ and $\cos(\omega_{\mathrm{IF}}t)$. The output from the lower multiplier is delayed by 90°, so the upper and lower signals at the input to the adder are $\mp\sin(\omega_{\mathrm{IF}}t)$ and $\sin(\omega_{\mathrm{IF}}t)$. Thus, for an input frequency of $\omega_{\mathrm{L.O}}. - \omega_{\mathrm{IF}}$, the output of the adder is 2 $\sin(\omega_{\mathrm{IF}}t)$, but when the input frequency is $\omega_{\mathrm{L.O}}. + \omega_{\mathrm{IF}}$, the output of the adder is

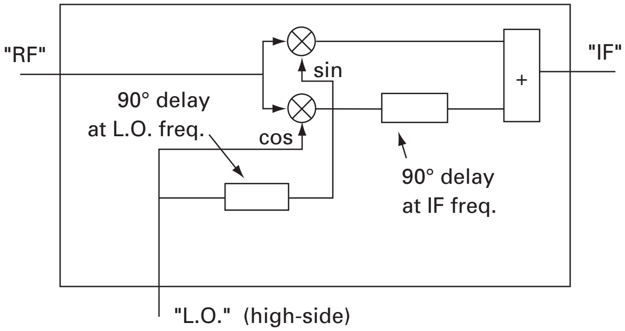

Figure 7.6. Image rejection mixer.

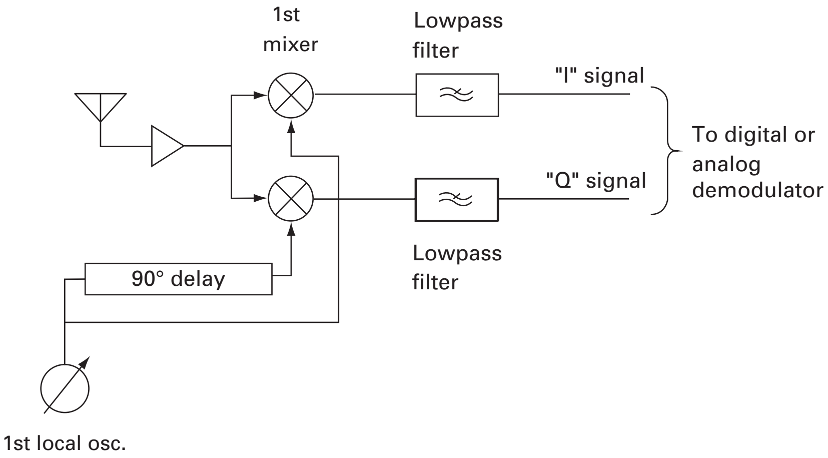
zero. Thus, this mixer rejects signals above the L.O. frequency. The same circuit crops up in Chapter 8, as a *single-sideband generator*. In practice this circuit might provide 20–40 dB of image rejection. It can be used together with the standard filtering techniques to get further rejection.

Zero IF frequency – direct conversion receivers

The evolution of the superhet, which was always toward higher IF frequencies and multiple conversions, has taken a new twist with the advent of the nearly limitless signal processing power available from DSP chips. Direct conversion receivers, in a reversion to the heterodyne architecture, shift the center frequency of the desired signal, ω_C, all the way to zero Hz ("baseband"). Generally this requires that the signal be mixed separately with local oscillator signals $\cos(\omega_C t)$ and $\sin(\omega_C t)$ to preserve all the signal information. To see this, note that the input signal, which is sinusoidal, will, in general, be out of phase at times with $\cos(\omega_C t)$ and at other times with $\sin(\omega_C t)$. Thus, the outputs of the "cosine mixer" or "sine mixer" can go to zero but, together, these "I" (in-phase) and "Q" (quadrature) signals contain all the signal information. To see this, note that the original signal could be easily reconstructed from the I and Q signals. Lowpass filtering of the I and Q signals determines the passband of the receiver, e.g., 5-kHz rectangular lowpass filters on the I and Q signals would give the receiver a flat passband extending 5 kHz above and 5 kHz below the L.O. frequency. The classic image problem, severe at low IF frequencies, disappears when the IF frequency is zero. The low-frequency I and Q signals can be digitized directly for subsequent digital processing and demodulation (see Problem 7.8). No bulky IF bandpass filters are required. Even tiny surface acoustic wave (SAW) bandpass filters are huge, compared to the real estate on DSP chips. With this architecture, nearly 100% of a receiver can be incorporated on a chip, including a tunable frequency synthesizer to produce the L.O. signals. Figure 7.7 shows a block diagram of a direct-conversion receiver. Everything on this diagram plus an L.O. synthesizer is available on a single chip intended for use in HD television receivers.

Figure 7.7. Direct conversion receiver.



7.4.2 Automatic gain control

Nearly every receiver has some kind of automatic gain control (AGC) to adjust the gain of the RF and/or IF amplifiers according to the strength of the input signal. Without this feature the receiver will overload; overdriven amplifiers go nonlinear (“clip”) and the output will be distorted as well as too loud. The output sound level of an FM receiver, depending on the design of the demodulator, may not vary with signal level but overloading the IF amplifier stages will still produce distortion, so FM receivers also need AGC. Television receivers need accurate AGC to maintain the correct contrast level (analog TV) or threshold levels (digital TV). Any AGC circuit is a feedback control system. In simple AM receivers the diode detector provides a convenient dc output voltage that can control the bias current (and hence gain) of the RF amplifiers. The controlled bias current can also be used to drive a signal strength indicator.

7.5 Noise blankers

Many receivers, including most television receivers, have a noise blanker circuit to reduce the effects of impulse noise such as the spiky noise produced by automobile ignition systems. Here the interfering pulses are of such short duration that the IF stages can be gated off briefly while the interference is present. The duty cycle of the receiver remains high and the glitch is all but inaudible (or invisible). An important consideration is that the gating must be done before the bandwidth is made very narrow since narrow filters elongate pulses.

7.6 Digital signal processing in receivers

Advances in digital electronics, notably fast A-to-D conversion and processors, make it possible to do all-digital filtering and detection in a receiver. Any desired filter amplitude and phase response can be realized.

Besides direct-conversion receivers on a chip, there are many single-chip superhet chips, usually using image cancelling mixers followed by digital bandpass filters operating at low IF frequencies. Adaptive digital filters can correct for propagation problems such as multipath signals. Digital demodulators allow the use of elaborate signal encoding which provides high spectral efficiency (bits/sec/Hz) as well as error correction through the use of redundant bits. Digital modulation techniques are discussed in Chapter 22.

Problems

Problem 7.1. The FM broadcast band extends from 88 to 108 MHz. Standard FM receivers use an IF frequency of 10.7 MHz. What is the required tuning range of the local oscillator?

Problem 7.2. Why are airplane passengers asked not to use radio receivers while in flight?

Problem 7.3. Two sinusoidal signals that are different in frequency, if simply added together, will appear to be a signal at a single frequency but amplitude modulated. This "beat" phenomenon is used, for example, to tune two guitar strings to the same frequency. When they are still at slightly different frequencies, the sound seems to pulsate slowly at a rate equal to their frequency difference. Show that

$$\sin([\omega_0 - \delta\omega]t) + \sin([\omega_0 + \delta\omega]t) = A(t)\sin(\omega_0 t)$$

where

$$A(t) = 2\cos(\delta\omega t).$$

(Note that this addition is a linear process; no new frequencies are generated.)

Problem 7.4. Using an AM receiver in an environment crowded with many stations, you will sometimes hear an annoying high-pitched 10 kHz tone together with the desired audio. If you rock the tuning back and forth the pitch of this tone does not change. What causes this?

Problem 7.5. When tuning an AM receiver, especially at night, you may hear "heterodynes" or whistling audio tones that change frequency as you slowly tune the dial. What causes this? Can it be blamed on the receiver? (Answer: Yes.)

Problem 7.6. Using modern components and digital control, we could build good TRF radios. What advantages would such a radio have over a superheterodyne? What disadvantages?

Problem 7.7. You may have observed someone listening to distorted sound from an AM radio whose tuning is not centered on the station. Often this mistuning is done deliberately when the listener has impaired high-frequency hearing and/or the radio has insufficient bandwidth. What is going on here? Why would a radio not have sufficient bandwidth and why would insufficient bandwidth cause some listeners to tune slightly off station?

Problem 7.8. Design a direct-conversion AM broadcast receiver using digital processing of the I and Q signals. Assume that the L.O. frequency may not be set exactly equal to the frequency of the desired station. Hint: compute the input signal amplitude from the digitized I and Q signals. Then feed this stream of amplitudes into a D-to-A converter.

CHAPTER

8

Suppressed-carrier AM and quadrature AM (QAM)

Viewed just in the time domain, ordinary AM, as used in broadcasting, seems so obvious that one would scarcely imagine how it might be done otherwise. But viewed in the frequency domain, as in Chapter 6, this system shows some obvious inefficiencies. First, most of the average transmitted power (about 95% when transmitting typical audio material) is in the carrier, which is a spike or "delta function" in the frequency domain. Since its amplitude and frequency are constant, it carries virtually no information. The information is in the sidebands. Could broadcasters just suppress the carrier to reduce their electric power costs by 95%? Second, the upper and lower sidebands are mirror images of each other, so they contain the same information. Could they not suppress (filter away) one sideband, making room for twice as many stations on the AM band? The answer to both questions is yes but, in both cases, the simple AM receiver, with its envelope detector, will no longer work properly. Economics favored the simplicity of the traditional AM receiver until it because possible to put all the receiver signal processing on an integrated-circuit chip, where the additional complexity can have negligible cost. In this chapter we examine alternate AM systems that remove the carrier and then at AM systems that reduce the signal bandwidth or double the information carried in the original bandwidth.

8.1 Double-sideband suppressed-carrier AM

Let us look at a system that removes the carrier at the transmitter and regenerates it at the receiver. It is easy enough to modify the transmitter to eliminate the carrier. Review the circuit diagram given previously for an AM transmitter (Figure 6.2a). If we replace the bias battery by a zero-volt battery (a wire), the carrier disappears. The resulting signal is known as *Double-Sideband Suppressed-Carrier* (DSBSC). To restore the missing carrier we might try the receiver circuit shown in Figure 8.1. The locally generated carrier, from a *beat frequency oscillator* (BFO), is simply added back into the IF signal, just ahead

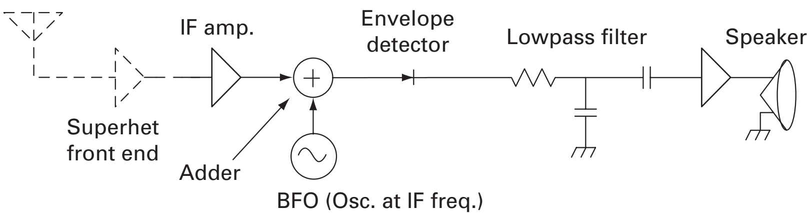

Figure 8.1. Hypothetical DSBSC receiver: additive carrier reinsertion and envelope detection.

of the envelope detector. The energy saved by suppressing the carrier can increase battery lifetime in walkie-talkies by a factor of maybe 20. The modulation schemes used in many cell phones (after the first generation) likewise do away with battery-draining constant carriers.

In a superheterodyne receiver, we only have to generate this carrier at one frequency, the intermediate frequency (IF). As you would expect, the added carrier must have the right frequency. But it must also have the right phase. Suppose, for example, that the modulation is a single audio tone at 400 Hz. If the replacement carrier phase is off by 45°, the output of the envelope detector will be severely distorted. And if the phase is off by 90° the output of the detector will be a tone at 800 Hz (100% distortion!). These example waveforms are shown in Figure 8.2.

Correct carrier reinsertion is fairly easy if the transmitter provides a low-amplitude “pilot” carrier to provide a phase reference. In the model transmitter of Figure 6.2(a) we would go back to using a bias battery, but it would have a low voltage. In principle, the receiver could have a tuned IF amplifier with a narrowband gain peak at the center frequency to bring the pilot carrier up to full level. The most common method, however, is to use a VCO for the BFO in Figure 8.1, together with a feedback circuit to phase lock it to the pilot carrier.

8.2 Single-sideband AM

The requirement for correct BFO phasing is not critical if only one of the two sidebands is transmitted. The sidebands are mirror images of each other so they carry the same information and one will do. We will discuss later three methods to eliminate one of the sidebands from a DSBSC signal, but the first and most obvious method is to use a bandpass filter to select the desired sideband. The resulting signal is known as *Single-Sideband Suppressed-Carrier* (SSBSC) or simply as *Single-Sideband* (SSB). Take the previous example of a single 400-Hz audio tone. The SSB transmitter will put out a single frequency, 400 Hz above the frequency of the (suppressed) carrier if we have selected the upper sideband. This signal will appear in the receiver 400 Hz away from the IF center frequency. Suppose we are still using the BFO and envelope detector. The

$t := 0, 0.1 .. 300$

carrier(t) := sin(t)

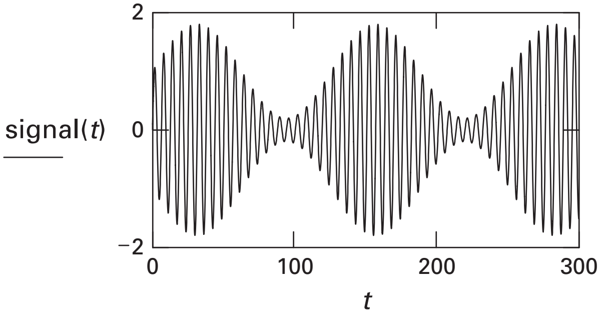
audio(t) := $0.8 \cdot \sin(0.05 \cdot t)$ Audio is sine wave at 1/20 carrier frequency

dssc(t) := audio(t)·carrier(t) Double sideband suppressed carrier (sidebands alone)

Note that dssc(t) = $1/2(\cos(0.95t) - \cos(1.05)t)$

signal(t) := carrier(t) + dssc(t) Carrier plus sidebands = (1 + audio)(carrier) = normal AM

(a) Sidebands plus correct carrier. (note that the envelope is the sinewave audio)

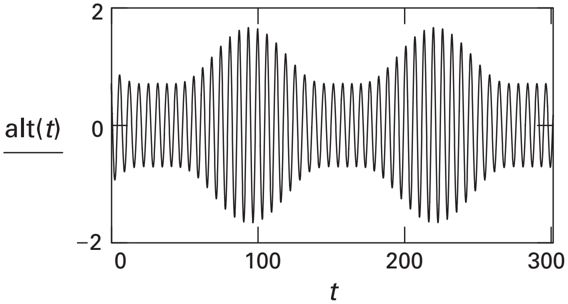


alt(t) := dssc(t) + $\cos(t + \frac{\pi}{4})$

Give the re-injected carrier a 45° phase error.

(b) Sidebands with carrier 45° out of phase

(Note envelope distortion)



alt2(t) := dssc(t) + cos(t)

Here the re-injected carrier has a 90° phase error.

(c) Sidebands with carrier 90° out of phase

(Note that the envelope has twice the audio frequency – total distortion)

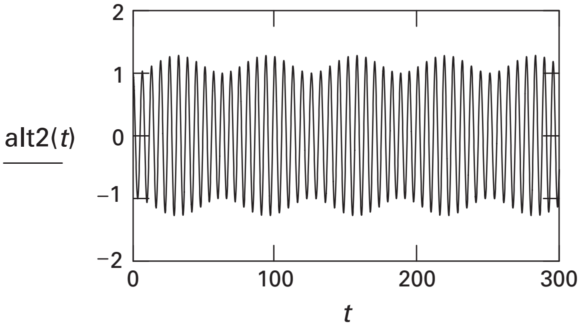


Figure 8.2. Detection of DSSC by adding a local carrier.

envelope of the signal-plus-BFO will indeed be an undistorted sine wave at 400 Hz. So far, so good. But suppose the signal had been two tones, one at 400 Hz and one at 600 Hz. When the BFO carrier is added, the resulting envelope will have tones at 400 and 600 Hz but it will also have a component at 200 Hz (600 − 400) which is distortion. Unwanted signals are produced by the IF components beating with each other; their strength is proportional to the product of the two IF signals. The strength of each wanted component, on the other hand, is proportional to the product of its amplitude times the amplitude of the BFO. If the BFO amplitude is much greater than the IF signal the distortion can be reduced.

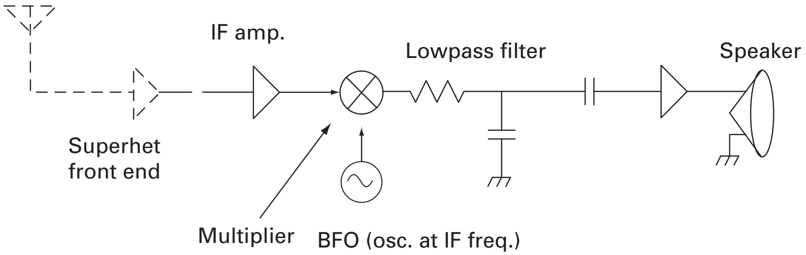
8.3 Product detector

The distortion described above can be avoided by using a *product detector* instead of an envelope detector. In the receiver shown in Figure 8.3, the product detector is just the familiar multiplier (a.k.a. mixer).

The output of this detector is, by the distributive law of multiplication, the sum of the products of each IF signal component times the BFO signal. There are no cross-products of the various IF signal components. Product detectors are also called "baseband mixers" or "baseband detectors," because they translate the sideband components all the way down to their original audio frequencies.

While a product detector does not produce cross-products (intermodulation distortion) of the IF signal components, the injected carrier should ideally have the correct phase. The wrong phase is of no consequence in our single-tone example. But when the signal has many components, their relative phases are important. A waveform will become distorted if all its spectral components are given an identical phase shift (see Problem 8.3). It is only when every component is given a phase shift proportional to its frequency that a waveform is not distorted but only delayed in time. Therefore a single-sideband transmitter, like the double-sideband transmitter, should really transmit a pilot carrier and the receiver should lock its BFO phase to this pilot. Some SSB systems do just that. But for voice communications it is common to use no pilot. Speech remains intelligible and almost natural-sounding even when the BFO phase is

Figure 8.3. SSBSC receiver using a product detector.



wrong.[1] The BFO can even be slightly off frequency. When the frequency is too high, a demodulated upper sideband (USB) voice signal has a lower than natural pitch. When it is too low, the pitch is higher than natural.

Finally, what happens if we try to use a product detector with a free-running (not phase locked) BFO to receive DSBSC? If the BFO phase is off by 90°, the detector produces no output. If the BFO phase happens to be correct, the output will have maximum amplitude. For an intermediate-phase error the amplitude will be reduced.

Advantages of SSB

Single-sideband, besides not wasting power on a carrier, uses only half the bandwidth, so a given band can hold twice as many channels. Halving the receiver bandwidth also halves the background noise so there is a 3-dB improvement over conventional AM in signal-to-noise ratio. When a spectrum is crowded with conventional AM signals, their carriers produce annoying beat notes in a receiver (a carrier anywhere within the receiver passband appears to be a sideband belonging to the spectrum of the desired signal). With single-sideband transmitters there are no carriers and no beat notes. Radio amateurs, the military, and aircraft flying over oceans use SSB for short-wave (1.8–30 MHz) voice communication.

8.4 Generation of SSB

There are at least three well-known methods to generate single-sideband. In the filter method of Figure 8.4, a sharp bandpass filter removes the unwanted sideband. This filter usually uses crystal or other high-Q mechanical resonators and has many sections. It is never tunable, so the SSB signal is generated at a single frequency (a transmitter IF frequency) and then mixed up or down to the desired frequency. The filter, in as much as it does not have infinitely steep skirts, will cut off some of the low-frequency end of the voice channel.

The phasing method uses two multipliers and two phase-shift networks to implement the trigonometric identity:

$$\cos(\omega_{\mathrm{c}}t)\cos(\omega_{\mathrm{a}}t) \pm \sin(\omega_{\mathrm{c}}t)\sin(\omega_{\mathrm{a}}t) = \cos([\omega_{\mathrm{c}} \mp \omega_{\mathrm{a}}]t). \qquad (8.1)$$

The subscripts “a” and “c” denote the audio and (suppressed) carrier frequencies. If the audio signal is $\cos(\omega_{\mathrm{a}}t)$, we have to generate the $\sin(\omega_{\mathrm{a}}t)$ needed for the second term. A 90° audio phase shift network can be built with passive components or digital signal processing techniques. The audio phase-shift network is usually implemented with two networks, one ahead of each mixer. Their phase *difference* is close to 90° throughout the audio band. The second term also

---

[1] Human perception of speech and even music seems to be remarkably independent of phase. When an adjustable allpass filter is used to produce arbitrary phase vs. frequency characteristics (while not affecting the amplitude), test subjects find it difficult or impossible to distinguish phase-modified audio from the original source.

requires that we supply sin($\omega_c t$) but, since ω_c is fixed, anything that provides a 90° shift at this one frequency will suffice. Figure 8.5 illustrates the phasing method used to generate an upper sideband (USB) signal.

If the adder is changed to a subtractor (by inverting the polarity of one input), the output will be the upper rather than the lower sideband.

A third method [2] needs neither a sharp bandpass filter nor phase-shift networks. Weaver's method, shown in Figure 8.6, uses four multipliers and two lowpass filters. The trick is to mix the audio signal with a first oscillator whose frequency, ω_0, is in the center of the audio band. The outputs of the first

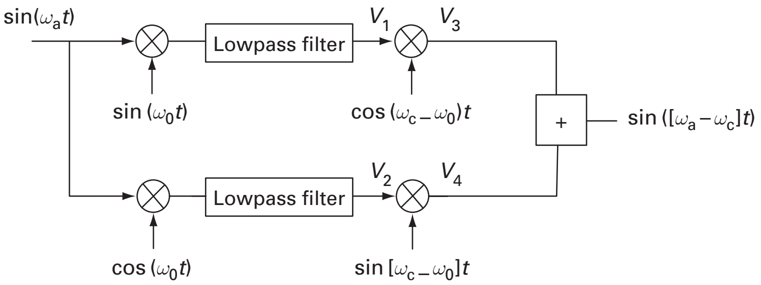

Figure 8.6. SSB generator – Weaver method.

set of mixers have the desired 90° phase difference. The second set of mixers then works the same way as the two mixers in the phasing method.

Referring to Figure 8.6,

$$V_1(t) = \text{lowpass }[\sin(\omega_a t)\sin(\omega_0 t)] = {}^1\!/_2 \cos([\omega_a - \omega_0]t) \tag{8.2}$$

$$V_2(t) = \text{lowpass }[\sin(\omega_a t)\cos(\omega_0 t)] = {}^1\!/_2 \sin([\omega_a - \omega_0]t) \tag{8.3}$$

$$\begin{aligned} V_3(t) &= {}^1\!/_2 \cos[(\omega_c - \omega_0)t]\cos[(\omega_a - \omega_0)t] \\ &= {}^1\!/_4 \cos([\omega_a - \omega_c]t) + {}^1\!/_4 \cos([\omega_a + \omega_c - 2\omega_0]t) \end{aligned} \tag{8.4}$$

$$\begin{aligned} V_4(t) &= {}^1\!/_2 \sin[(\omega_c - \omega_0)t]\sin[(\omega_a - \omega_0)t] \\ &= {}^1\!/_4 \cos[(\omega_a - \omega_c)t] - {}^1\!/_4 \cos[(\omega_a + \omega_c - 2\omega_0)t] \end{aligned} \tag{8.5}$$

$$V_{\mathrm{ou}}\mathrm{t}(t) = V_3(t) + V_4(t) = {}^1\!/_2 \cos\,[(\omega_c - \omega_a)t]. \tag{8.6}$$

We see from Equation (8.6) that this particular arrangement generates the lower sideband.

8.5 Single-sideband with class C, D, or E amplifiers

The three methods described above for generating a single-sideband signal are done in low-level circuitry. Linear amplifiers then produce the required power for the antenna. There is, however, a way to use a class-C or class-D amplifier with simultaneous phase modulation and amplitude modulation to produce SSB. This follows from the fact that any narrowband signal (CW, AM, FM, PM, SSB, DSB, narrowband noise, etc.) is essentially a sinusoid at the center frequency, ω_0, whose phase and amplitude vary on a time-scale longer than $(\omega_0)^{-1}$. Suppose we have generated SSB at low level. We can envelope-detect it, amplify it, and use the amplified envelope to AM-modulate the class-C or class-D amplifier. At the same time we can phase-modulate the amplifier with the phase determined from the low-level SSB signal. The low-level signal is simply amplitude-limited and then used to drive the modulated amplifier. The point is that the high-power SSB signal is produced with an amplifier that has close to 100% efficiency. Moreover, an existing AM transmitter can be converted to single-sideband by making only minor modifications.

8.6 Quadrature AM (QAM)

We noted above that a product detector used for DSBSC will produce no output if the BFO phase is wrong by 90°. It follows that two independent DSBSC signals can be transmitted over the same channel. At the receiver, the phase of the BFO selects one or the other. This is known as quadrature AM (QAM). Note that the carrier can be suppressed, but retaining at least a low-power pilot carrier provides a phase reference for the receiver. Figure 8.7 shows the transmitter (a) and receiver (b) for a QAM system. Here, the receiver uses a narrowband filter to isolate the pilot carrier and then amplifies it to obtain a reconstituted BFO or LO, depending on whether the receiver is a superheterodyne or uses direct conversion to baseband. In practice, carrier regeneration is almost always done with a phase lock loop.

Figure 8.7. QAM:
(a) transmitter; (b) receiver.

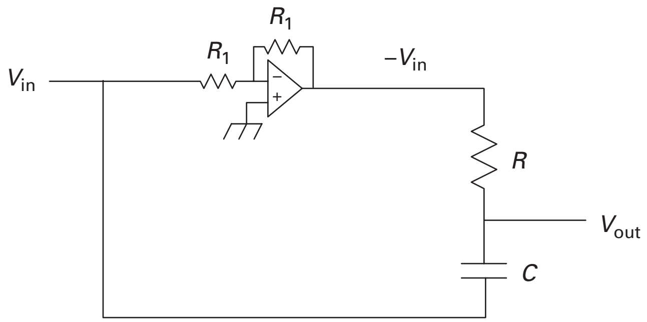
The U.S. NTSC and European PAL standards for color television use QAM to transmit a pair of video color difference signals. In the NTSC system, these so-called *I* and *Q* signals (In-phase and Quadrature) are multiplied by sine and cosine versions of a 3.579-MHZ oscillator signal and the resulting DSBSC signals are added to the normal video ("luminance") signal. Other uses of QAM include delivery of digital TV signals to set-top converters in some cable television systems and data distribution in some LANs.

The QAM system of Figure 8.7 could also be used to broadcast AM stereo sound, with both the L + R (left plus right) and L − R signals fitting into the channel used traditionally for L + R alone. However, such a QAM stereo signal would not be compatible with the envelope detector in standard AM receivers. Several compatible analog systems were developed and used for AM stereo, but at this writing, both AM and FM stations are adopting compatible *hybrid digital* (HD) systems in which the digital signals occupy spectral space on either side of the conventional analog signal. This system, which uses *COFDM* modulation, is discussed in Chapter 22.

Problems

Problem 8.1. Demonstrate for yourself the kind of phase distortion that will occur when the BFO in a product detector does not have the same phase as the suppressed carrier. Use the Fourier decomposition of a square wave: $V(t) = \sin(\omega t) + 1/3 \sin(3\omega t) + 1/5 \sin(5\omega t) + \ldots$. Have your computer plot $V(\theta) = \sin(\theta) + 1/3 \sin(3\theta) + 1/5 \sin(5\theta) + \cdots + 1/9 \sin(9\theta)$ for θ from 0 to 2π. Then plot $V'(\theta) = \sin(\theta+1) + 1/3 \sin(3\theta+1) + 1/5 \sin(5\theta+1) + \cdots + 1/9 \sin(9\theta+1)$, i.e., the same function but with every Fourier component given an equal phase shift (here 1 radian). Would you expect these waveforms to sound the same? Consider the case in which the phase shift is 180°. This just inverts the waveform. Is this a special case or is an inverted audio waveform actually distorted?

Problem 8.2. The phase-shift networks used in the phasing method of single-sideband generation have a flat amplitude vs. frequency response – they are known as *allpass* filters. Allpass filters have equal numbers of poles (all in the left-hand plane) and zeros (all in the right-hand plane). Find the amplitude and phase response of the network shown below, which is a first-order allpass filter. (Note that the inverting op-amp is used only to provide an inverted version of the input.)



Problem 8.3. The most general allpass filter can be obtained by cascading first-order allpass sections (Problem 8.2) with second-order allpass sections. Find the amplitude and phase response of the network shown below, a second-order allpass filter.

CHAPTER

9

Class-C, D, and E power RF amplifiers

Class-C, D, and E RF power amplifiers are all about high efficiency. They are used in large transmitters and industrial induction heaters, where high efficiency reduces the power bill and saves on cooling equipment, and also in the smallest transmitters, such as cell phones, where high efficiency increases battery life. These amplifiers are so nonlinear (the output signal amplitude is not proportional to the input signal amplitude), they might better be called synchronized sine wave generators. They consist of a power supply, at least one switching element (a transistor or vacuum tube), and an *LCR* circuit. The "*R*" is the load, R_{L}, often the radiation resistance of an antenna, equivalent to a resistor. The *LC* network is resonant at the operating frequency. The output sine-wave amplitude, while not a linear function of the input signal amplitude, *is* proportional to the power supply voltage. Thus, these amplifiers can be amplitude modulated by varying the supply voltage. Of course they can also be frequency modulated by varying the drive frequency (within a restricted bandwidth, determined by the *Q* of the *LC* circuit). Finally, they can be used as frequency multipliers by driving them at a subharmonic of the operating frequency.

9.1 The class-C amplifier

Figure 9.1 shows a class-C amplifier (a), together with an equivalent circuit (b). The circuit looks no different from the class-B amplifier of Figure 3.15 or a small-signal class-A amplifier. But here the active device (transistor or tube) is used not as a continuously variable resistor, but as a switch. To simplify the analysis, we consider the switch to have a constant on-resistance, *r*, and infinite off-resistance. This model is a fairly good representation of a power FET, when used as a switch.

The switch is closed for less than half the RF cycle, during which time the power supply essentially "tops off" the capacitor, restoring energy that the load has sapped from the resonant circuit during the cycle. The switch has internal resistance (i.e., loss), so in recharging the capacitor, some energy is lost in the

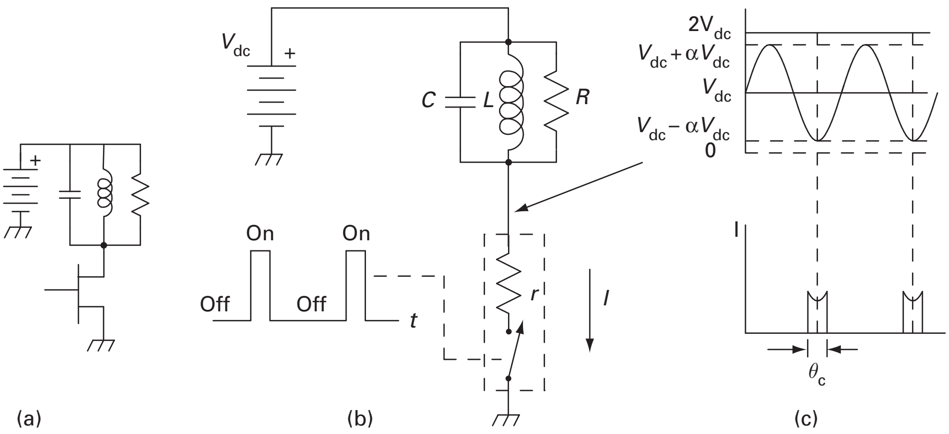

Figure 9.1. Class-C amplifier operation.

switch. Normally the LC circuit has a high Q (at least 5) so its flywheel action minimizes distortion of the sine wave caused by the abrupt pull-down of the switch and by the damping caused by the load. The drive is shown as a rectangular pulse but is often a sine wave, biased so that conduction takes place just around the positive tips. Class-C amplifiers are normally run in saturation, meaning that the switch, when on, always has its lowest possible resistance, ideally much less than the load resistance.

9.1.1 Simplified analysis of class-C operation

The simplified analysis, which we will also use later to analyze the class-E amplifier, is based on the assumption that the LC circuit provides enough flywheel effect to maintain a perfect sine wave throughout the cycle, including the interval when the resistive switch is closed. With this assumption, let us analyze the circuit of Figure 9.1 to find the output voltage and, thereby, the power and the efficiency. Referring to the figure, θ_c is the conduction angle, V_{dc} is the supply voltage, r is the on-resistance of the switch, and αV_{dc} is the peak voltage of the sine wave. We can find α as follows. The input power (the power supplied by the battery) must be equal to the sum of the output power (the power dissipated in R) plus the power dissipated in the switch resistance r. These terms are given respectively by the average of the battery voltage times the current, $(\alpha V_{dc})^2/(2R)$, and the average of I^2/r. The power equation becomes

$$\frac{1}{2\pi}\int_{\theta_c/2}^{\theta_c/2} V_{dc}\left(\frac{V_{dc}-\alpha V_{dc}\cos\theta}{r}\right)\mathrm{d}\theta = \frac{(\alpha V_{dc})^2}{2R} + \frac{1}{2\pi}\int_{-\theta_c/2}^{\theta_c/2}\left(\frac{V_{dc}-\alpha V_{dc}\cos\theta}{r}\right)^2 r\mathrm{d}\theta. \tag{9.1}$$

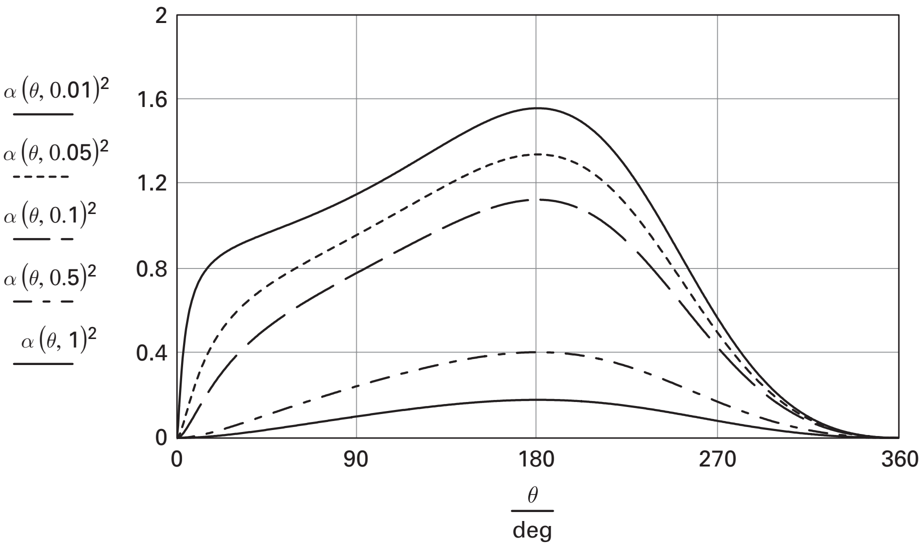

Figure 9. 2. Class-C output power ($\alpha 2$) vs. conduction angle for five values of r/R. The efficiency is given by the output power divided by the power supplied by the battery.

Rearranging this equation, we get

$$\frac{1}{\pi r/R}\int_{0}^{\theta_c/2}(1-\alpha\cos\theta)(\alpha\cos\theta)\mathrm{d}\theta-\frac{\alpha^2}{2}=0. \tag{9.2}$$

Carrying out the integral in Equation (9.2) and solving for α, we find

$$\alpha(\theta_c, r/R)=\frac{2\sin(\theta_c/2)}{\theta_c/2+\sin(\theta_c)/2+\pi r/R}. \tag{9.3}$$

The quantity α^2, proportional to the output power, is plotted in Figure 9.2 for five values of r/R, the ratio of the switch resistance to the load resistance.

The middle value, $r/R = 0.1$, is typical in actual practice. Maximum power is produced for a conduction angle of 180°, i.e., if the switch is closed during the entire negative voltage loop. If the conduction angle exceeds 180°, the incursions into the positive loop extract energy from the tuned circuit and the power is reduced. Note that α^2, and therefore α, can be greater than unity, especially when the conduction angle is 180°. We will see below, however, that much higher efficiency is obtained for conduction angles substantially less than 180°. The efficiency is given by the output power divided by the power supplied by the battery:

$$\eta(\theta_c, r/R)=\frac{(\alpha V_{\mathrm{dc}})^2/2R}{\frac{1}{2\pi}\int_{-\theta_c/2}^{\theta_c/2} V_{\mathrm{dc}}(V_{\mathrm{dc}}-\alpha V_{\mathrm{dc}}\cos\theta'/r)\mathrm{d}\theta'}. \tag{9.4}$$

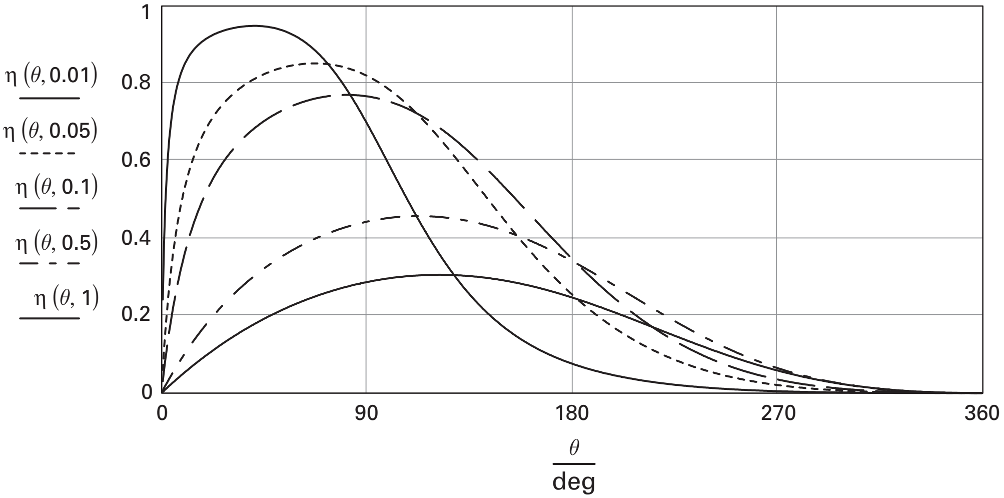

Figure 9.3. Class-C efficiency vs. conduction angle for five values of *r*/*R*.

Evaluating the integral in Equation (9.4) we find

$$\eta(\theta_c, r/R) = \frac{(\pi r/R)\alpha^2}{\theta_c - 2\alpha \sin(\theta_c/2)}, \tag{9.5}$$

where α is given by Equation (9.3). This expression for efficiency is plotted in Figure 9.3 for the same five values of r/R. For $r/R = 0.1$, the efficiency is a maximum at about 90°.

Note that this amplifier model, assuming a constant resistance in the switch, can be solved exactly by finding the general solution for the transient waveform during the switch-off period, as well as the transient waveform during the switch-on period. Because the differential equations are of second order, these general solutions will each have two adjustable parameters. The parameters are found by imposing the boundary conditions that, across the switch openings and closings, the voltage on the capacitor is continuous and the current through the inductor is continuous.

9.1.2 General analysis of a class-C operation with a nonideal tube or transistor

The above analysis will not give accurate results for class-C amplifiers made with tubes or bipolar transistors, because these devices do not have the simple constant on-resistance characteristic of a FET. Nevertheless, their nonlinear characteristics are specified graphically on data sheets, and accurate class-C analyses can be done numerically. The method is basically the same as the simplified analysis; one assumes the resonant *LC* circuits at the input and output have enough *Q* to force the input and output waveforms to be sinusoidal. For this analysis, the device characteristics are plotted in a "constant current" format: in the case of a tube, curves of constant plate current are plotted on a graph whose axes are plate voltage and grid voltage. Sinusoidal plate and grid voltages are assumed and a numerical integration of plate current × plate voltage, averaged through one complete cycle, gives the power dissipated in the device. The power supply voltage times the *average* current gives the total input power. The difference is the power delivered to the load. The designer selects a device and a power supply voltage and assumes trial waveforms with different bias points and sine-wave amplitudes. Usually several trial designs are needed to maximize output power with the given device or to maximize efficiency for a specified output power. A class-C amplifier can approach 100% efficiency, but only in the limit that the output power goes to zero. We will see below that class-D and E amplifiers can approach 100% efficiency and still produce considerable power.

9.1.3 Drive considerations

Class-C amplifiers using vacuum tubes[1] nearly always drive the control grid positive when the tube is conducting. The grid draws current and dissipates power. Data sheets include grid current curves so that the designer can use the procedure outlined above to verify that the chosen operating cycle stays within both the maximum plate dissipation rating and the maximum grid dissipation rating. When tetrodes are used, a third analysis must be done to calculate the screen grid dissipation.

9.1.4 Shunt-fed class-C amplifier

In Figure 9.1, since the switch and the *LCR* tank circuit are in series, they can be interchanged, allowing the bottom of the tank to be at ground potential, which is often a convenience. But the usual way to put the tank at dc ground is to use the shunt-fed configuration shown in Figure 9.4(c).

In the shunt-fed circuit, an RF choke connects the dc supply to the transistor and a blocking capacitor keeps dc voltage off the tank circuit. The RF choke has

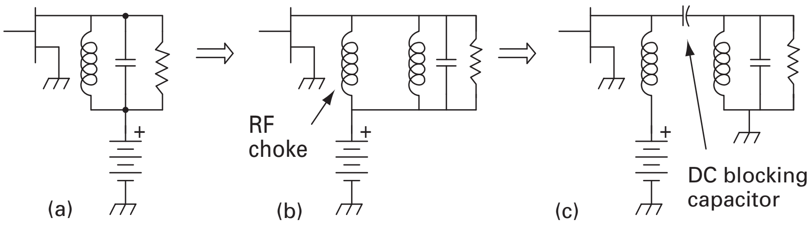

Figure 9.4. Equivalence of series-fed and shunt-fed circuits.

---

[1] A triode vacuum tube is analogous to an NPN transistor. The tube's plate, control grid, and cathode correspond respectively to the transistor's collector, base, and emitter. Tetrode tubes have an additional grid, the screen grid, between the control grid and the plate. The screen grid is usually run at a fixed bias voltage and forms an electrostatic shield between the control grid and the plate [5].

a large inductance, so the current through it is essentially constant. The switch pulls pulses of charge from the blocking capacitor. This charge is replenished by the current through the choke. Figure 9.4 shows, from right to left, the equivalence of the shunt-fed and series-fed circuits. Note that the series-fed and shunt-fed equivalence applies as well to amplifiers of class-A, B, or C and for large-signal or small-signal operation.

9.1.5 The class-C amplifier as a voltage multiplier

An important property of the saturated class-C amplifier is that the peak voltage of the output RF sine wave is directly proportional to the supply voltage ($V_{\text{pk}} = \alpha V_{\text{dc}}$). In the standard saturated operation, the proportionality constant, α, is about 0.9. The class-C amplifier is therefore equivalent to a voltage multiplier which forms the product of a nearly unit-amplitude sine wave times the power supply voltage. Modulating (varying) the power supply voltage of a class-C amplifier is the classic method used in AM transmitters. (Note that this useful property of a class-C (or D or E) amplifier would be considered a defect for an op-amp circuit – poor power supply rejection.)

9.1.6 The class-C amplifier as a frequency multiplier

If the class-C amplifier drive circuit furnishes a turn-on pulse only every other cycle, you can see that the decaying oscillation of the tank circuit voltage will execute two cycles between refreshes. Of course there will be a greater voltage droop, producing less output power, but note that the circuit becomes a frequency doubler. If the circuit is pulsed only on every third cycle, it becomes a tripler, etc. It is common to use a cascade of frequency multipliers to produce a high RF frequency that is a multiple of the frequency of a stable low-frequency oscillator. Class-D and class-E amplifiers can also be used as frequency multipliers.

9.2 The class-D RF amplifier

Class-D amplifiers can, in principle, achieve 100% efficiency. At least two switches are required, but neither is forced to support simultaneous voltage and current. The *class-D series resonant amplifier* is shown in Figure 9.5(a).

A single-pole double-throw switch produces a square-wave voltage. The series LC filter lets the fundamental sine-wave component reach the load, R_{L}. The bottom of the switch could be connected to a negative supply but ground will work since the resonating capacitor provides ac coupling to the load resistor. A real circuit is shown in Figure 9.5(b); two transistors form the switch. This is a push–pull circuit, i.e., the transistors are driven out-of-phase so that when one is on the other is off. Let us find the voltage on the load. Since the capacitor also acts as a dc block, we can consider this square wave to be

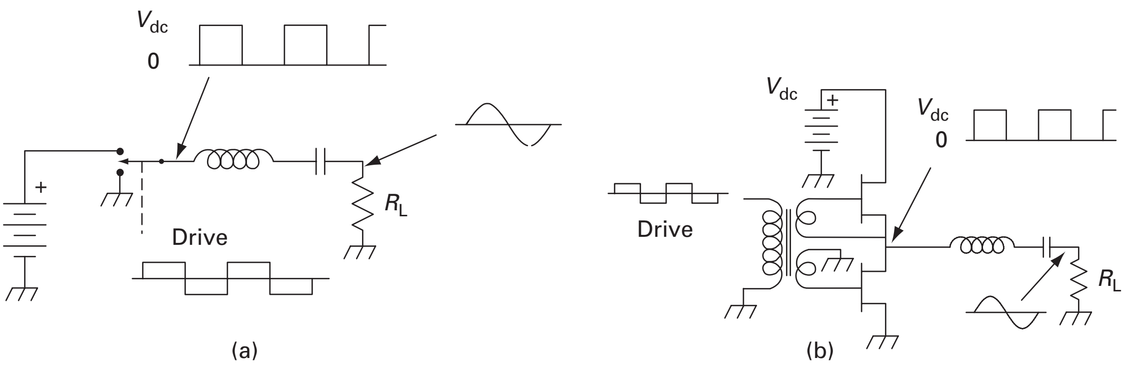

Figure 9.5. Class-D series resonant amplifier.

symmetric about zero, swinging from $-V_{dc}/2$ to $+V_{dc}/2$. The square wave is equivalent to a Fourier series, i.e., a sum of sine waves whose frequencies are the fundamental, and odd multiples of the fundamental. The series resonant *LC* filter passes the fundamental sinusoidal component of the square wave. We can find the amplitude of the output sine wave by equating the dc input power to the sine-wave output power. They must be equal, since the circuit has no lossy element other than R_L, the load. Since both the voltage and current change sign during the negative half of the cycle, the power is the same in the negative half-cycle as in the positive half-cycle. The power delivered by the dc supply is therefore the product of the square-wave voltage, $V_{dc}/2$, times the average of the positive current in the series *LCR*. The current can be written as $I(t) = I_{pk}\sin(\omega t)$ and the average positive current is $\langle|I|\rangle = (2/\pi)\ I_{pk} = (2/\pi)\ V_{pk}/R_L$, where V_{pk} is the peak value of the sine-wave voltage on the load. Equating the power from the supply to the sine-wave power on the load, we have $(V_{dc}/2)\cdot(2/\pi)(V_{pk}/R_L) = 2V_{dc}^2/(R_L)$. Solving for V_{pk}, we find $V_{pk} = 2V_{dc}/\pi$.

To estimate the loss, we will assume the FETs have constant on-resistance, *r*. The current through the load passes through one or the other of the switches, so the ratio of output power to switch power is $(I^2R_L)/(I^2\,r)$ and the efficiency is $\eta = R_L/(R_L{+}r)$. You can see that, inas much as $r \ll R_L$, the efficiency can approach 100%. However, there is another, more important, source of loss in this class-D amplifier. Each switching transistor has parasitic capacitance which is abruptly charged and discharged through the transistor's resistance once per cycle. The energy lost is $\frac{1}{2}CV^2$ per transition so, for the circuit of Figure 9.5, the switching losses would be $4 \times \frac{1}{2}CV_{dc}^2 \times f$. Suppose the frequency, f, is 10 MHz and the FET switches each have, say, 200 pF of parallel capacitance. With a supply voltage of 200 volts, this would produce a loss of 160 watts! This loss can be avoided by using an alternate topology, the parallel resonant class-D amplifier.

9.2.1 Parallel-resonant class-D RF amplifiers

The class-D amplifier of Figure 9.6 consists of a square-wave *current source* driving a parallel *LCR* circuit. In this circuit, a large inductor (RF choke)

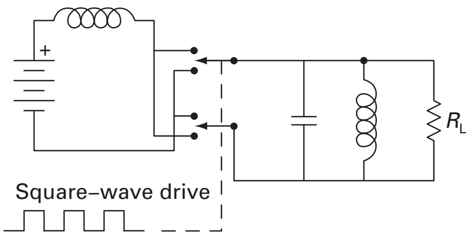

Figure 9.6. Class-D parallel-resonant RF amplifier operation.

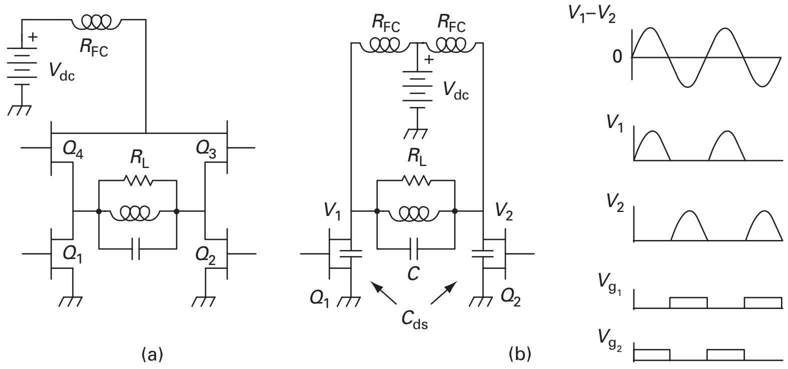

Figure 9.7. Practical class-D parallel-resonant RF amplifiers.

provides the constant current. A DPDT switch commutates the load, effectively forming a square-wave current source.

Two practical versions of this circuit are shown in Figure 9.7. In (a) the peak sine-wave voltage on the load, R_L, will be $\pi V_{\mathrm{dc}}/2$ and the dc supply current will be $\pi^2 V_{\mathrm{dc}}/(8R_{\mathrm{L}})$. For the appealing circuit in (b), these quantities are πV_{dc} and $\pi^2 V_{\mathrm{dc}}/(2R_{\mathrm{L}})$. (See problem 9.4.) But the beauty of the parallel class-D amplifier is that the voltage on the parasitic capacitances of the transistors (drain-to-source capacitance, shown in dotted lines in Figure 9.7b) is zero at the instants the switches open or close. Thus, there is no lossy abrupt charging or discharging of these parasitic capacitors. (Refer to the waveforms in Figure 9.7b. Note that the value of C is effectively increased by C_{ds}, the parasitic capacitance of one transistor – first one, then the other.)

9.3 The class-E amplifier

We have seen that a class-C amplifier can be built with a single transistor and that its efficiency is high, relative to class-B and class-A amplifiers. The class-D switching amplifier, on the other hand can, in principle, achieve 100% efficiency, but requires two transistors. The *class-E amplifier* [4], has both virtues: single transistor operation and up to 100% efficiency. Figure 9.8 shows the circuit.

Figure 9.8. Class-E amplifiers.

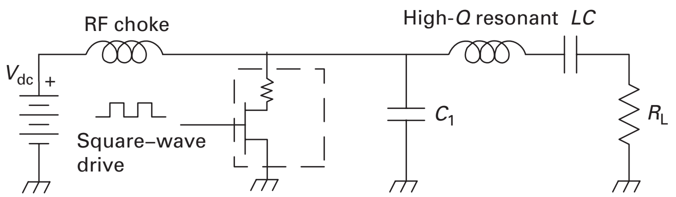

Figure 9.9. Class-E amplifier equivalent circuit.

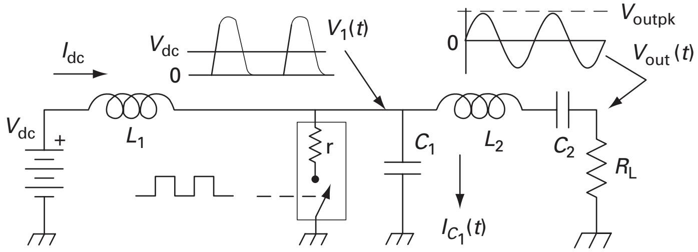

The transistor is used as a switch: fully on or fully off. An equivalent circuit is shown in Figure 9.9, where the transistor is represented as a switch. The switch operates with a 50% duty factor, so the voltage at the switch, $V_1(t)$, is forced to be zero for half the cycle (or almost zero if we consider the switch to have a small series resistance, r).

During the other half-cycle, $V_1(t)$ consists of a rounded positive pulse. The power supply is connected through L_1, an RF choke (a high-value inductor). The choke and the switch form a *flyback* circuit in which the power supply pumps energy into the inductor while the switch is closed and the inductor pumps energy into the rest of the circuit while the switch is open. Since there can be no dc drop across the choke, you can see that the pulses in $V_1(t)$ at the switch must have an average amplitude equal to twice the power supply voltage. The key to the efficiency of this circuit is that it can be designed so that the voltage $V_1(t)$ has fallen to zero at precisely the instant the switch closes, i.e., the capacitor C_1 is shorted out without a sudden lossy discharge. Note that C_1 includes the transistor's parasitic capacitance. The RF choke, L_1, is large enough to ensure that the dc supply current, I_{dc}, has essentially no ac component, i.e., the inductor current's increase and decrease during the flyback cycle are much smaller than the average current.

A simplified description of the circuit operation is as follows. The pulses at C_1 are not square, but must have an average voltage of $2V_{dc}$. The waveform is a rough approximation to a sine wave with a peak voltage of V_{dc} plus an equal dc offset. The bandpass filter formed by L_2 and C_2 passes a good sine wave to the load, R_L. Let us now look in detail at the circuit operation and design.

9.3.1 Class-E amplifier design procedure

We have seen that we can expect this amplifier to furnish the load with a sine wave whose amplitude is something like V_{dc}, so the RF power output will be approximately ${V_{\mathrm{dc}}}^2/(2R_{\mathrm{L}})$. If a different power is desired, the resistance of the load, R_{L}, can be transformed to a different value using any of the techniques of Chapter 2. Next, we can simply pick a value for L_2 that will give a reasonably high Q, maybe 10, so that the waveform at the load will be a good sine wave, i.e., have minimal harmonic content. We are left with finding values for C_1 and C_2. So far, the only constraint on the circuit is the condition that $V_1(t)$ have fallen to zero at $\tau/2$, the instant of switch closure. It turns out that this can be satisfied over a range of combinations of C_1 and C_2 and that this provides a way to set the output power. Combinations with lower values of C_1 reduce the output power. However, it is possible and beneficial to impose a second constraint which will require a unique combination of C_1 and C_2. This constraint is that $\mathrm{d}V_1/\mathrm{d}t$, as well as $V_1(t)$, be zero at the instant the switch is closed. If this condition is met, the frequency of the amplifier can be shifted somewhat without seriously violating the condition that $V_1(\tau/2)$ be zero. Moreover, at high frequencies, where the transistor's switching time is relevant, $V_1(t)$ will at least remain close to zero during the switching process. Before outlining the analysis, we summarize the resulting design procedures as follows:

1. Pick a value for Q, say $Q = 10$. Then $\omega L_2 = QR_{\mathrm{L}}$.

$$\text{Pick } \omega \mathrm{L}_1 \text{ to be, say, } 100R_{\mathrm{L}}. \tag{9.6}$$

2. Calculate C_1 as follows:

$$\frac{1}{\omega C_1} = \frac{\pi}{2}\left(1 + \frac{\pi^2}{4}\right)R_{\mathrm{L}} = 5.45R_{\mathrm{L}}. \tag{9.7}$$

3. Calculate C_2 as follows:

$$\frac{1}{\omega C_2} = \omega L_2 - \frac{\left(\frac{\pi^2}{8} - \frac{1}{2}\right)}{\left(1 + \frac{\pi^2}{4}\right)}\frac{1}{\omega C_1} = \omega L_2 - 0.212\frac{1}{\omega C_1}. \tag{9.8}$$

4. The amplitude of the output sine wave (the voltage on R_{L}) is

$$V_{\mathrm{out_{pk}}} = V_{\mathrm{dc}}\frac{2}{\sqrt{1 + \frac{\pi^2}{4}}} = 1.07V_{\mathrm{dc}}. \tag{9.9}$$

5. The output power is given by

$$P_{\mathrm{out}} = \frac{(V_{\mathrm{out_{pk}}})^2}{2R_{\mathrm{L}}} = 1.154\frac{V_{\mathrm{dc}}^2}{2R_{\mathrm{L}}}. \tag{9.10}$$

6. The average current drawn from the power supply is

$$I_{\mathrm{dc}} = \frac{V_{\mathrm{out_{pk}}}}{2R_{\mathrm{L}}} = 0.577\frac{V_{\mathrm{dc}}}{R_{\mathrm{L}}}. \tag{9.11}$$

9.3.2 Class-E circuit analysis

This section is included for the reader who wants to understand the derivation of the above design formulas. We will analyze the circuit assuming $r = 0$ and afterward estimate the loss when r is small compared with R_{L}. The switch will be open whenever $\sin(\omega t)$ is positive, i.e., it opens at $t = 0$, closes at $\omega t = \pi$, etc. Because of the high Q of the series combination, L_2C_2, we will again use the simplifying assumption that the load voltage is a perfect sine wave, $V_{\mathrm{RL}} = V_{\mathrm{out_{pk}}}(t)\sin(\omega t+\phi)$ where ϕ is a phase shift to be determined [3]. As with the class-C amplifier, an exact analysis requires finding the properly connected switch-open and switch-closed transient solutions. Assuming the sine wave, the current into the load is given by $I_{\mathrm{RL}}(t) = (V_{\mathrm{out_{pk}}}/R_{\mathrm{L}})\sin(\omega t + \phi)$.

By inspection of Figure 9.9, we can immediately write an equation for the current through the capacitor C_1 while the switch is open:

$$I_{C_1}(t) = C_1\frac{\mathrm{d}V_1}{\mathrm{d}t} = I_{\mathrm{dc}} - \frac{V_{\mathrm{out_{pk}}}}{R_{\mathrm{L}}}\sin(\omega t + \phi). \tag{9.12}$$

Imposing the condition that I_{C_1} be zero at $\omega t = \pi$, we find that

$$\sin(\phi) = \frac{-I_{\mathrm{dc}}R_{\mathrm{L}}}{V_{\mathrm{out_{pk}}}}. \tag{9.13}$$

We can integrate Equation (9.12) to get $V_1(t)$, the voltage on the capacitor while the switch is open:

$$V_1(t) = \frac{1}{C_1}\left(I_{\mathrm{dc}}t + \frac{V_{\mathrm{out_{pk}}}}{\omega R_{\mathrm{L}}}\cos(\omega t + \phi) - \frac{V_{\mathrm{out_{pk}}}}{\omega R_{\mathrm{L}}}\cos(\phi)\right), \tag{9.14}$$

where the last term is a constant of integration, added to satisfy the condition $V_1(0) = 0$, imposed by the switch having been in its closed state before $t = 0$. Next, imposing the condition that V_1 be zero also at $\omega t = \pi$, Equation (9.14) gives us

$$\cos(\phi) = \frac{\pi}{2}\frac{I_{\mathrm{dc}}R_{\mathrm{L}}}{V_{\mathrm{out_{pk}}}}. \tag{9.15}$$

We can combine Equations (9.13) and (9.15), using $\cos^2\theta + \sin^2\theta = 1$, to find

$$\frac{V_{\mathrm{out_{pk}}}}{I_{\mathrm{dc}}R_{\mathrm{L}}} = a \quad \text{and} \quad \sin(\phi) = \frac{-1}{a}, \quad \text{where} \quad a = \sqrt{\frac{\pi^2}{4} + 1}. \tag{9.16}$$

From this point, it remains to express $V_1(t)$ and the load current as complex constants times $\mathrm{e}^{\mathrm{j}\omega t}$ (the actual voltage and current are, of course, the real parts) and calculate the ratio, which must be equal to the complex impedance looking into the $L_2C_2R_L$ series circuit, $Z = R_L + j(\omega L_2 - 1/(\omega C_2))$.

The load current, $(V_{pk}/R_L)\sin(\omega t+\phi) = a\ I_{dc}\ \sin(\omega t+\phi)$, corresponds to the complex current $I(t) = -j\ a\ I_{dc}\ e^{j(\omega t+\phi)}$, since $\mathrm{Re}(-j\ a\ I_{dc}\ e^{j(\omega t+\phi)}) = a\ I_{dc}\ \sin(\omega t+\phi)$. Since the voltage $V_1(t)$ is not a sine wave, we have to find the complex representation of its fundamental Fourier component by evaluating the integral

$$\text{complex } V(t) = e^{j\omega t}\frac{2}{\tau}\int_0^{\pi/\omega} V(t)e^{-j\omega t}dt. \tag{9.17}$$

Note that the upper limit of the integral would normally be $2\pi/4$ but by integrating over only the first half-cycle, we account for the fact that the closed switch forces $V_1(t)$ to be zero during the second half-cycle. We can rewrite Equation (9.14) in terms of a and I_{dc}:

$$V_1(t) = \frac{I_{dc}}{C_1}\left(t + \frac{a}{\omega}\cos(\omega t + \phi) - \frac{a}{\omega}\cos(\phi)\right). \tag{9.18}$$

Evaluating the integral in Equation (9.17), and then setting the ratio *complex* $V_1(t)$ / *complex* $I(t)$ equal to the impedance, $R_L + j(\omega L - 1/(\omega C_2))$, results in the formulas for C_1 and C_2 (Equations 9.7 and 9.8).

9.3.3 Efficiency of the class-E amplifier

We will now assume that r is not zero, but still small enough that we can use the currents derived above, where r was taken as zero. Power is dissipated in r when the switch is closed. The current through r is just

$$I_r(t) = I_{dc} - \frac{V_{out_{pk}}}{R_L}\sin(\omega t + \phi), \tag{9.19}$$

which is the same as Equation (9.12), except that now we assume any current flowing in the capacitor is negligible compared with the current flowing through the closed switch.

The instantaneous power dissipated in r is

$$(I_r(t))^2 r = \left(I_{dc} - \frac{V_{out_{pk}}}{R_L}\sin(\omega t + \phi)\right)^2 r \tag{9.20}$$

and the average power dissipation in r is, therefore, given by

$$\begin{aligned}\langle (I_r(t))^2 r\rangle &= \left\langle \left(I_{dc} - \frac{V_{out_{pk}}}{R_L}\sin(\omega t + \phi)\right)^2\right\rangle r \\ &= \frac{1}{\tau}\int_{\tau/2}^{\tau}\left(I_{dc} - \frac{V_{out_{pk}}}{R_L}\sin(\omega t + \phi)\right)^2 r dt,\end{aligned} \tag{9.21}$$

where the period, τ, is just $2\pi/\omega$. Evaluating this integral and using Equations (9.15) and (9.16), we find

$$\langle (I_r(t))^2 r \rangle = \frac{r}{R_\mathrm{L}^2} \left(\frac{3 {V_{\mathrm{out}_\mathrm{pk}}}^4}{8 {V_\mathrm{dc}}^2} + \frac{{V_{\mathrm{out}_\mathrm{pk}}}^2}{4} \right). \tag{9.22}$$

To get the fractional power loss, just divide this by the power out, $V_{\mathrm{out}_\mathrm{pk}}/(2R_\mathrm{L})$.

9.3.4 Class-E design example

The formulas above were used to design a class-E amplifier designed to produce a 1-MHz, 12-V peak sine wave on a 50-ohm load, using a 12-V power supply. The component values were as follows: $L_1 = 1$ mH, $C_1 = 584$ pF, $L_2 = 79.6$ µH, $C_2 = 360$ pF, and $R_\mathrm{L} = 50$ ohms. If the transistor has an on-resistance of 0.5 ohms, the fractional loss will be 1.9% (98% efficiency). A SPICE analysis of this circuit shows the second harmonic power at the load to be 26 dB below the fundamental power. The 3-dB bandwidth is about 15%.

9.4 Which circuit to use: class-C, class-D, or class-E?

Remember that the high-efficiency amplifiers discussed in this chapter are narrowband and nonlinear. They are ideal for producing conventional signals with AM, pulse, or phase modulation, such as radio broadcast signals and signals from cell phones. Lower efficiency linear class-A, AB, or B amplifiers are used with more complicated signals such as the superposition of many individual signals from a cellular base station or from a direct broadcast television satellite.[2] AM and FM broadcast transmitters have historically used class-C vacuum tube amplifiers. This type of transmitter is still widely used. Tubes are available with maximum plate dissipations of up to more than 1 MW. Typical class-C amplifiers have efficiencies of 75–85%, so a single large tube can produce in excess of 6 MW of RF power. The highest power used in radio broadcasting is about 2 MW, but amplifiers (or class-C oscillators) for much higher power are found in industrial heating applications such as curing plywood and welding. Many new designs use class-D and class-E solid-state amplifier modules, with the power from multiple modules being combined to achieve the desired total power. The complexity of using many modules is sometimes offset by the ability to “hot swap” defective modules without interrupting operations. The switching amplifiers, class-D and class-E, benefit from advances in transistor technology and have reached GHz frequencies.

---

[2] In principle, class-C, D, and E amplifiers can reproduce any type of band-limited signal by using simultaneous amplitude and phase modulation, as in the efficient amplification of single-sideband signals discussed in Chapter 8.

Problems

Problem 9.1. For the shunt-fed class-C amplifier of Figure 9.4(c), sketch the waveforms of the voltage on each side of the blocking capacitor and of the current through the blocking capacitor.

Problem 9.2. Suppose the simple series class-D amplifier of Figure 9.5(b) is driving a 50-ohm resistive load at a frequency of 1 MHz. The values of the inductor and capacitor are 9.49 μH and 2.67 nF (equal and opposite reactances at 1 MHz). This resonant circuit passes the 1-MHz component of the square wave and greatly reduces the harmonics. By what factor is the 3-MHz (i.e., third harmonic) power delivered to the load lower than the fundamental (1-MHz) power? Hints: in a square-wave, the amplitude of the third harmonic is one-third of the amplitude of the fundamental. Remember that at 1 MHz, $X_L = X_C$ while at 3 MHz, X_L is increased by a factor of 3 and X_C is decreased by a factor of 3.

Problem 9.3. A single-tube class-C amplifier with 75% efficiency is providing 500 kW of continuous cw output power. The supply voltage is 60 kV and the conduction angle is 90°. What is the average current drawn from the power supply? Answer: 11.1 amperes. What is the average current when the tube is on? Answer: 44.4 amperes.

Problem 9.4. (a) Consider the class-D amplifier of Figure 9.7(a). Show that the peak sine-wave voltage on the load, R_L, will be $\pi V_{dc}/2$ and the dc supply current will be $\pi^2 V_{dc}/(8R_L)$. Hint: since the efficiency is 100% (there are no lossy components except the load), the power supplied by the dc source will be $I \cdot V_{dc}$ where I is the constant current flowing through the RF choke. But the power from the supply can also be written as V_{dc} times the average of the absolute value of the sine wave on the load. (The average of $|A\sin(\theta)|$ is $2A/\pi$.)

(b) For the amplifier of Figure 9.7(b), show that the peak sine-wave voltage on the load will be πV_{dc} and the dc supply current will be $\pi^2 \mathrm{V}_{dc}/(2R_L)$.

CHAPTER

10

Transmission lines

We draw circuit diagrams with "lumped"components: ideal *R*'s, *C*'s, *L'*s, transistors, etc., connected by lines that represent zero-length wires. But all real wires, if not much shorter than the shortest relevant wavelength, are themselves complicated circuit elements; the current is not the same everywhere along such a wire, nor is voltage uniform, even if the wire has no resistance. On the other hand, when interconnections are made with transmission lines, which are well-understood circuit elements, we can accurately predict circuit behavior. In this section we will consider two-conductor lines such as coaxial cables and open parallel wire lines. "Microstrip lines" (conducting metal traces on an insulation layer over a metal ground plane) behave essentially in the same way, but they have some subtle complications, which are mentioned in Appendix 10.1.

10.1 Characteristic impedance

The first thing one learns about transmission lines is that they have a parameter known as *characteristic impedance*, denoted Z_0. How "real" is characteristic impedance? If we connect an ordinary dc ohmmeter to the end of a 50-ohm cable will it indicate 50 ohms? Yes, if the cable is *very* long, so that a reflection from the far end does not arrive back at the meter before we finish the measurement. Otherwise, the meter will simply measure whatever is connected to the far end, which could be short, an open circuit, or a resistance. However, using a pulse generator and an oscilloscope, you can easily make an ohmmeter set-up that is fast enough that, even for a short cable, you can determine V_{in} and I_{in} and then calculate $V_{\text{in}}/I_{\text{in}} = Z_0$.

To make a theoretical determination of Z_0, we first model the transmission line as a ladder network made of shunt capacitors and series inductors, as shown in Figure 10.1.

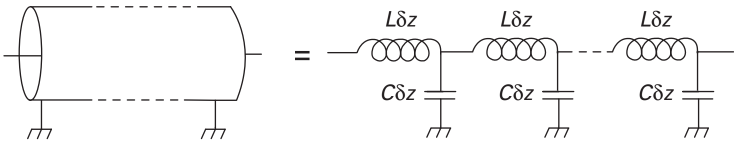

Figure 10.1. Transmission line model – a ladder network of infinitesimal *LC* sections.

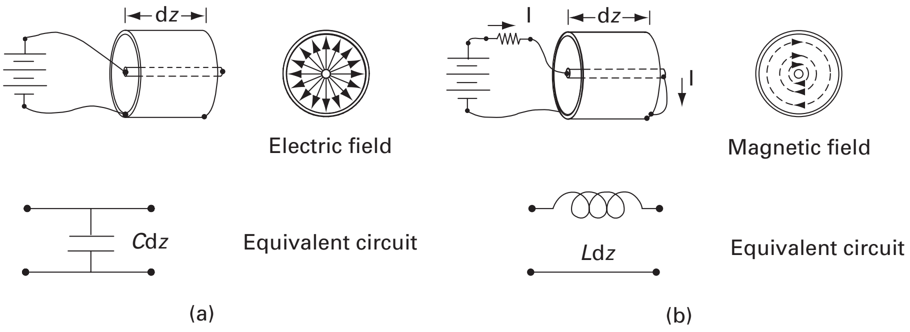

Figure 10.2. Capacitance and inductance per unit length.

To see that this model is reasonable, consider Figure 10.2(a), which shows the electric field lines in a length of coaxial cable connected to a voltage source. The field lines are radial and their number is obviously proportional to the length of the cable, so that capacitance per unit length is a constant. Likewise, a current through the cable (b) sets up a magnetic field, so another characteristic of the cable is its inductance per unit length. We will follow common convention and use the symbols C and L to denote capacitance and inductance per unit length. That convention is obvious when capacitors and inductors are labeled, respectively, $C\delta z$ and $L\delta z$, where δz is a short increment of length along the z-axis, i.e., parallel to the cable.

Every increment of a transmission line contributes series inductance and shunt capacitance; the ladder network shown in Figure 10.1 models a real transmission line in the limit that δz goes to zero. For some situations, e.g., baseband telephony and digital data transmission through long cables, the model must also include series and shunt resistance. At radio frequencies, however, the series reactance is usually much greater than the series resistance and the shunt reactance is usually much less than the shunt resistance so both resistances can be neglected. (See Problem 10.3.)

To see that $Z_0{}^2 = L/C$, consider the circuit of Figure 10.3, where we have added another infinitesimal LC section to the model transmission line, which is either infinitely long or terminated with a resistance equal to the characteristic impedance, so as to appear infinitely long. After adding the section, the line is still infinitely long and the impedance looking into it must still be Z_0. If the voltage and current at the input of the line were V and I, they will be modified to become $V+\delta V$ and $I+\delta I$ at the input to the new section. (This does not imply an increase in power; $V+\delta V$ and $I+\delta I$ are merely phase-shifted versions of V and I.)

Since the impedance looking into the line must stay the same, we have

$$\frac{V + \delta V}{I + \delta I} = \frac{V}{I}, \tag{10.1}$$

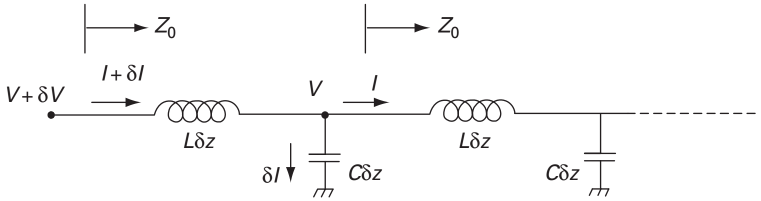

Figure 10.3. Adding another infinitesimal section must leave Z_0 unchanged.

from which $\delta V/\delta I = V/I = Z_0$.

Using this, and substituting $\delta I = (C\delta z)\,\mathrm{d}V/\mathrm{d}t$ and $\delta V = (L\delta z)\,\mathrm{d}/\mathrm{d}t(I+\delta I)$ and ignoring the vanishingly small $\delta z\,\delta I$ term, we have

$$Z_0 = \frac{\delta V}{\delta I} = \frac{L\delta z\,(\mathrm{j}\omega I)}{C\delta z\,(\mathrm{j}\omega V)} = \frac{L}{C}\,Z_0^{-1}. \tag{10.2}$$

Looking at the first and last terms of this equation, we see that $Z_0 = (L/C)^{1/2}$. Note: you can verify that, because δV and δI are infinitesimal, the above equations are the same if the network starts with a capacitor instead an inductor.

To evaluate Z_0, it is sufficient to know either L or C, since it follows from electrodynamics that they are related by $LC = \varepsilon_r/c^2$ where ε_r is the dielectric constant (relative to vacuum), and c is the speed of light. This relation between L and C holds for any two-conductor structure with translational symmetry such as an unlikely transmission line consisting of a square inner conductor inside a triangular outer conductor.

For a coaxial transmission line, $C = 2\pi\varepsilon_r\varepsilon_0/\ln(b/a)$ farads/meter, where a and b are the inner and outer radii and ε_0, the "permittivity of free space," is equal to $(4\pi\times 10^{-7}c^2)^{-1}$. Using this, together with the relation $LC = \varepsilon_r/c^2$, gives us $Z_0 = (\varepsilon_r)^{-1/2}\,60\ln(b/a)$. Note that Z_0 depends on the ratio a/b, but not on the size of the cable.

10.2 Waves and reflected waves on transmission lines

We will use a simple ac analysis to show that an applied sinusoidal voltage causes a spatial voltage sine wave to propagate down the line: Let us apply a voltage $e^{j\omega t}$ and find the voltage drop across an incremental length of line (see Figure 10.4).

Since we already know the input impedance is Z_0, the input current must be V/Z_0 and the voltage across the inductor can be written $\delta V = -(V/Z_0)(\mathrm{j}\omega L\delta z)$. But this is just the differential equation

$$\frac{\mathrm{d}V}{\mathrm{d}z} = -\mathrm{j}\omega\frac{L}{Z_0}V = -\mathrm{j}\omega\sqrt{LC}\,V. \tag{10.3}$$

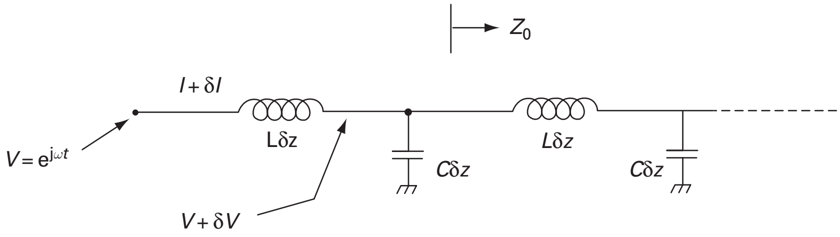

Figure 10.4. Finding the change in voltage, δV, over a distance δz.

The solution to this familiar equation is

$$V = V_f e^{-j\omega\sqrt{LC}z} = V_f e^{-jkz} \quad \text{where} \quad k = \omega\sqrt{LC}, \tag{10.4}$$

where V_f is a constant, the amplitude. The constant k is known as the *propagation constant* and is the number of radians the wave progresses per unit length. The wave therefore repeats in a distance (the wavelength) given by $\lambda = 2\pi/k$. Since $V/I = Z_0$, the current along the line is also a wave: $I = (V_f/Z_0)e^{-jkz}$. If we include the otherwise implicit multiplicative time dependence factor $e^{j\omega t}$, the voltage is

$$V = V_f e^{j\omega t} e^{-jkz} = V_f e^{j(\omega t - kz)}. \tag{10.5}$$

This is just a sine wave running in the forward z-direction. The complex exponential now contains space as well as time but, as always, the physical voltage is the real part, i.e., Re[$V_f e^{j(\omega t - kx)}$] which is a weighted superposition of $\sin(\omega t - kz)$ and $\cos(\omega t - kz)$. For a point of constant phase, $\omega t - kz = \text{constant}$, we have $\delta z/\delta t = \omega/k$. This velocity, $\omega/k = c/\sqrt{\varepsilon_r}$, is known as the *phase velocity*, v_{phase}. Figure 10.5 shows a forward-running wave on a coaxial cable. The electric and magnetic field lines are drawn only at the points where they reach their peak values. A graph shows the spatial distribution. Everything has the same phase, i.e., the voltage, current, and charge density all rise and fall together along the z-axis. Note that a wave of amplitude V transfers power at a rate $|V|^2/(2Z_0)$.

A transmission line can equally well support waves running in the negative z-direction. If we had assumed a current in the $(-z)$-direction, the phase would progress as $\omega t + kz$. A transmission line in a circuit operating at a frequency ω will, in general, have both a forward wave and a reverse wave. The waves have complex amplitudes, V_f and V_r, each containing magnitude and phase. Of course both waves have the same frequency and propagation constant. We regard current as positive when it is in the (+z)-direction, so the current of a forward wave is $I_f(z,t) = V_f(z,t)/Z_0$, but the current of a reverse wave is $I_r(z,t) = -V_r(z,t)/Z_0$, since the reverse wave is traveling in the $(-z)$-

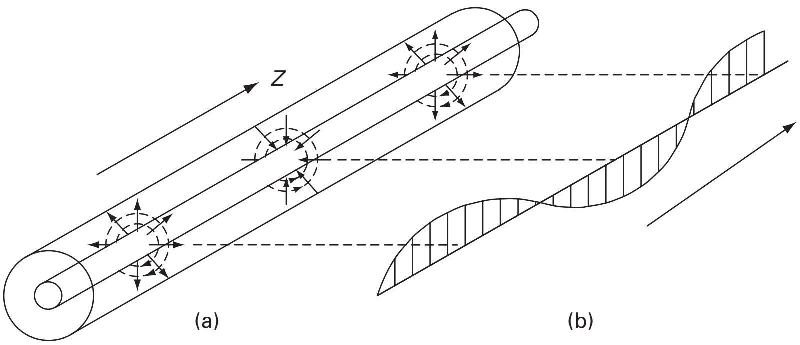

Figure 10.5. Forward wave on a transmission line.

direction. Together, the forward and reverse waves are, in general, equivalent to a stationary (*standing*) wave plus a single propagating wave.

Note also that the phase velocity is independent of ω; there is no dispersion in this kind of lossless transmission line. Therefore, if we apply an arbitrary voltage waveform, $V_{\text{arb}}(t)$, at the input to the line, this waveform, considered as a Fourier superposition of sine waves, will propagate down the line without distortion. At any point z, the voltage will be $V_{\text{arb}}(t - z/v_{\text{phase}})$, a delayed but undistorted version of the input signal. For example, if, at $t = 0$, we connect a dc voltage to the line, a step function propagates down the line.

The *electrical length* of a line is the phase change imparted by the line. For example, a "quarter wave line" imparts a 90° phase shift, $kl = \pi/2$, and therefore $l = \pi/(2k) = \pi c/(2\omega\sqrt{\varepsilon_r}) = (c/f)/(4\sqrt{\varepsilon_r}) = 1/4(\lambda_0/\sqrt{\varepsilon_r})$, where λ_0 is the wavelength in free space.

Standing waves

When both a forward and a reverse wave are present on a transmission line the voltage along the line, which is the sum of the contributions from the two waves, forms an interference pattern or standing wave. To see this, let $V(z,t) = V_f e^{j(\omega t - kz)} + V_r e^{j(\omega t + kz)}$. The real parts of these two rotating phasors will be in phase at points along the transmission line which are separated by $\lambda/2$. At these points, the magnitude of the sum will be $|V_f| + |V_r|$. Halfway between these points, the real parts of the phasors will be out of phase and the magnitude of the sum will be $||V_f| - |V_r||$. The ratio of these maximum and minimum voltage magnitudes is called the *voltage standing wave ratio*: $\text{VSWR} = (|V_f| + |V_r|)/||V_f| - |V_r||$. If $|V_f| = |V_r|$ there is only a standing wave and the VSWR is infinite. When $|V_f| \neq |V_r|$, the weaker one, along with an equal portion of the stronger one, form a standing wave, leaving the remainder of the stronger one as a travelling wave.

10.3 Modification of an impedance by a transmission line

From the discussion above, you can see that a transmission line terminated by a resistor of value Z_0 will always present an input impedance of Z_0. But a piece of transmission line that is terminated with an arbitrary impedance, $Z \neq Z_0$, as shown in Figure 10.6, will produce a modified ("transformed") impedance, Z'.

This figure shows a line of length l whose right-hand end ($z=0$) is connected to some impedance Z_L (L denotes "load"). Assume that some constant ac source produces a constant incident wave traveling to the right, $V_f e^{-jkz}$ (we will not bother writing the always present factor $e^{j\omega t}$), and that Z_L causes a constant reflected wave, $\Gamma\, V_f e^{jkz}$, to travel to the left.[1] The factor Γ is known as the *reflection coefficient*. At any point, z, the voltage on the line is $V(z)=V_f e^{-jkz}+\Gamma\, V_f e^{jkz}$. The corresponding current is $I(z)=(V_f/Z_0)(e^{-jkz}-\Gamma e^{jkz})$. The minus sign occurs because the current in the reflected wave flows in the negative z-direction. At the right-hand end ($z=0$), the load ensures that $V(0)/I(0)=Z_L$. This will give us Γ:

$$\frac{V(0)}{I(0)}=Z_L=\frac{(1+\Gamma)}{(1-\Gamma)/Z_0} \quad \text{so} \quad \frac{Z_L}{Z_0}=\frac{(1+\Gamma)}{(1-\Gamma)} \quad \text{and} \quad \Gamma=\frac{(Z_L-Z_0)}{(Z_L+Z_0)}. \tag{10.6}$$

Putting this expression in Equation (10.6) for Γ, together with the expressions for $V(z)$ and $I(z)$, we can immediately find $V(-l)/I(-l)$ which is what we are after, i.e., Z', the input impedance at a point l to the left of the load:

$$\begin{aligned} Z' &= \frac{V(-l)}{I(-l)} = \frac{e^{-jk(-l)}+\Gamma e^{jk(-l)}}{e^{-jk(-l)}/Z_0-\Gamma e^{jk(-l)}/Z_0} \\ &= Z_0\frac{(Z_L+Z_0)e^{jkl}+(Z_L-Z_0)e^{-jkl}}{(Z_L+Z_0)e^{jkl}-(Z_L-Z_0)e^{-jkl}} \end{aligned}$$

or

$$Z' = Z_0\frac{Z_L+jZ_0\tan(kl)}{Z_0+jZ_L\tan(kl)}. \tag{10.7}$$

$I(z)=\frac{e^{-jkz}}{Z_0}-\frac{\Gamma e^{jkz}}{Z_0}$

Figure 10.6. An impedance is modified when seen through a transmission line.

---

[1] Since everything is linear, superposition holds and the incident and reflected waves do not collide or interact in any way. They simply pass through one another unaltered. At any point, the current is the sum of their currents and the voltage is the sum of their voltages.

This important result, the modification of an impedance Z_L by a length l of transmission line, is not hard to remember; it has no minus signs and is symmetric. Just remember (1+j tan)/(1+j tan). Once you have written this framework, you will remember how to put in the coefficients. Some important special cases are listed below:

- If $Z_L = Z_0$, then $Z' = Z_0$ for any length of line.
- If $Z_L = 0$ (a short) then $Z' = jZ_0\tan(kl)$, a pure reactance, which is inductive[2] for $kl < \pi/2$, then capacitive, etc.
- If Z_L = infinity (an open circuit) then $Z' = Z_0/j\tan(kl)$ which is capacitive for $kl < \pi/2$, then inductive, etc.
- An impedance is left unchanged by a line of arbitrary Z_0 whose length is a half-wave ($kz = \pi$) or any integral multiple of a half-wave.
- A quarter-wave line ($kz = \pi/2$) or an odd multiple of a quarter-wave line, *inverts* an impedance: $Z' = Z_0^2/Z_L$. A short is transformed into an open and an open into a short, an inductor is transformed into a capacitor and vice versa, etc.

10.4 Transmission line attenuation

In a lossy transmission line, i.e., a line that causes attenuation of the signal, the e^{-jkz} or e^{jkz} spatial dependence of the wave is replaced by $e^{-jkz}\, e^{-\alpha z} = e^{-j(k-j\alpha)z}$ (forward wave) or $e^{jkz}\, e^{\alpha z} = e^{j(k-j\alpha)z}$ (reverse wave), where α is the attenuation constant. In a distance $1/\alpha$, the amplitude falls by a factor 1/e and the power falls by a factor $(1/e)^2$. Note that k for a lossless line is simply replaced by $k - j\alpha$, i.e., the propagation constant becomes complex. You can put this complex k into the "tan tan" formula to see how an impedance is modified by a lossy cable.

Transmission line attenuation is usually expressed in units of dB/meter. To find α for a line whose loss is A_L dB/m, note that, since the amplitude falls by a factor $e^{-\alpha\cdot 1}$ in 1 meter, we can write $-A_L = 10\log(e^{-\alpha\cdot 1})^2 = -20\alpha\log(e)$ from which $\alpha = A_L/(20\log(e))$.

10.5 Impedance specified by reflection coefficient

We have seen that an impedance Z produces a reflection coefficient given by $\Gamma = (Z - Z_0)\,/\,(Z + Z_0)$. This relation is easily inverted, $Z = Z_0(1+\Gamma)/(1-\Gamma)$, so there is a one-to-one mapping between Z and Γ. In antenna and microwave work, especially when using S-parameter analysis (Chapter 28), it is customary to think in terms of Γ, rather than Z.

One big advantage of working in the complex Γ-plane is that the modification of an impedance (represented by its equivalent Γ) is extremely simple. The reflection coefficient for the given impedance as seen through a length l of transmission line is just

---

[2] Note that "inductive" does not mean equivalent to a lumped inductor since $Z_0\tan(kl) = Z_0\tan(\omega l/v_{\text{phase}})$ is not proportional to ω, except for small kl. Likewise, a short open-ended line is not equivalent to a lumped capacitor, except for small $\omega l/v_{\text{phase}}$.

$$\Gamma' = \Gamma e^{-j2kl}, \tag{10.8}$$

which means we simply rotate the point clockwise around the origin ($\Gamma = 0$) by an angle $2kl$ to give Γ', the modified reflection coefficient. This is easy to see: when we add a length of cable, the incident wave's phase is delayed by kl getting to the end of the cable and the reflected wave is delayed by the same kl getting back again. The effect of a cable is therefore to rotate the complex number Γ clockwise by an angle $2kl$.[3] (Since the time dependence is $e^{j\omega t}$, the round-trip time delay is a clockwise displacement.) Keep in mind that the Γ-plane is a complex plane but that it is *not* the $R + jX$ plane. Let us look at a few special points in the Γ-plane.

1. The center of the plane, $\Gamma = 0$, corresponds to a reflected wave of zero amplitude, so this point represents the impedance $Z_0 + j0$.
2. The magnitude of Γ (radius from the origin) must be less than or equal to unity for passive impedances. Otherwise the reflected wave would have more power than the incident wave.
3. The point $\Gamma = -1 + j0$ corresponds to $Z = 0$, a short circuit.
4. The point $\Gamma = 1 + j0$ corresponds to $Z = \infty$, an open circuit.
5. Points on the circle $|\Gamma| = 1$ correspond to pure reactances, $Z = 0 + jX$. All points inside this circle map to impedances with positive nonzero R.
6. The point $\Gamma = 0 + j1$ corresponds to an inductance, $Z = 0 + jZ_0$. All points in the top half of the Γ-plane are "inductive," i.e., $Z = R + j|X|$ or, equivalently, $Y = G - j|B|$.
7. The point $\Gamma = 0 - j1$ corresponds to a capacitance, $Z = 0 - jZ_0$. All points in the bottom half of the Γ-plane are "capacitive," i.e., $Z = R - j|X|$ or, equivalently, $Y = G + j|B|$.

These special cases of mapping of Z into Γ are shown in Figure 10.7.

In the Γ-plane, if you plot $\Gamma = R + jX$, where R is a constant and X varies, you will get a circle centered on the real axis and tangent to the line $\mathrm{Re}(\Gamma) = 1$. For every value of R there is one of these "resistance circles." The resistance circle for $R = 0$ is the unit circle in the Γ-plane. The resistance circle for $R = \infty$ is a circle of zero radius at the point $\Gamma = 1 + j0$. Likewise, if you plot $\Gamma(R + jX)$ where X is a constant and R varies, you will get "reactance circles" centered on the line $\mathrm{Re}(\Gamma) = 1$ and tangent to the line $\mathrm{Im}(\Gamma) = 0$. These circles are shown in Figure 10.8.

If you now trim the circles to leave only the portions within the $|\Gamma| = 1$ circle (corresponding to passive impedances, i.e., impedances whose real part is

---

[3] If the line is lossy, the magnitude of Γ decreases as it rotates around the origin, forming a spiral. For a long enough length of lossy line, Γ spirals all the way into the origin producing $Z = Z_0$, no matter what value of Z terminates the far end of the cable.

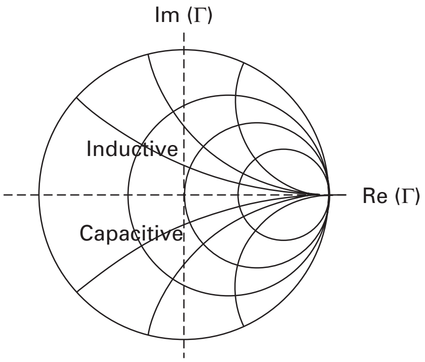
positive) you are left with a useful piece of graph paper, the famous *Smith chart*, shown in Figure 10.9.

The circular R and X "axes" on the Smith chart allow you to locate the Γ-point that corresponds to $Z = R + jX$. We have already seen that when we have located an impedance on the Γ-plane, we can find how that impedance is modified by a length of transmission line (whose Z_0 is the same as the Z_0 used to draw the chart) by rotating the point clockwise around the origin. We simply rotate the point clockwise around the origin by an angle equal to twice the electrical length of the line. The values of R and X corresponding to the rotated point can be read



Im (Γ)
Inductive
Re (Γ)
Capacitive

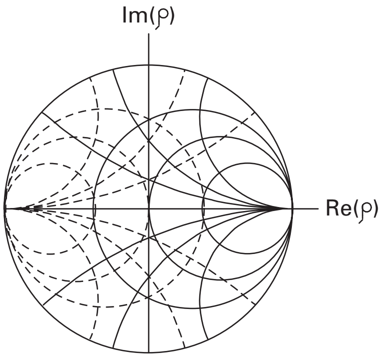
off the chart's R and X "axes." We can also use the chart to find how an impedance is modified by adding a series R or series X. In this operations, the Smith chart can be considered something of a calculator. Note that the Smith chart can also be made with G and B "axes". As you might guess, these produce "G circles" and "B circles" as shown in Figure 10.10.

Sometimes the Smith chart contains G and B circles as well as R and X circles. This full-blown chart, which can be quite dense, is shown in Figure 10.11. Again, remember the Smith chart is actually a rectangular graph of Γ; the x-axis is Re(Γ) and the y-axis is Im(Γ). Because only the area inside the circle $|\Gamma| = 1$, i.e., $x^2+y^2 = 1$, is used, the Smith chart resembles a polar graph. And, indeed, when we rotate a point around the origin to how a transmission line modifies an impedance, we are using it in a polar fashion. Sometimes the Smith chart is scaled for a specific Z_0 (usually 50 ohms or 75 ohms). Other charts are normalized; the $R = 1$ circle would be the 50-ohm circle if we are dealing with 50-ohm cable, etc.

Figure 10.11. Smith chart with *R*, *X*, *G*, and *B* circles.



10.6 Transmission lines used to match impedances

Designing a matching network becomes an exercise in moving from a given Γ to a desired Γ′ in the reflection plane. Working graphically, it is often easy to find a matching strategy. Let us use the Smith chart and revisit the 1000-ohm-to-50-ohm matching circuit example of Chapter 2.

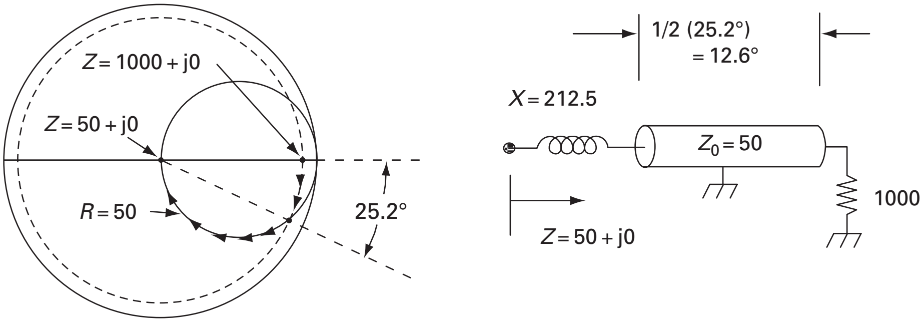


Figure 10.12. Conversion from 1000 ohms to 50 ohms – transmission line and inductor circuit.

I. The starting impedance, 1000 ohms, and the final target impedance, 50 ohms, are indicated on the chart in Figure 10.12. Also shown is the 50-ohm circle. We can use a (50-ohm) transmission line to move along the dashed circle until we reach the 50-ohm circle. Now we have $R = 50$ plus a capacitive reactance. A series inductor will cancel the capacitive reactance, taking us to $Z = 50+j0$ (the center of the chart).

II. Another solution (Figure 10.13) would be to use a longer piece of cable to circle most of the chart, hitting the 50-ohm circle in the top half of the plane. At this point we have $Z = 50 + jX$ where X is positive (inductive). We can add a series capacitor to cancel this X and again arrive at $Z = 50 + j0$.

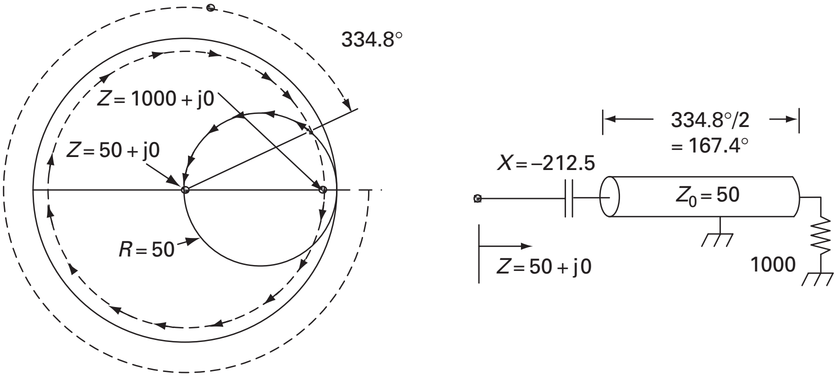

Figure 10.13. Transmission line and capacitor matching circuit.

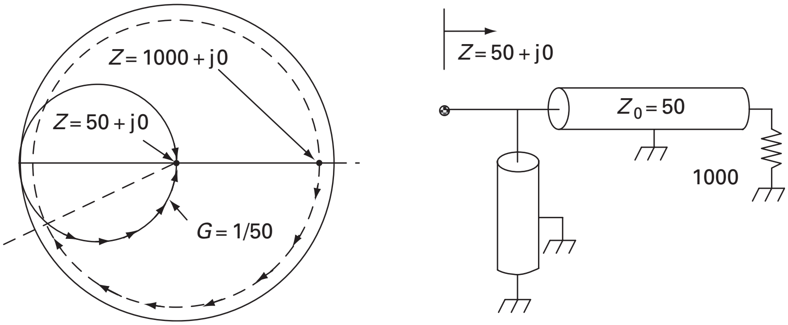

Figure 10.14. Series and shunt transmission line matching circuit.

III. So far we have only used series elements. Let us now start by traveling around to the $G = 1/50$ circle. Then we can add a shunt element to reach the center of the chart. The first intersection of the $G = 1/50$ circle is in the lower half-plane (capacitive) so, to get from this point to the center, we need a shunt inductor. Instead of a lumped inductor we might use a shorted length of transmission, as shown in Figure 10.14, to make a matching circuit using only transmission line elements.

IV. Figure 10.15 shows a solution that uses no transmission line. We start on the $G = 1/1000$ circle, at $G = 0$. If we apply shunt reactance we can move along this circle. Let us pick shunt inductance which will move us upward along the G circle to the 50-ohm circle. We now have $R = 50$, but there is inductive reactance. As in the above example, we can now cancel the inductance reactance with a series capacitor. This is just the L-network found in Chapter 2.

V. If we had used shunt capacitance rather than shunt inductance, we would have moved downward to the 50-ohm circle, as shown in Figure 10.16. The remaining series capacitance can be cancelled with an inductor. This produces an L-network where the positions of the L and C are reversed.

Figure 10.15. *LC* matching network.

Constant B circle
Constant G circle
+R
Constant R line
Constant X line
−X

In these examples, our final impedance was at the center of the chart ($Z = 50 + j0$), but you can see that these techniques allow us to transform any point on the chart (i.e., any impedance) into any other point on the chart (any other impedance).

The Smith chart is a favorite because it handles networks that include transmission lines as well as inductors and capacitors. If we did not care about transmission lines, then any chart that maps R, X into G, B would do. For example, take the R, X plane (half-plane, since we will exclude negative R). Draw in the curves for $G =$ constant and $B =$ constant. The resulting chart, shown in Figure 10.17, can be used to design lumped element L, C,R ladder networks, such as the networks of Figures 10.15 and 10.16.

Appendix 10.1. Coaxial cable – Electromagnetic analysis

This chapter began with a derivation of Z_0 based on an equivalent lumped-element circuit model of a transmission line. That derivation required only elementary ac circuit theory, but is a rather indirect approach to what is really a problem in electromagnetics. Even then, some electromagnetic theory is needed to derive the expressions for capacitance and inductance per unit length.

An electromagnetic analysis of a coaxial transmission line is presented here for the reader who has some familiarity with Maxwell's equations. We make use of the fact that the propagation velocity of a *TEM wave*[4] is given by $v = (\mu\varepsilon)^{-1/2}$, where μ is the magnetic permeability and ε is the electrical permitivity of the material through which the fields propagate.[5]

To find the impedance of the coaxial line, we will first assume that the current on the inner conductor is given by $I = I_0 \cos(\omega t - kz)$, which is a wave traveling in the $(+z)$-direction. This is illustrated in Figure 10.18.

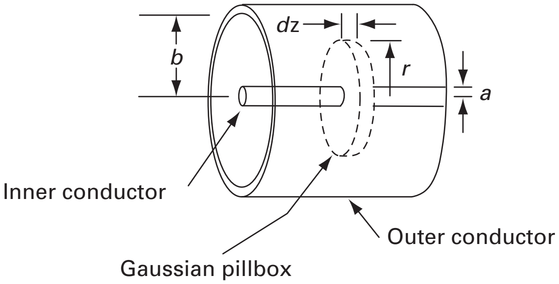

Figure 10.18. Transmission line element.

We will then proceed to find the charge density, the electric field, and then the voltage, which will have the form $V_0 \cos(\omega t - kz)$. Once we have the voltage, the characteristic impedance is simply given by V_0/I_0. (Note that the current in the outer conductor is just the negative of the current in the inner conductor.)

---

[4] In a TEM wave, by definition, both the electric field and the magnetic field are transverse, i.e., perpendicular to the direction along which the wave propagates. In most applications of coaxial cables and parallel-wire transmission lines, the wavelength is much greater than the transverse dimensions of the line and only TEM waves can propagate. Waves in free space are also TEM waves.

[5] To find the propagation velocity of a TEM wave: The variables t and z appear in E_x, E_y, B_x, and B_y only in the factor $e^{j(\omega t - kz)}$. Using the condition $E_z = 0$, the x-component of the Maxwell equation $\mathrm{curl}(E) = -\partial B/\partial t$ gives us $B_x = -(k/\omega)E_y$. Likewise, using the condition $B_z = 0$, the y-component of the Maxwell equation $\mathrm{curl}(B/\mu) = \partial(\varepsilon E)/\partial t$ gives us $B_x = -(\omega\mu\varepsilon/k)E_y$. Equating these two expressions for B_x gives $k^2 = \omega^2\mu\varepsilon$.

Consider an incremental segment of the inner conductor from z to $z + \delta z$. The rate at which charge accumulates on this element is $\partial/\partial t\ (\rho_L)\delta z$, where ρ_L is the charge per unit length. But the rate at which charge accumulates in δz is nothing more than the difference between the current flowing into δz and the current flowing out of δz. Therefore, we can write

$$\frac{\partial \rho_L}{\partial t} = \frac{-\partial I}{\partial z} = -k\, I_0 \sin(\omega t - kz). \tag{10.9}$$

Integrating $d\rho_L/dt$ with respect to time gives us the linear charge density (coulombs/meter):

$$\rho_l(z,t) = \frac{1}{\omega}(kI_0 \cos(\omega t - kz)) = \frac{kI_0}{\omega}\cos(\omega t - kz). \tag{10.10}$$

Now that we know the charge density, we can find the electric field. The field is radial with field lines like spokes of a wheel. Imagining a Gaussian “pillbox” of radius r and height δz around the center conductor, we use Gauss’s law: the integral of the E field over the sidewall surface must be equal to the enclosed charge divided by ε:

$$E(r,z,t)(2\pi r\delta z) = \frac{1}{\varepsilon}\rho_l(z,t)\delta z. \tag{10.11}$$

Substituting for λ and solving for E, we have

$$E(r,z,t) = \frac{kI_0 \cos(\omega t - kz)}{2\pi r\varepsilon\omega}. \tag{10.12}$$

Integrating this electric field from $r = a$ to $r = b$ gives us the voltage between the inner and outer conductors:

$$V(z,t) = \int_a^b E(r,z,t)dr = \frac{kI_0 \cos(\omega t - kz)\ln(b/a)}{2\pi\varepsilon\omega}. \tag{10.13}$$

Finally, we divide $V(z,t)$ by $I(z,t)$ to get the characteristic impedance:

$$Z_0 = \frac{V(z,t)}{I(z,t)} = \frac{k\ln(b/a)}{2\pi\varepsilon\omega} = \frac{\ln(b/a)}{2\pi\varepsilon v} = \frac{1}{2\pi}\left(\frac{\mu}{\varepsilon}\right)^{1/2}\ln(b/a), \tag{10.14}$$

which is the same as the result we obtained using the δL δC ladder network equivalent circuit.

This derivation (as well as the LC derivation) for Z_0 is for TEM waves, where both $\boldsymbol{E}$ and $\boldsymbol{H}$ are perpendicular to z. For TEM solutions to exist, the line must be uniformly filled with homogenous dielectric material or vacuum. The dielectric can be lossy, but the metal conductors must, strictly speaking, have no resistance. In practice, these conditions are usually not satisfied perfectly, and the waves will be slightly different from the TEM waves corresponding to ideal conditions. In particular, the waves will have a small E_z or H_z field, or both. Microstrip lines are a case of nonuniform dielectric; some of the E-field lines arch through the air above the conductor, before plunging through the dielectric to the ground plane. The wave must have a unique phase velocity, but $(\mu\varepsilon)^{-1/2}$ has one value in the air and another value in the dielectric. The waves, therefore, cannot be TEM. They turn out to have both E_z and H_z components. Known as quasi-TEM waves, they show some frequency dependence in both Z_0 and v_{phase}, which can be important at millimeter-wave frequencies. Closed form expressions have not been derived for a microstrip; designers find Z_0 and v_{phase} vs. frequency by using graphs or approximate formulas based on numerical solutions of Maxwell's equations.

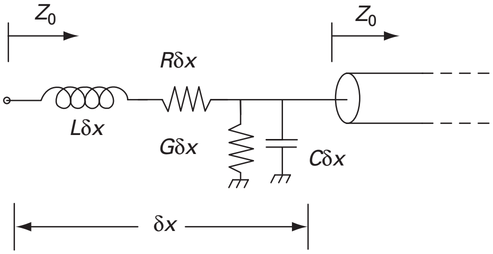
Problems

Problem 10.1. A common 50-ohm coaxial cable, RG214, has a shunt capacitance of 30.8 pF/ft. Calculate the series inductance per ft and the propagation velocity.

Problem 10.2. (a) Use the "tan tan" formula to show that a short length, δz, of transmission line, open-circuited at the far end, behaves as a capacitor, i.e., that it has a positive susceptance, directly proportional to frequency. Express the value of this capacitor in terms of the cable's capacitance per unit length. (Hint: $\tan(\theta) \approx \theta$ for small θ.)

(b) Show that a short length, δz, of transmission line, short-circuited at the far end, acts as an inductor, i.e., that it has a negative susceptance inversely proportional to frequency. Express the value of this inductor in terms of the cable's inductance/unit length.

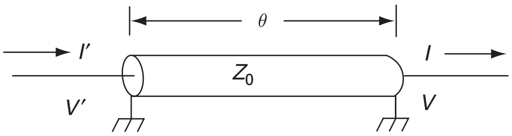
Problem 10.3. (a) Find a formula for the characteristic impedance of a lossy cable where the loss can be due to a series resistance per unit length, R, as well as a parallel conductance per unit length, G. R represents the ohmic loss of the metal conductors while G represents dielectric loss.



Hint: You can generalize the result for the lossless cable by simply replacing L by $L+R/(j\omega)$ and C by $C+G/(j\omega)$.

(b) Find the formula for the propagation constant k of this lossy cable. Hint: apply the substitutions given above to the formula $k = \omega\sqrt{LC}$. What distance (in wavelengths) is required to reduce by 1/e the power of a signal at frequency ω_1 if $R/(\omega_1) = 0.01L$?

Problem 10.4. If the (sinusoidal) voltage, V, and current, I, at the right-hand end of a transmission line are given, find the corresponding voltage, V', and current, I', at the left-hand end.



Hint: assume the (complex) voltage on the line is given by $V(\phi) = V_F e^{-j\phi} + V_R e^{j\phi}$. The corresponding current is given by $Z_0 I(\phi) = V_F e^{-j\phi} - V_R e^{j\phi}$. Let $\phi = 0$ at the right-hand end. Show that $V_F = (V + IZ_0)/2$ and $V_R = (V - IZ_0)/2$. Then show that, at the left-hand end, where $\phi = -\theta$, that $V' = V\cos\theta + IZ_0\, j\sin\theta$ and $I' = I\cos\theta + j\sin\theta\, V/Z_0$.

Problem 10.5. Use the results of Problem 10.4 to upgrade your ladder network analysis program (Problem 1.3) to handle another type of element, a series lossless transmission line. Three parameters are necessary to specify the line. These could be the characteristic impedance, the physical length, and the velocity of propagation. For convenience in later problems, however, let the three parameters be the characteristic impedance (Z_0), the electrical length (θ_0) in degrees for a particular frequency, and that frequency (f_0). A 50-ohm cable that has an electrical length of 80° at 10 MHZ would appear in the circuit file as "TL, 50, 80, 10E6." For any frequency, f, the electrical length is then $\theta = \theta_0 f/f_0$.

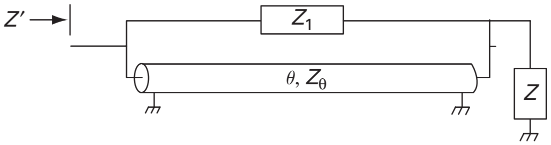
Example answer: For the MATLAB program shown in Problem 1.3, insert the following lines of code in "elseif chain":

```
elseif strcmp(component,'TL')==1
ckt_index=ckt_index+1; Z0=ckt{ckt_index}; %characteristic impedance
ckt_index=ckt_index+1; refdegrees=ckt{ckt_index};%electrical length
ckt_index=ckt_index+1; reffreq=ckt{ckt_index};   %at ref. frequency
eleclength= pi/180*f(i)*(refdegrees/reffreq);
Iold=I; I=I*(cos(eleclength))+V*(1j/Z0*sin(eleclength));
V=V*(cos(eleclength))+1j*Z0*Iold*(sin(eleclength));
```

Problem 10.6. Use your program to analyze the circuit of Figure 10.13. Assume a design frequency, say 1 MHZ, in order to determine the value of the capacitor. Run the analysis from 0 to 2 MHz. Then make the transmission line 360° longer and repeat the analysis. What form will the response take if the transmission line is made very long?

Problem 10.7. A 50-ohm transmission line is connected in parallel with an equal length transmission line of 75 ohms, i.e., at each end the inner conductors are connected and the outer conductors are connected. The cables have equal phase velocities. Show that the characteristic impedance of this composite transmission line is given by (50·75)/(50+75), i.e., the characteristic impedances add like parallel resistors.

Problem 10.8. In the circuit shown below, the impedance, Z, is modified by a transmission line in parallel with a lumped impedance, Z_1, which could be an R, C, or L or a network.



Show that the admittance looking in from the left, $Y' = 1/Z'$, is given by

$$\frac{1}{Z'} = Y' = Y_0 \frac{Y + \mathrm{j}Y_0 \tan\theta + \left(2Y_1 - \dfrac{2Y_1}{\cos\theta} + \mathrm{j}\dfrac{YY_1}{Y_0}\tan\theta\right)}{Y_0 + \mathrm{j}Y\tan\theta + (\mathrm{j}Y_1\tan\theta)}.$$

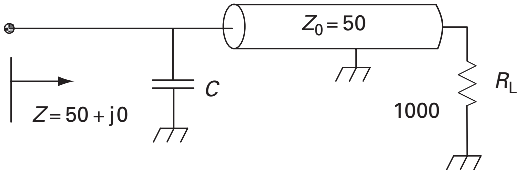
Hint: extend the argument used in the text to find Z' for a cable without a bridging lumped element. Assume a forward and reverse wave in the cable with amplitudes 1 and Γ. The voltage on the cable is then $V(z) = e^{j\omega t}\,(e^{-jkz} + \Gamma e^{jkz})$ and the current is $I(z) = Z_0^{-1} e^{j\omega t}\,(e^{-jkz} - \Gamma e^{jkz})$. The current into Z is the sum of the current from the cable and the current from Z_1 while the current into the circuit is the sum of the current into the cable and the current into Z_1.

Problem 10.9. Using a 50-ohm network analyzer, it is found that a certain device, when tested at 1 GHz, has a (complex) reflection coefficient of 0.6 at an angle of −22° (standard polar coordinates: the positive x-axis is at 0° and angles increase in the counterclockwise direction).

(a) Calculate the impedance, R+jX.

(b) Find the component values for both the equivalent series R_sC_s circuit and the equivalent parallel R_pC_p circuit that, at 1 GHz, represent the device.

Problem 10.10. The circuit below matches a 1000-ohm load to a 50-ohm source at a frequency of 10 MHz. The characteristic impedance of the cable is 50 ohms.



(a) Make a Smith chart sketch that shows the derivation of this circuit.

(b) Find the length of the (shortest) cable and the value of the capacitor. Specify the length in degrees and the capacitance in picofarads. Calculate these values rather than reading them from an accurately drawn Smith chart.

(c) Use your ladder network analysis program (Problems 1.3 and 10.5) to find the transmission from 9 MHz to 11 MHz in steps of 0.1 MHz.

Problem 10.11. Find a transmission line element to replace the capacitor in the circuit of Problem 10.9.

Problem 10.12. Suppose that a transmission line has small shunt susceptance (capacitive or inductive) at a point z. By itself, this will cause a small reflection. If an identical shunt reactance is placed one quarter-wave from the first, its reflection will compensate the first and the cable will have essentially perfect transmission. Show that this is the case (a) analytically, using the "tan tan" formula for Z' and B', and (b) graphically, using the Smith chart (the area around the center of the chart).

Problem 10.13. Find the size and position of the constant resistance circles on the normalized Smith chart. Use the following procedure:

We have $z(x)=r+\mathrm{j}x$ where x is a variable and r is a constant. This vertical line in the z-plane maps into the ρ-plane via the equation $\rho(x)=[z(x)-1]/[z(x)+1]$. We want to show that the locus of points in the ρ-plane is a circle with radius $1/(r+1)$ centered at $[r/(r+1), 0]$.

Assume that the locus will be a circle centered on the real axis at $[a,0]$. Write the equation $|\rho(x)-a|=\mathit{radius}$. This equation has the form

$$|[N_{\mathrm{Re}}(x)+\mathrm{j}N_{\mathrm{Im}}(x)]/[D_{\mathrm{Re}}(x)+\mathrm{j}\,D_{\mathrm{Im}}(x)]|=\mathit{radius}, \tag{1}$$

where $N_{\mathrm{Re}}(x)$ and $N_{\mathrm{Im}}(x)$ are the real and imaginary parts of the numerator and $D_{\mathrm{Re}}(x)$ and $D_{\mathrm{Im}}(x)$ are the real and imaginary parts of the denominator. If every point on the circle is to have the same value of r, the radius of the circle must be independent of x.

$$\begin{aligned}|\rho(x)-a|^2 &= [(N_{\mathrm{Re}}(x))^2+(N_{\mathrm{Im}}(x))^2]/[(D_{\mathrm{Re}}(x))^2+(D_{\mathrm{Im}}(x))^2]=\mathit{radius}^2\\ &= \text{function only of } r.\end{aligned} \tag{2}$$

In this case, the way to satisfy Equation (2) is to set $N_{\mathrm{Re}}(x)/D_{\mathrm{Re}}(x)=-N_{\mathrm{Im}}(x)/D_{\mathrm{Im}}(x)$.

This will let us find a and *radius*. Other ways to make the radius constant will produce circles on which both r and x vary.

CHAPTER

11 Oscillators

Oscillators are autonomous dc-to-ac converters. They are used as the frequency-determining elements of transmitters and receivers and as master clocks in computers, frequency synthesizers, wristwatches, etc. Their function is to divide time into regular intervals. The invention of mechanical oscillators (clocks) made it possible to divide time into intervals much smaller than the Earth's rotation period and much more regular than a human pulse rate. Electronic oscillators are analogs of mechanical clocks.

11.1 Negative feedback (relaxation) oscillators

The earliest clocks used a "verge and foliot" mechanism which resembled a torsional pendulum but was not a pendulum at all. These clocks operated as follows: torque derived from a weight or a wound spring was applied to a pivoted mass. The mass accelerated according to Torque $= I\,\mathrm{d}^2\theta/\mathrm{d}t^2$ (the angular version of $F = ma$). When θ reached a threshold, θ_0, the mechanism reversed the torque, causing the mass to accelerate in the opposite direction. When it reached $-\theta_0$ the torque reversed again, and so on. The period was a function of the moment of inertia of the mass, the magnitude of the torque, and the threshold setting. These clocks employed negative feedback; when the controlled variable had gone too far in either direction, the action was reversed. Most home heating systems are negative feedback oscillators; the temperature cycles between the turn on and turn off points of the thermostat. Negative feedback electronic oscillators are called "relaxation oscillators." Most of these circuits operate by charging a capacitor until its voltage reaches an upper threshold and then discharging it until the voltage reaches a lower threshold voltage. In Figure 11.1(a), when the voltage on the capacitor builds up to about 85 V, the neon bulb fires. The capacitor then discharges quickly through the ionized gas (relaxes) until the voltage decays to about 40 V. The bulb then extinguishes and the cycle begins anew.

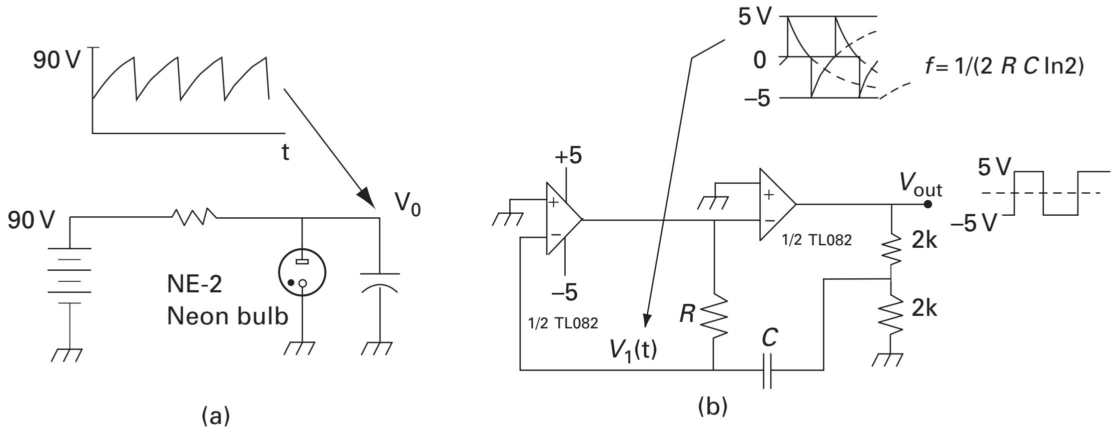


Figure 11.1. Relaxation (negative feedback) oscillators.

The circuit of Figure 11.1(b) alternately charges the capacitor, *C*, until its voltage reaches 2.5 V, and then discharges it until the voltage has fallen to −2.5 V. ($V_1(t)$ decays alternately toward +5 or −5 volts. When it reaches zero volts, the left-hand op-amp abruptly saturates in the opposite direction, kicking $V_1(t)$ to the voltage it had been approaching. The voltage then begins to decay in the opposite direction, and so forth.) Voltage-to-frequency converters are usually relaxation oscillators in which the control voltage determines the slope, and hence the oscillation period, of a fixed-amplitude sawtooth wave. Relaxation oscillators typically contain waveforms that are ramps or exponential decays. In the verge and foliot clock, the angle $\theta(t)$ consists of a sequence of parabolic arcs. Note that relaxation oscillators are nonlinear circuits which switch alternately between a charge mode and a discharge mode. Positive feedback oscillators, the main subject of this chapter, are nominally linear circuits. They generate sine waves.

11.2 Positive feedback oscillators

Clock makers improved frequency stability dramatically by using a true pendulum, a moving mass with a restoring force supplied by a hair spring or gravity.[1] As first observed by Galileo, a pendulum has its own natural frequency, independent of amplitude. It moves sinusoidally in simple harmonic motion. A pendulum clock uses *positive* feedback to push the pendulum in the direction of its motion, just as one pushes a swing to restore energy lost to friction.

[1] The Salisbury Cathedral clock, when installed around 1386, used a verge and foliot mechanism. Some 300 years later, after Christian Huygens invented the pendulum clock based on Galileo's observations of pendulum behavior, the Salisbury clock was converted into a positive feedback pendulum clock, its present form.

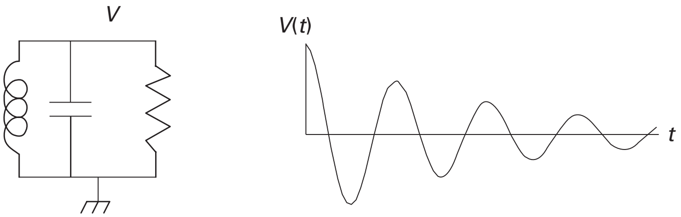

Figure 11.2. Damped oscillation in a parallel *LCR* circuit.

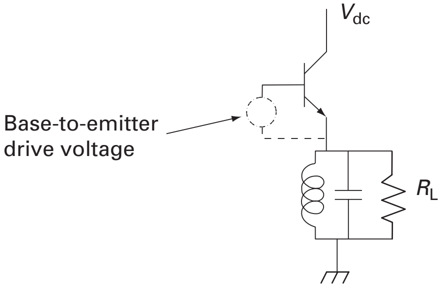

Figure 11.3. Transistor and dc supply replace energy lost to damping.

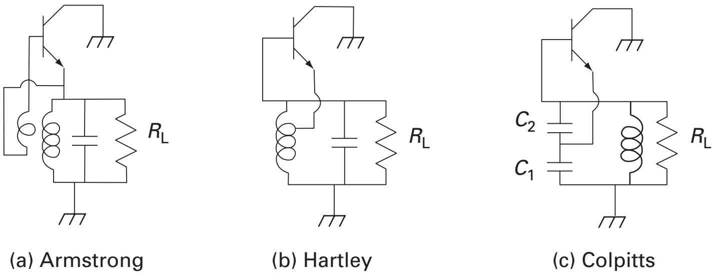
Electronic versions of the pendulum clock are usually based on resonators such as parallel or series *LC* circuits or electromechanical resonators such as quartz crystals. They use positive feedback to maintain the oscillation. A resonator with some initial energy (inductor current, capacitor charge, or mechanical kinetic energy) will oscillate sinusoidally with an exponentially decaying amplitude as shown in Figure 11.2. The decay is due to energy loss in the load and in the internal loss of the finite-Q resonator. In Figure 11.2 the resonator is a parallel *LCR* circuit.

To counteract the exponential decay, a circuit pumps current into the resonator when its voltage is positive and/or pulls current out when its voltage is negative. Figure 11.3 shows how a transistor and a dc supply can provide this energy. In this example circuit, the transistor is shown in the emitter-follower configuration simply because it is so easy to analyze; the emitter voltage tracks the base voltage and the base draws negligible current. The single transistor cannot supply negative current but we can set it up with a dc bias as a class-A amplifier so that current values less than the bias current are equivalent to negative current.

All that remains to complete this oscillator circuit is to provide the transistor drive, i.e., the base-to-emitter voltage. We want to increase the transistor's conduction when the output voltage (emitter voltage) increases, and we see that the emitter voltage has the correct polarity to be the drive signal. Since an emitter follower's voltage gain is slightly less than unity, the base needs a drive



(a) Armstrong (b) Hartley (c) Colpitts

Figure 11.4. Feedback loop details define (a) Armstrong; (b) Hartley; (c) Colpitts oscillators.

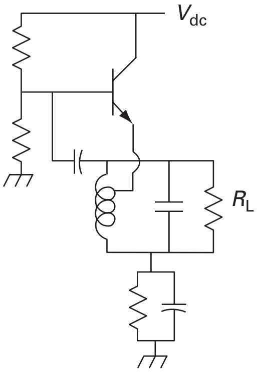


Figure 11.5. Hartley oscillator circuit including bias circuitry.

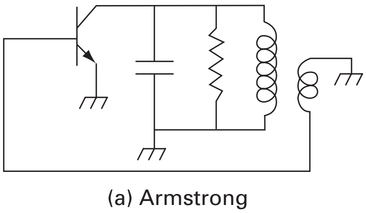
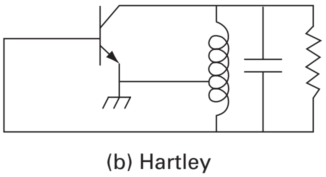
signal with slightly more amplitude than the sine wave on the emitter. Figure 11.4 shows three methods to provide this drive signal. The Armstrong oscillator adds a small secondary winding to the inductor. The voltage induced in the secondary adds to the emitter voltage. The Hartley oscillator accomplishes the same thing by connecting the emitter to a tap slightly below the top of the inductor. This is just an autotransformer version of the Armstrong oscillator if the magnetic flux links all the turns of the inductor. But the top and bottom portions of the inductor do not really have to be magnetically coupled at all; most of the current in the inductor(s) is from energy stored in the high-Q resonant circuit. This current is common to the two inductors so they essentially form a voltage divider. (Note, though, that the ratio of voltages on the top and bottom portions of the inductor ranges from the turns ratio, when they are fully coupled, to the square of the turns ratio, when they have no coupling.) If we consider the totally decoupled Hartley oscillator – no mutual inductance – and then replace the inductors by capacitors of equal (but opposite) reactance and replace the capacitor by an inductor, we get the Colpitts oscillator. Note that each oscillator in Figure 11.4 is an amplifier with a positive feedback loop. No power supply or biasing circuitry is shown in these figures; they simply indicate the ac signal paths.

Using the Hartley circuit as an example, Figure 11.5 shows a practical circuit. It includes the standard biasing arrangement to set the transistor's operating point. (A resistor voltage divider determines the base voltage and an emitter resistor then determines the emitter current, since V_{be} will be very close to 0.7 V.) A blocking capacitor allows the base to be dc biased with respect to the emitter. A bypass capacitor puts the bottom of the resonant circuit at RF ground.

In practice, one usually finds oscillators in grounded emitter circuits, as shown in Figure 11.6. The amplitude of the base drive signal must be much smaller than the sine wave on the resonant circuit. Moreover, the polarity of the base drive signal must be inverted with respect to the sine wave on the collector. You can inspect these circuits to see that they do satisfy these conditions. But, on closer inspection, you can note the circuits are *identical* to the circuits of Figure 11.4, except that the ground point has been moved from the collector to





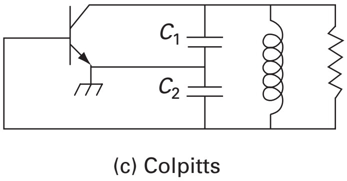


Figure 11.6. Grounded-emitter oscillator circuits.

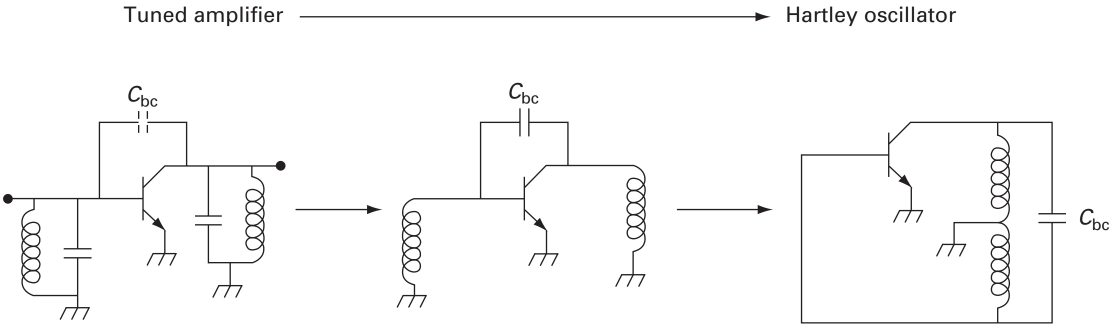
the emitter. In these oscillators, an amplifier is enclosed in a positive feedback loop. But, because there is no input signal to have a terminal in common with the output signal, oscillators, unlike amplifiers, do not have common-emitter, common-collector, and common-base versions.

The Colpitts oscillator, needing no tap or secondary winding on the inductor, is the most commonly used circuit. Sometimes the transistor's parasitic collector-to-emitter capacitance is, by itself, the top capacitor, C_1, so this capacitor may appear to be missing in a circuit diagram. A practical design example for the Colpitts circuit of Figure 11.6(c) is presented later in this chapter.

11.2.1 Unintentional oscillators

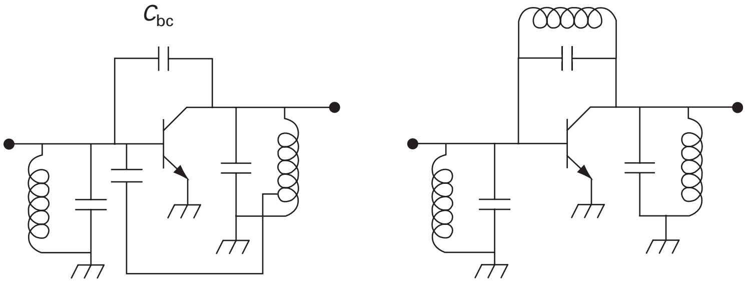
In RF work it is common for a casually designed amplifier to break into oscillation. One way this happens is shown in Figure 11.7. The circuit is a basic common-emitter amplifier with parallel resonant circuits on the input and output (as bandpass filters and/or to cancel the input and output capacitances of the transistor). When the transistor's parasitic base-to-collector capacitance is included, the circuit has the topology of the decoupled Hartley oscillator. If the feedback is sufficient, it will oscillate. The frequency will be somewhat lower than that of the input and output circuits so that they look inductive as shown in the center figure. This circuit known as a TPTG oscillator, form Tuned-Plate Tuned-Grid, in the days of the vacuum tube.

Figure 11.7. Tuned amplifier as an oscillator



With luck, the loop gain of any amplifier will be less than unity at any frequency for which the total loop phase shift is 360° and an amplifier will be stable. If not, it can be *neutralized* to avoid oscillation. Two methods of neutralization are shown in Figure 11.8.

Figure 11.8. Amplifier neutralization.

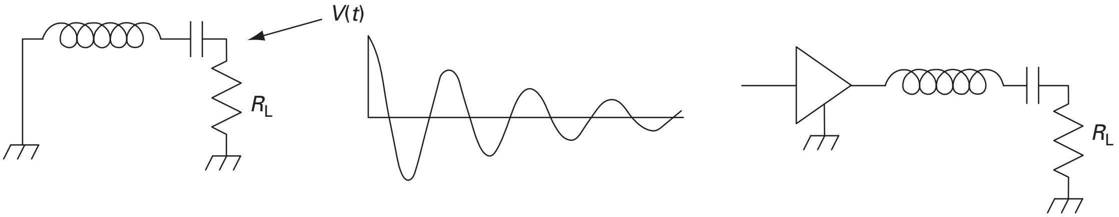


In Figure 11.8(a), a secondary winding is added to provide an out-of-phase voltage which is capacitor-coupled to the base to cancel the in-phase voltage coupled through C_{bc}. In Figure 11.8(b), an inductor from collector to base resonates C_{bc} to effectively remove it (a dc blocking capacitor would be placed in series with this inductor). In grounded-base transistor amplifiers and grounded-grid vacuum tube amplifiers the input circuit is shielded from the output circuit. These are stable without neutralization (but provide less power gain than their common-emitter and common-cathode-counterparts).

11.2.2 Series resonant oscillators

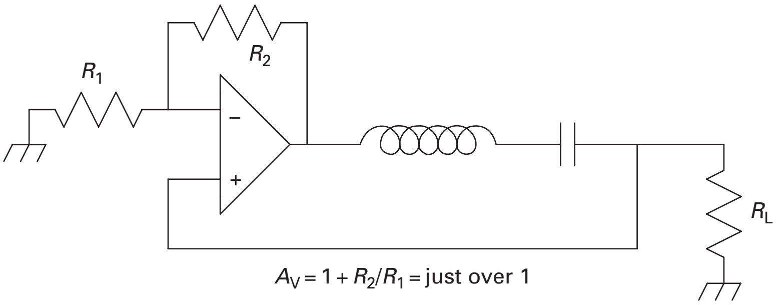
The oscillators discussed above were all derived from the parallel resonant circuit shown in Figure 11.2. We could just as well have started with a series *LCR* circuit. Like the open parallel circuit, a shorted series *LCR* circuit executes an exponentially damped oscillation unless we can replenish the dissipated energy. In this case we need to put a voltage source in the loop which will be positive when the current is positive and negative when the current is negative, as shown in Figure 11.9.

Figure 11.9. Series-mode oscillator operation.



While a bare transistor with base-to-emitter voltage drive makes a good current source for a parallel-mode oscillator, a low-impedance voltage source is needed for a series-mode oscillator. In the series-mode oscillator shown in Figure 11.10, an op-amp with feedback is such a voltage source.

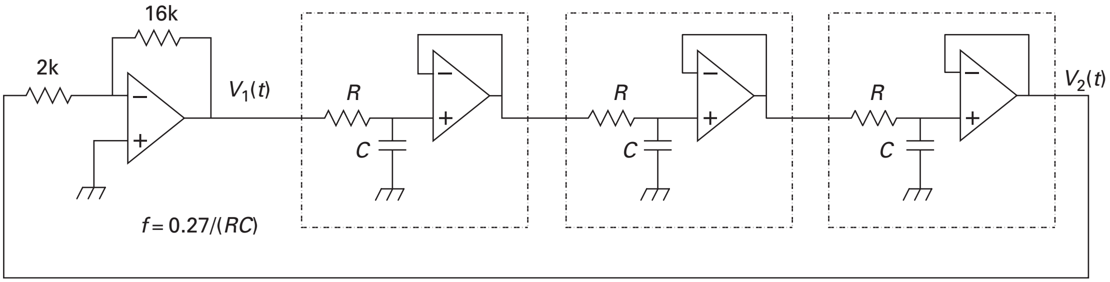
Figure 11.10. An op-amp series-mode oscillator.



Since no phase inversion is provided by the tank circuit, the amplifier is connected to be noninverting. An emitter-follower has a low output impedance and can be used in a series-mode oscillator (see Problem 11.4). When the series *LC* circuit is replaced by a multisection RC network, the resulting oscillator is commonly known as a *phase-shift oscillator* (even though every feedback oscillator oscillates at the frequency at which the overall loop phase shift is 360°). An *RC* phase-shift oscillator circuit is shown in Figure 11.11. Op-amp voltages followers make the circuit easy to analyze.

For the three cascaded *RC* units, the transfer function is given by $V_2(t)/V_1(t) = 1/(\omega RC{+}1)^3$. The inverting amplifier at the left provides a voltage gain of $-16/2 = -8$, so $V_1(t)/V_2(t) = -8$. Combining these two equations yields a cubic equation with three roots: $\omega RC = 3\mathrm{j}$, $\sqrt{3}$, and $-\sqrt{3}$. The first root corresponds to an exponential decay of any initial charges on the capacitors while the two imaginary roots indicate that the circuit will produce a steady sine-wave oscillation whose frequency is given by $\omega RC = \sqrt{3}$. In practice, the 16k resistor would be increased to perhaps twice that value to ensure oscillation. Note that

Figure 11.11. An *RC* phase-shift oscillator.



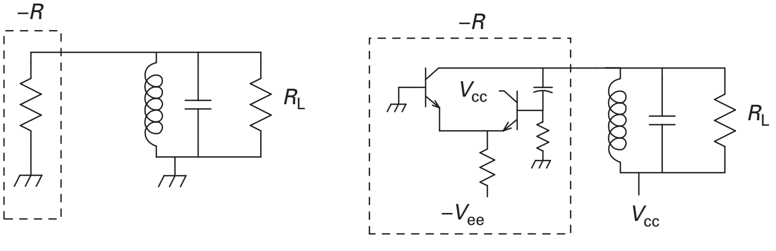
this circuit is a positive-feedback sine-wave oscillator even though it does not contain a resonator. When the 16k resistor value is increased, the loop gain for the original frequency becomes greater than unity, but for the new gain, there will be a nearby complex frequency, $\omega - \mathrm{j}\alpha$, for which the loop gain is unity. The time dependence therefore becomes $\mathrm{e}^{\mathrm{j}(\omega-\mathrm{j}\alpha)t} = \mathrm{e}^{\mathrm{j}\omega t}\mathrm{e}^{\alpha t}$, showing that the oscillation amplitude grows as $\mathrm{e}^{\alpha t}$. This circuit illustrates how any linear circuit with feedback will produce sine-wave oscillations if there is a (complex) frequency for which the overall loop gain is unity and the overall phase shift is 360°. (Of course α must be positive, or the oscillation dies out exponentially.)

11.2.3 Negative-resistance oscillators

In the circuits described above, a transistor provides current to an *RLC* circuit when the voltage on this circuit is positive, i.e., the transistor behaves as a negative resistance. But the transistor is a three-terminal device and the third terminal is provided with a drive signal derived from the *LCR* tank. Figure 11.12 shows how two transistors can be used to make a two-terminal negative resistance that is simply paralleled with the *LCR* tank to make a linear sine wave oscillator that has no feedback loop.

The two transistors form an emitter-coupled differential amplifier in which the resistor to $-V_{\mathrm{ee}}$ acts as a constant current source, supplying a bias current, I_0. The input to the amplifier is the base voltage of the right-hand transistor. The output is the collector current of the left-hand transistor. The ratio of input to output is $-4V_{\mathrm{T}}/I_0$, where V_{T} is the thermal voltage, 26 mV. This ratio is just the negative resistance, since the input and output are tied together. This negative-resistance oscillator uses a parallel-resonant circuit, but a series-resonant version is certainly possible as well.

Any circuit element or device that has a negative slope on at least some portion of its I–V curve can, in principle, be used as a negative resistance. Tunnel diodes can be used to build oscillators up into the microwave frequency range. At microwave frequencies, single-transistor negative-resistance oscillators are common. A plasma discharge exhibits negative resistance and provided a pre-vacuum tube method to generate coherent sine waves. High-efficiency



(a) (b)

Figure 11.12. A negative-resistance oscillator.

Poulsen arc transmitters, circa World War I, provided low-frequency RF power exceeding 100 kW.

11.3 Oscillator dynamics

These resonant oscillators are basically linear amplifiers with positive feedback. At turn-on they can get started by virtue of their own noise if they run class A. The tiny amount of noise power at the oscillation frequency will grow exponentially into the full-power sine wave. Once running, the signal level is ultimately limited by some nonlinearity. This could be a small-signal nonlinearity in the transistor characteristics. Otherwise, the finite voltage of the dc power provides a severe large-signal nonlinearity, and the operation will shift toward class-C conditions. The fact that amplitude cannot increase indefinitely shows that some nonlinearity is operative in every real oscillator. Any nonlinearity causes the transistor's low- frequency $1/f$ noise to mix with the RF signal, producing more noise close to the carrier than would exist for linear operation. An obvious way to mitigate large-signal nonlinearity is to detect the oscillator's output power and use the detector voltage in a negative feedback arrangement to control the gain. This can maintain an amplitude considerably lower than the power supply voltage. Alternatively, if the oscillator uses a device (transistor or op-amp circuit) with a soft saturation characteristic, the amplitude will reach a limit while the operation is still nearly linear. For example, the amplifier in the oscillator of Figure 11.10 might have a small cubic term, i.e., $V_{\mathrm{OUT}} = AV_{\mathrm{IN}} - BV_{\mathrm{IN}}^3$, where B/A is very small (see Problem 11.5).

11.4 Frequency stability

Long-term (seconds to years) frequency fluctuations are due to component aging and changes in ambient temperature and are called *drift*. Short-term fluctuations, known as oscillator noise, are caused by the noise produced in the active device, the finite loaded Q of the resonant circuit, and nonlinearity in the operating cycle. The higher the Q, the faster the loop phase-shift changes with frequency. Any disturbances (transistor fluctuations, power supply variations changing the transistor's parasitic capacitances, etc.) that tend to change the phase shift will cause the frequency to move slightly to reestablish the overall 360° shift. The higher the resonator Q, the smaller the frequency shift. Note that this is the *loaded Q*, so the most stable oscillators, besides having the highest Q resonators, are loaded as lightly as possible. In LC oscillators, losses in the inductor almost always determine the resonator Q. A shorted piece of transmission line is sometimes used as a high-Q inductor. Chapter 24 treats oscillator noise in detail.

11.5 Colpitts oscillator theory

Let us look in some detail at the operation of the Colpitts oscillator. Figure 11.13 shows the Colpitts oscillator of Figure 11.6(c) redrawn as a small-signal equivalent circuit (compare the figures). The still-to-be-biased transistor is represented as a voltage-controlled current source. The resistor r_{be} represents the small-signal base-to-emitter resistance of the transistor.

The parallel combination of L and the load resistor, R, is denoted as Z, i.e., $Z = \mathrm{j}\omega LR/(\mathrm{j}\omega L+R) = j\omega L_{\mathrm{S}} + R_{\mathrm{S}}$, where L_{S} and R_{S} are the component values for the equivalent series network. Likewise, it is convenient to denote ${r_{\mathrm{be}}}^{-1}$ as g. The voltage V_{be}, a phasor, is produced by the current I (a phasor) from the current source. This is a linear circuit, so V_{be} can be written as $V_{\mathrm{be}} = I\,Z_{\mathrm{T}}$, where Z_{T} is a function of ω. We will calculate this "transfer impedance" using standard circuit analysis. Since the current I is proportional to V_{be}, we can write an equation expressing that, in going around the loop, the voltage V_{be} exactly reproduces itself :

$$-g_{\mathrm{m}}V_{\mathrm{be}}Z_{\mathrm{T}} = V_{\mathrm{be}} \quad \text{or} \quad \frac{1}{Z_{\mathrm{T}}} = -g_{\mathrm{m}}. \tag{11.1}$$

This equation will let us find the component values needed for the circuit to oscillate at the desired frequency, i.e., the values that will make the loop gain equal to unity and the phase shift equal 360°.

We can arbitrarily select L, choosing an inductor whose Q is high at the desired frequency. Equation (11.1), really two equations (real and imaginary parts), will then provide values for C_1 and C_2. To derive an expression for Z_{T}, we will assume that $V_{\mathrm{be}} = 1$ and work backward to find the corresponding value of I. With this assumption, inspection of Figure 11.13 shows that the current I_1 is given by

$$I_1 = \mathrm{j}\omega C_2 + g. \tag{11.2}$$

Now the voltage V_{c} is just the 1 volt assumed for V_{be} plus I_1Z, the voltage developed across Z:

$$V_{\mathrm{c}} = 1 + (\mathrm{j}\omega C_2 + g)Z. \tag{11.3}$$

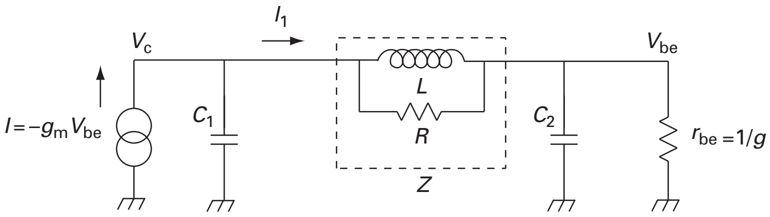


Figure 11.13. Colpitts oscillator small-signal equivalent circuit.

Finally, the current I is just the sum of I_1 plus $V_c \, j\omega C_1$, the current going into C_1:

$$I = (j\omega C_2 + g) + [1 + (j\omega C_2 + g)Z]\, j\omega C_1. \tag{11.4}$$

Since we had assumed that $V_{be} = 1$, we have $Z_T = 1/I$ or

$$\frac{1}{Z_T} = j\omega C_2 + g + [1 + (j\omega C_2 + g)Z]\, j\omega C_1. \tag{11.5}$$

Using this, the condition for oscillation, Equation (11.1) becomes

$$g_m + j\omega C_2 + g + [1 + (j\omega C_2 + g)Z]\, j\omega C_1 = 0. \tag{11.6}$$

The job now is to solve Equation (11.6) for C_1 and C_2. If we assume that ω is real i.e., that the oscillation neither grows nor decays, we find from the imaginary part of this equation, that

$$\frac{C_2 + C_1 + gR_S C_1}{L_S C_1 C_2} = \omega^2 \tag{11.7}$$

and, from the real part, that

$$\omega^2 C_1 C_2 R_S + g(\omega^2 L_S C_1 - 1) = g_m. \tag{11.8}$$

Solving Equations (11.7) and (11.8) simultaneously for C_2 and C_1 produces

$$C_2 = \frac{g_m L_S}{2R_S}\left(1 + \sqrt{\frac{4R_S(1 + gR_S)(g_m + g)}{{g_m}^2 L_S \omega^2}}\right) \tag{11.9}$$

and

$$C_1 = \frac{C_2}{\omega^2 L_S C_2 - 1 - gR_S}. \tag{11.10}$$

Normally C_2 will have a much larger value than C_1 and $\omega \approx 1/\sqrt{LC_1}$. Moreover, the second term in the square root of Equation (11.9) is usually much less than unity so $C_2 \approx g_m L_S / R_S$.

11.5.1 Colpitts oscillator design example

Let us design a practical grounded-emitter Colpitts oscillator. Suppose this oscillator is to supply 1 mW at 5 MHz and that it will be powered by a 6 V dc supply. Assuming full swing, the peak output sine wave voltage will be 6 V. The output power is given by $0.001\ \text{W} = (6\ \text{V})^2/(2R_L)$ so the value of the load resistor, R_L, will be 18 k ohms. Assuming class-A operation, the bias current in the transistor is made equal to the peak current in the load: $I = I_{pk} = 6\ \text{V}/18\ \text{k} = 0.33\ \text{mA}$. If we let the emitter biasing resistor be 1.5 k, the emitter bias voltage will be $1500 \times 0.33\ \text{mA} = 0.5\ \text{V}$. Assuming the typical 0.7 V offset between the base and emitter, the base voltage needs to be 1.2 V. A voltage divider using a 40 k resistor and a 10 k resistor will produce 1.2 V from the 6 V

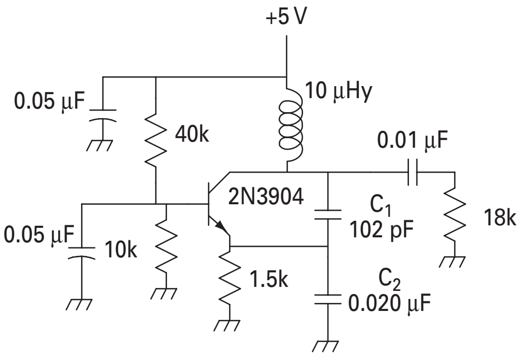

Figure 11.14. Colpitts oscillator: 5 MHz, 1 mW.

supply. These bias components are shown in the schematic diagram of Figure 11.14.

A 0.05 μF bypass capacitor pins the base to ac ground and another bypass capacitor ensures that the dc input is held at a firm RF ground. Note that the 1.5 k emitter bias resistor provides an unwanted signal path to ground. This path could be eliminated by putting an inductor in series with the bias resistor as an RF choke, but this is not really necessary; the1.5k resistor is in parallel with C_2, which will have such a low reactance that the resistor will divert almost no current from it.

With the biasing out of the way, we now deal with the signal components. The transconductance of the transistor is found by dividing the bias current, I_0, by 26 mV, the so-called thermal voltage,[2] i.e., $g_m = 0.33$ mA/ 26 mV = 0.013 mhos. The small-signal base-to-emitter resistance, r, is given by $r = \beta V_{\text{thermal}}/I_0$. For a typical small-signal transistor, such as a 2N3904, β is about 100, so r_{in} = 100·0.026 V/0.33 mA = 8000 ohms.

Using Equation (11.9) and (11.10), the values of C_1 and C_2 are 102 pF and 0.023 μF, respectively. These are the values for which the oscillator theoretically will maintain a constant amplitude. In practice, we increase the feedback by decreasing the value of C_2 to ensure oscillation. This produces a waveform that grows exponentially until it reaches a limit imposed by circuit nonlinearity. The frequency becomes complex, i.e., ω becomes $\omega - \mathrm{j}\alpha$ and the time dependence therefore becomes $\mathrm{e}^{\mathrm{j}(\omega - \mathrm{j}\alpha)t} = \mathrm{e}^{\mathrm{j}\omega t}\mathrm{e}^{\alpha t}$. Suppose we want α to be, say 10^5, which will cause oscillation to grow by a factor e every 10 μsec. (Fast growth would be important if, for example, the oscillator is to be rapidly pulsed on and off.) How do we find the value of C_2 to produce the desired α? To avoid doing more analysis, it is convenient to use a standard computer program such as Mathcad to find the root(s) of Equation (11.6) for trial values of C_2. In this example, if we decrease C_2 to 0.020 μF, we obtain the desired α.

---

[2] The thermal voltage is given by $V_{\text{thermal}} = 0.026\text{V} = kT/e$, where k is Boltzman's constant, T is the absolute ambient temperature, and e is the charge of an electron.

Problems

Problem 11.1. Draw a schematic diagram (without component values) for a bipolar transistor Colpitts oscillator with the collector at ground for both dc RF. Include the biasing circuit. The oscillator is to run from a positive dc supply.

Problem 11.2. Design (without specifying component values) a single-transistor series-mode oscillator based on the emitter follower circuit.

Problem 11.3. A simple computer simulation can illustrate how an oscillator builds up to an amplitude determined by the nonlinearity of its active element. The program shown below models the negative-resistance oscillator of Figure 11.12(a). The *LC* resonant frequency is 1 Hz. This network is in parallel with a negative-resistance element whose voltage vs. current relation is given by $I = -(1/R_n)*(V - \varepsilon V^3)$, to model the circuit of Figure 11.12. The small-signal (negative) resistance is just $-R_n$. The term $-\varepsilon V^3$ makes the resistance become less negative for large signals. The program integrates the second-order differential equation for $V(t)$ and plots the voltage versus time from an arbitrary initial condition, $V = 1$ volt.

Run this or an equivalent program. Change the value of the load resistor *R*. Find the minimum value of *R* for sustained oscillation. Experiment with the values of *R* and R_n. You will find that when the loaded *Q* of the *RLC* circuit is high, the oscillation will be sinusoidal even when the value of the negative resistor is only a fraction of *R*. When *Q* is low (as it is for $R = 1$), a low value of R_n such as $R_n = 0.2$ will produce a distinctly distorted waveform.

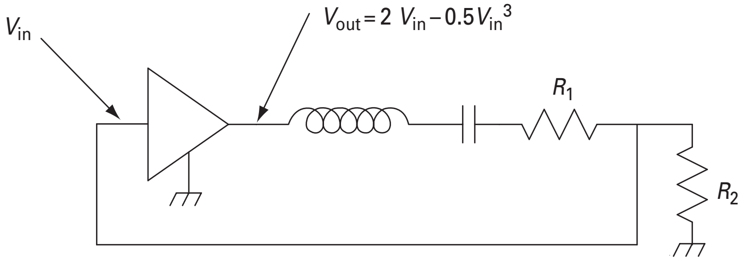
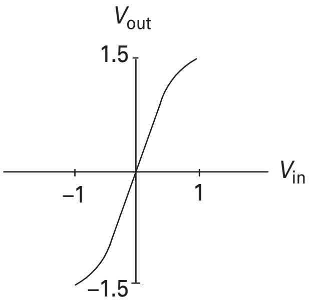
Problem 11.4. In the oscillator shown below, the voltage gain of the amplifier decreases with amplitude. The voltage transfer function is $V_{\text{out}} = 2\,V_{\text{in}} - 0.5V_{\text{in}}^3$. This characteristic will limit the amplitude of the oscillation.





Find the ratio R_2/R_1 in order that the peak value of the sine wave V_{in} will be one volt. Hint: assume $V_{in} = \sin(\omega t)$. The amplifier output is then $2\ \sin(\omega t)\ -0.5\sin^3(\omega t)$. The second term resembles the sine wave but is more peaked. The *LC* filter will pass the fundamental Fourier component of this second term. Find this term and add it to $2\sin(\omega t)$. Then calculate the ratio R_2/R_1 so that the voltage divider output is $\sin(\omega t)$.

CHAPTER

12

Phase lock loops and synthesizers

Oscillators whose frequencies are derived from a stable reference source are used in transmitters and receivers as L.O.'s for accurate digital tuning. A VCO in a loop that tracks the frequency excursions of an incoming FM signal is a commonly used FM detector. The first widespread use of phase lock loops was in television receivers where they provide noise-resistant locking of the horizontal sweep frequency to the synchronization pulses in the signal.

12.1 Phase locking

A phase lock loop (PLL) circuit forces the phase of a voltage-controlled oscillator (VCO) to follow the phase of a reference signal. Once lock is achieved, i.e., once the phases stay close to each other, the frequency of the VCO will be equal to the frequency of the reference. In one class of applications, the PLL is used to generate a stable signal whose frequency is determined by an unstable (noisy) reference signal. Here the PLL is, in effect, a narrow bandpass filter that passes a carrier, while rejecting its noise sidebands. Examples include telemetry receivers that lock onto weak pilot signals from spacecraft and various "clock smoother" circuits. It is often necessary to lock an oscillator to the suppressed carrier of a modulated signal, an operation known as carrier recovery. In yet another class of applications the PLL is designed to detect all the phase fluctuations of the reference. An example is the PLL-based FM demodulator where the VCO reproduces the input signal, which is usually in the IF band. The voltage applied by the loop to the VCO is proportional to the instantaneous frequency (in as much as the VCO has a linear voltage-to-frequency characteristic), and this voltage is the audio output.

12.1.1 Phase adjustment by means of frequency control

In a PLL, the VCO frequency, rather than phase, is determined by the control voltage, but it is easy to see how frequency control provides phase adjustment.

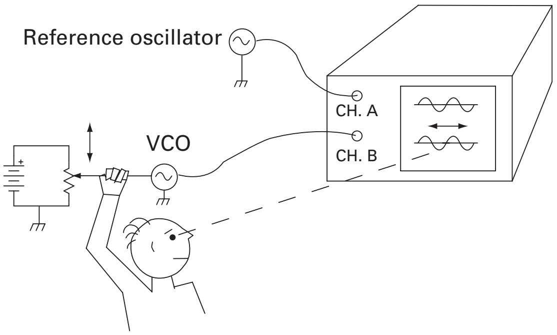


Figure 12.1. Phase lock loop concept.

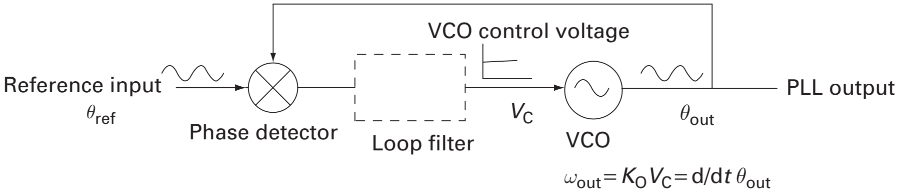

Figure 12.2. Phase lock loop block diagram.

Suppose you have two mechanical clocks. You want to make Clock *B* agree with Clock *A*. You notice that Clock *B* is consistently five minutes behind Clock *A*. You could exert direct phase control, using the time adjustment knob to set Clock *B* ahead 5 min to agree with Clock *A*. Or you could use frequency control, regulating the speed of Clock *B* to run somewhat faster. Once Clock *B* catches up with Clock *A*, you reset the frequency control to its original value. You may have done an electronic version of this in the lab (Figure 12.1). Suppose you have a two-channel oscilloscope. The first channel displays a sine wave from a fixed-frequency reference oscillator. The scope is synchronized to this reference oscillator so Channel *A* displays a motionless sine wave. Channel *B* is connected to a variable frequency oscillator which might be a laboratory instrument with a frequency knob or a VCO fitted with a potentiometer. Suppose the frequencies are the same. Then the sine wave seen on Channel *B* is also motionless. If you lower the VCO frequency slightly, the Channel *B* trace will drift to the right. And if you raise the VCO frequency, the trace will drift to the left. To align the two traces, you can shift the frequency slightly to let the Channel *B* trace drift into position, and then return the VCO frequency to the reference frequency value to stop the drift. The operator keeps the traces aligned and is therefore an element of this phase lock loop.

To automate the loop we use an electronic phase detector, i.e., an element that produces a voltage proportional to the phase difference between the reference and the VCO. Figure 12.2 shows the block diagram for a PLL.

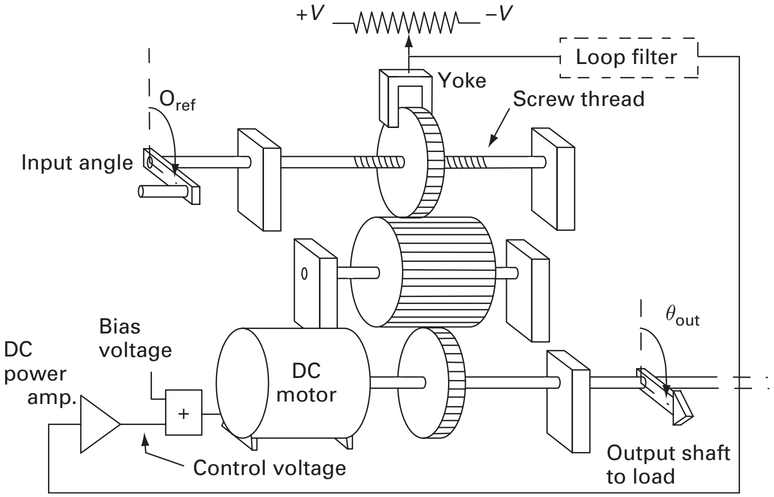
If the VCO phase gets behind (lags) the reference phase, the phase detector will produce a positive "error voltage" which will speed up the VCO. As the phase error then decreases, the error voltage also decreases and the VCO slows back down. The exact way in which equilibrium is established, i.e., the mathematical form of the VCO phase, $\theta_{\text{out}}(t)$, depends on the yet-unspecified loop filter or "compensation network," shown as a dotted box in Figure 12.2. We will examine phase detectors and loop filters below.

12.1.2 Mechanical analog of a PLL

The PLL is a feedback control system – a servo. The electromechanical system shown in Figure 12.3 is a positioning servo. If an operator adjusts the input crank angle, the output shaft automatically turns so that the output angle, θ_{out}, tracks the input shaft angle, θ_{ref}. The gear teeth are in constant mesh but the top gear can slide axially. A dc motor provides torque to turn the output shaft. The input shaft might be connected to the steering wheel of a ship while the output shaft drives the rudder.

Consider the operation of this servo system. Assume for now that the voltage, V_{bias}, is set to zero, and that the system is at rest. When the input and output angles are equal, the slider on the potentiometer is centered and produces zero error voltage. But suppose the reference phase gets slightly ahead of the output phase – maybe the input crank is abruptly moved clockwise. During this motion, the threads on the input shaft have caused the top gear to slide to the left, producing a positive voltage at the output of the potentiometer. This voltage is passed on by the loop filter to the power amplifier and drives the motor clockwise, increasing θ_{out}. This rotates the top gear clockwise. The input shaft is now stationary, so the top gear moves along the threads to the right, reducing the potentiometer output voltage back to zero. The output angle (output phase) is again in agreement with the input or "reference" angle (input phase). In this system the gear/screw thread mechanism is the phase detector. Note that the

Figure 12.3. Positioning system with feedback control – a mechanical phase lock loop.



range of this phase detector can be many turns – the number of threads on the shaft. The negative feedback error signal provides the drive to force the (high-power) output to agree with the (low-power) input command.

We see how this mechanical system operates as a power-steering servo. To see that it can also operate as a PLL, suppose that an operator is cranking the input shaft at a constant or approximately constant rate (input frequency). We will now set the bias voltage so that, with the bias voltage alone, the motor turns at the nominal input frequency. (A VCO can be regarded as having an internal bias that determines its nominal frequency, i.e., its frequency when the control voltage is zero.) At equilibrium, the top gear is being turned by the middle gear but the threaded shaft is turning just as fast. The top gear therefore does not move along the threads, but stays at an equilibrium position. The output frequency is locked to the input frequency. How about the phases; will they also agree exactly? They did in the power steering model,[1] but now, with continuous rotation, they may not. The key is the loop filter. Suppose the loop filter is just a piece of wire (no filter at all). If the input frequency changes from its nominal value, there will have to be a constant phase error in order to keep the potentiometer off-center and produce a control voltage which will add to or subtract from the bias voltage. How much phase error (*tracking* error) is necessary depends on the gain of the power amplifier. Increasing the gain of the amplifier/motor and/or the gain (sensitivity) of the phase detector will reduce the error. But, if the loop filter contains an integrator, the control voltage will be the integral of the error voltage history. The steady-state error voltage can be zero. In fact, it *must* be zero, on average, or the integrator output, and hence the output frequency, would increase indefinitely.

Note: a servo's *type* is given by the number of integrators contained in its loop. Even without an integrator in the loop filter block, a PLL contains one integrator, the VCO, since phase is the time integral of frequency. In the mechanical analog, rotation angle is the integral of angular velocity.

12.1.3 Loop dynamics

Let us now look at how a PLL responds to disturbances in the input phase. We have already described qualitatively the response to a step function; the loop catches up with the reference. The way in which it catches up, i.e., quickly, slowly, with overshoot, or with no overshoot, depends on the loop filter and the characteristics of the phase detector, amplifier and motor. An exact analysis is straightforward if the entire system is *linear*, i.e., if the system can be described with linear differential equations. In this case it can be analyzed with the standard techniques applied to linear electronic circuits, i.e., complex numbers, Fourier and Laplace transforms, superposition, etc. In the PLL, the loop filter is linear since it consists of passive components: resistors, capacitors, and op-amps. The VCO is linear if its frequency is strictly proportional to the control voltage. Of course, over a small operating region, any smooth voltage–frequency characteristic is approximately linear. The most commonly used phase detector is a simple multiplier (mixer). You can show[2] that it produces an error voltage proportional to $\sin(\theta_{\text{out}}(t)-\theta_{\text{ref}}(t)+\pi/2)$. For small x, $\sin(x) \approx x$, so a multiplier is a fairly linear phase detector over a restricted region around $\pi/2$. The phase detector in our mechanical analog is linear over a range limited only by the length of the screw thread.

---

[1] We will assume the motor speed is proportional to the applied voltage, independent of load.

To describe the loop dynamics, we will find its response to an input phase disturbance, $\theta_{\text{dist\_in}} = e^{j\omega t}$. The complete input function is therefore $\theta_{\text{ref}}(t) = \omega_0 t + e^{j\omega t}$. Since the system is linear, we invoke superposition to note that the output will consist of a response to the $\omega_0 t$ term plus an output response to the $e^{j\omega t}$ disturbance term. The input term, $\omega_0 t$, results in an output contribution $\omega_0 t + \Theta$, where the constant Θ might be 90°, if the phase detector is a mixer, and might include another constant, if the nominal frequency of the VCO is not quite ω_0 and the loop filter includes no integrator. Since the input disturbance function is sinusoidal, the output response to it will also be sinusoidal, $A(\omega)e^{j\omega t}$, where the complex amplitude $A(\omega)$ is known as the input-to-output transfer function. Before we can calculate the transfer function, we must specify the loop filter.

12.1.4 Loop filter

A standard filter for type-II loops uses an op-amp to produce a weighted sum of the phase detector output plus the integral of the phase detector output. Figure 12.4 shows the circuit commonly used.

Note that if we let C go to infinity and set $R_2 = R_1$, the response of this filter is just unity (except for a minus sign) so this circuit will serve to analyze the type-I PLL as well as the type-II PLL. Remembering that the negative input of the op-amp is a virtual ground, we can write the transfer function of this filter.

$$\frac{-V_2}{V_1} = \frac{R_2 + 1/j\omega C}{R_1} = \frac{R_2}{R_1} + \frac{1}{j\omega C R_1} = \frac{\tau_2}{\tau_1} - \frac{j}{\omega\tau_1}. \tag{12.1}$$

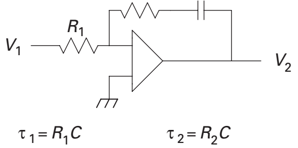


Figure 12.4. Loop filter circuit.

---

[2] Just expand the product $\cos(\omega_0 t + \theta_{\text{out}}(t))\cos(\omega_0 t + \theta_{\text{ref}}(t))$ and ignore (filter off) components at $2\omega_0$.

In the time domain, the relation between V_2 and V_1 is given by

$$\frac{dV_2}{dt} = \frac{-R_2}{R_1}\frac{dV_1}{dt} - \frac{V_1}{R_1 C}. \tag{12.2}$$

12.1.5 Linear analysis of the PLL

Figure 12.5. Type-II, second-order PLL block diagram.

For this linear system, let us find the frequency response of the output phase to a sinusoidal disturbance of the reference phase, $\theta_{dist}e^{j\omega t}$, where ω is the disturbing frequency. From inspection of Figure 12.5 we can write

$$-K_D(\theta_{out} - \theta_{dist})\left(\frac{\tau_2}{\tau_1} - \frac{j}{\omega\tau_1}\right)K_O = j\omega\theta_{out}. \tag{12.3}$$

Solving for θ, we have the frequency response

$$\frac{\theta_{out}(\omega)}{\theta_{dist}(\omega)} = \frac{1}{1 - \left[K_D K_O/(\omega^2\tau_1) + jK_D K_O \tau_2/(\omega\tau_1)\right]^{-1}}. \tag{12.4}$$

12.1.5.1 Frequency response of the type-I loop

We will look at the frequency response for the type-I loop by letting C go to infinity and letting $R_1 = R_2$, effectively eliminating the loop filter. The frequency response, Equation (12.4), becomes

$$\frac{\theta_{out}(\omega)}{\theta_{dist}(\omega)} \rightarrow \frac{1}{1 + j\omega/K}, \tag{12.5}$$

where $K = K_D K_O$, and is called the *loop gain*. The frequency response is identical to that of a simple RC lowpass filter with a time constant $RC = 1/K$. We saw earlier that a type-I PLL (a PLL with no integrator in the loop filter) needs high loop gain to have good tracking accuracy (the ability to follow a changing reference frequency without incurring a large phase error). Here we see that high gain implies a large bandwidth; the type-I PLL cannot have both high gain (for good tracking) and a narrow bandwidth (to filter out high-frequency reference phase noise).

12.1.5.2 Frequency response of the type-II loop

To deal with the type-II loop (the most common PLL) it is standard to define two constants, the *natural frequency*, ω_n, and the *damping coefficient*, ζ, as follows:

$$\omega_\text{n} = \sqrt{\frac{K_\text{O}K_\text{D}}{\tau_1}} \quad \zeta = \frac{\tau_2\omega_\text{n}}{2}. \tag{12.6}$$

We will see soon that these names relate to the transient response of the loop but, for now, we will substitute them into Equation (12.4), the expression for the frequency response, to get

$$\frac{\theta_\text{out}(\omega)}{\theta_\text{dist}(\omega)} = \frac{{\omega_\text{n}}^2 + 2\text{j}\omega\zeta\omega_\text{n}}{{\omega_\text{n}}^2 + 2\text{j}\omega\zeta\omega_\text{n} - \omega^2}. \tag{12.7}$$

This transfer function is plotted vs. ω/ω_n in Figure 12.6 for several different damping coefficients.

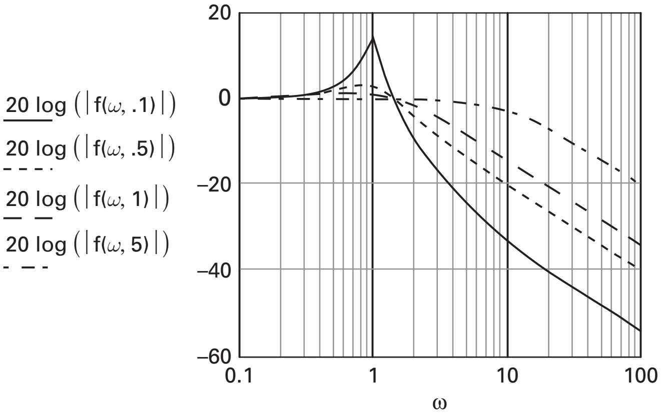

Figure 12.6. Frequency response vs. ω/ω_n for a second-order type-II loop with various damping coefficients.

12.1.5.3 Transient response

The transient response can be determined from the frequency response by using Fourier or Laplace transforms, but this loop is simple enough that we can work directly in the time domain. Equation (12.2) gives the time response for the loop filter. We assume the loop has been disturbed but the reference is now constant. By inspection of Figure 12.5 we can write

$$\frac{\text{d}V_1}{\text{d}t} = K_\text{D}K_\text{O}V_2 = KV_2. \tag{12.8}$$

Combining this with Equation (12.2) we get

$$\frac{\text{d}^2V_1}{\text{d}t^2} + K\frac{\tau_2}{\tau_1}\frac{\text{d}V_1}{\text{d}t} + \frac{K}{\tau_1}V_1 = 0 \quad \text{or} \quad \frac{\text{d}^2V_1}{\text{d}t^2} + 2\omega_\text{n}\zeta\frac{\text{d}V_1}{\text{d}t} + {\omega_\text{n}}^2V_1 = 0. \tag{12.9}$$

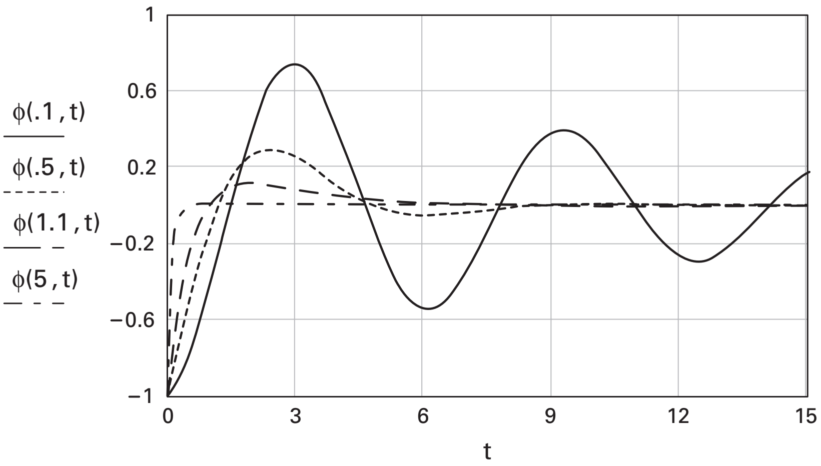

Figure 12.7. Phase error for a step of −1 radian in the reference phase at $t = 0$.

Assuming a solution of the form $e^{j\omega t}$, we find an equation for ω:

$$-\omega^2 + 2j\omega_n\zeta\omega + \omega_n^2 = 0. \tag{12.10}$$

The roots of this equation are

$$\omega = -\omega_n\zeta \pm \omega_n\sqrt{\zeta^2 - 1}. \tag{12.11}$$

When ζ is less than unity, the two solutions for ω are complex conjugates, giving sine and cosine oscillations with damped exponential envelopes. This is the underdamped situation. When ζ is greater than unity, the two solutions for ω are both damped exponentials, but with different time constants. If ζ is exactly unity, the two solutions are $e^{-\omega t}$ and $te^{-\omega t}$. In every case, a linear combination of the two appropriate solutions can match any given set of initial conditions, i.e., the $t = 0$ values of V_1 and $\mathrm{d}/\mathrm{d}t\, V_1$. Figure 12.7 shows the transient phase response to a step function in the reference phase of one radian at $t = 0$. This initial condition, $V_1(0) = -1$, determines the other initial condition, $\mathrm{d}V_1/\mathrm{d}t = 2\zeta\omega_n$, through the action of the loop filter circuit. Curves are shown for the recovery from this transient for damping coefficients of 0.1, 0.5, 1.1 and 5. In each case, $\omega_n = 1$. The underdamped cases show the trademark oscillatory behavior. When the damping is 5, the fast exponential recovery is essentially that of a wideband type-I loop.

Note: Equation (12.10) (which is the same as the denominator of the transfer function) is known as the *characteristic equation* of the system. Here it is a second-order equation and this type-II loop is therefore also a second-order loop. Equivalently, the order of a given system is the order of the differential equation describing its transient response.

12.1.6 A multiplier as a phase detector

A multiplier (mixer) is the most commonly used phase detector, especially at higher frequencies. When the reference sine wave is multiplied by the VCO sine wave, the usual sum and difference frequencies are generated. The desired baseband output is the difference component. If the VCO and reference frequencies are equal, this baseband component will be a dc voltage, zero when the VCO and reference phases differ by 90°, and linearly proportional to the phase difference in the vicinity of 90°. Therefore, when a multiplier is used as a phase detector, the loop will lock with the output phase 90° away from the reference phase. If this is a problem (in most applications it is not), a 90° phase shift network can be put at one of the multiplier inputs or in the output line. Note that a multiplier phase detector puts out zero volts when the phase shifts are different by 90° in either direction. One of these is a point of metastable equilibrium. As soon as it "falls off," the feedback will be positive, rather than negative, and the loop will rush to the stable equilibrium point.

As a phase detector, a mixer has a linear response of about $\pm \pi/4$, where $\sin(x) \approx x$. For somewhat larger phase differences, the sine curve flattens out and K_D begins to decrease. The system becomes nonlinear and the techniques of linear analysis fail. What is more important, if $\theta_{out} - \theta_{dist}$ needs to increase beyond $\pm \pi/2$, the $\sin(\theta_{out} - \theta_{dist})$ response of the mixer produces alternating positive and negative error signals, which will push the VCO frequency one way and then the other, and the loop will become unlocked. This is in contrast to the mechanical analog of Figure 12.3, whose phase detector range is 2π times the number of threads on the phase detector shaft. Electronic *phase/frequency detectors* (PFDs) are digital circuits that operate as linear phase detectors while the phase difference remains small, but then produce an output voltage proportional to the frequency difference, driving the loop in the correct direction to achieve lock. How a simple mixer-based PLL ever manages to lock without assistance is discussed below.

12.1.7 Frequency range and stability

The type-II loop can operate over the full range of the VCO since its integrator can build up as much bias as needed. The type-I loop, if $K_D K_O$ is small and if the phase detector has a limited range, may not be able to track over the full range of the VCO. Both the loops discussed above are unconditionally stable since the transient responses are decaying exponentials for any combination of the parameters K_D, K_O, R_1, R_2, and C. When you build one and it oscillates it is usually because you have high-frequency poles you did not consider (maybe in your op-amp or circuit parasitics) and you have actually built a higher-order loop.

12.1.8 Acquisition time

A high-gain type-I loop can achieve lock very quickly. A type-II loop with a small bandwidth can be very slow. Acquisition depends on some of the beat note from the phase detector getting through the filter to FM modulate the VCO. That beat note puts a pair of small sidebands on the VCO output. One of these sidebands will be at the reference frequency and will mix with the reference to produce dc with the correct polarity to push the VCO toward the reference frequency. The integrator gradually builds up this dc until the beat frequency comes within the loop bandwidth. From that point the acquisition is very fast. This reasoning, applied to the type-II loop, predicts an acquisition time of about $4f^2/B^3$ seconds where f is the initial frequency error and B is the bandwidth of the loop (see Problem 12.6). If the bandwidth is 10 Hz and the initial frequency error is 1 kHz, the predicted time is about one hour. (In practice, unavoidable offsets in the op-amp would make the integrator drift to one of the power supply rails and never come loose.) Obviously in such a case some assist is needed for a lockup. One common method is to add search capability, i.e., circuitry that causes the VCO voltage to sweep up and down until some significant dc component comes out of the phase detector. At that point the search circuit turns off and the loop locks itself up. The integrator can form part of the sweep circuit. Another way to aid acquisition is to use a frequency/phase detector instead of a simple phase detector. This is a digital phase detector which, when the input frequencies are different, puts out dc whose polarity indicates whether the VCO is above or below the reference. This dc quickly pumps the integrator up or down to the correct voltage for lock to occur. You will see these circuits described in Motorola literature. In digitally controlled PLLs, it is common for a microprocessor with a lookup table in ROM to pretune the VCO to the commanded frequency. This pretuning allows the loop to acquire lock quickly.

12.1.9 PLL receiver

There are many inventive circuits and applications in the literature on PLLs. Here is an example: deep space probes usually provide very weak telemetry signals. The receiver bandwidth must be made very small to reject noise that is outside the narrow band containing the modulated signal. A PLL can be used to do the narrowband filtering and to do the detection as well. One simple modulation scheme uses slow-frequency shift keying (FSK) where the signal is at one frequency for a “0” and then slides over to a second frequency for a “1.” The loop bandwidth of the PLL is made just wide enough to follow the keying. The control voltage on the VCO is used as the detected signal output. (With a wide loop bandwidth, such a circuit can demodulate ordinary FM audio broadcast signals.) In this narrowband example, the PLL circuit has the advantage that it will track the signal automatically when the transmitter frequency drifts or is Doppler shifted. Another modulation scheme uses phase shift keying (PSK). Suppose the transmitter phase is shifted 180° to distinguish a “1” from a “0.” This would confuse the PLL receiver because, for random data, the average output from the phase detector would be zero and the PLL would be unable to lock. A simple cure is to use the “doubling loop” shown in Figure 12.8. The incoming signal is first sent through a doubler to produce an output that looks like the output of a full-wave rectifier. (The waveform loops are positive no

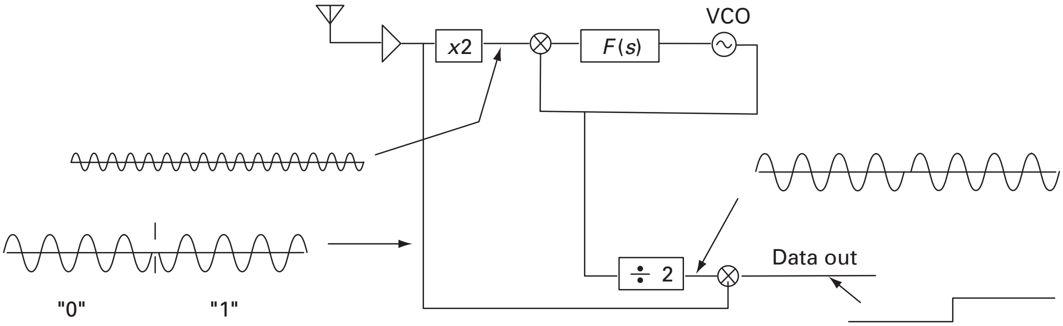

Figure 12.8. Doubling loop for detection of binary phase-shift modulation.

matter what the modulation does.) The VCO output frequency is then divided by two to produce a phase-locked reference. This reference is used as one input of a mixer. The other input of the mixer is the raw signal and the output is the recovered modulation.

12.2 Frequency synthesizers

By *frequency synthesizer* we usually mean a signal generator which can be switched to put out any one of a discrete set of frequencies and whose frequency stability is derived from a standard oscillator, either a built-in crystal oscillator or an external "station standard." Most laboratory synthesizers generate sine waves but some low-frequency synthesized function generators also generate square and triangular waves. General-purpose synthesizers have high resolution; the step between frequencies is usually less than 1 Hz and may be millihertz or even microhertz. Many television receivers and communications receivers have synthesized local oscillators. Special-purpose synthesizers may generate only a single frequency.

At least three general techniques are used for frequency synthesis. *Direct synthesizers* use frequency multipliers, frequency dividers, and mixers. *Indirect synthesizers* use phase lock loops. *Direct digital synthesizers* use a digital accumulator to produce a staircase sawtooth. A lookup table then changes the sawtooth to a staircase sinusoid, and a D-to-A converter provides the analog output. Some designs combine these three techniques.

12.2.1 Direct synthesis

The building blocks for direct synthesis are already familiar. Frequency multiplication can be done with almost any nonlinear element. A limiting amplifier (limiter) or a diode clipper circuit will convert sine waves into square waves, which include all the odd harmonics of the fundamental frequency. A delta function pulse train (in practice, a train of narrow pulses) contains all harmonics. When frequencies in only a narrow range are to be multiplied, class-C amplifiers can be used. (A child's swing does not need a push on each and every

cycle.) Frequency division, used in all three types of synthesizers, is almost always done digitally; the input frequency is used as the clock for a digital counter made of flip-flops and logic gates. Frequency translation can be done with any of the standard mixer circuits.

Single-frequency synthesizers are usually ad hoc designs; the arrangement of mixers, multipliers, and dividers depends on the ratio of the desired frequency and the reference frequency. As an example of direct synthesis, the circuit of Figure 12.9 generates 321 MHz from a 1-MHz standard. A prime factor of 321 is 107. It would be difficult to build a times-107 multiplier. This design uses only triplers and mixers. Laboratory instruments that cover an entire range of frequencies must, of course, use some general scheme of operation.

12.2.2 Mix and divide direct synthesis

Some laboratory synthesizers use an interesting mix and divide module. An *n*-digit synthesizer would use *n* identical modules. An example is shown in Figure 12.10. Each module has access to a 16-MHz source and ten other

reference sources from 20 to 29 MHz. (These references are derived from an internal or external standard, often at 5 MHz). In this kind of design the internal frequencies must be chosen carefully so that after each mixer the undesired sideband can be filtered out easily.

12.2.3 Indirect synthesis

The phase lock loop circuit of Figure 12.11 is an indirect synthesizer to generate the frequency Nf_{std}/M where N and M are integers. If the $\div N$ and/or the $\div M$ blocks are variable modulus counters, the synthesizer frequency is adjustable.

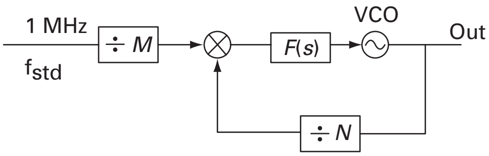

Figure 12.11. Basic indirect (PLL) synthesizer.

The 321-MHz synthesizer of Figure 12.9 could be built as the indirect synthesizer of Figure 12.11 by using a divide-by-321 counter (most likely a divide-by-3 counter followed by a divide-by-107 counter). Circuits like that of Figure 12.11 are used as local oscillators for digitally tuned radio and television receivers. For an AM broadcast band receiver, the frequency steps would be 10 kHz (the spacing between assigned frequencies). This requires that the phase detector reference frequency, f_{std}/M, be 10 kHz so only the modulus N would be adjustable. What about a synthesized local oscillator for a short-wave radio? We would probably want a tuning resolution of, say, 10 Hz. The reference frequency in the simple circuit of Figure 12.11 would have to be 10 Hz and the loop bandwidth would have to be about 2 Hz. This low bandwidth would make fast switching difficult. Moreover, with such a narrow loop bandwidth, the close-in noise of the VCO would not be cleaned up by the loop and the performance of the radio would suffer. For this application a more sophisticated circuit is needed. One method is to synthesize a VHF or UHF frequency with steps of 1 or 10 kHz, divide it to produce the necessary smaller steps, and then mix it to a higher frequency. Other circuits use complicated multiple loops. The newest receivers use L.O. synthesizers based on the principle of direct digital synthesis.

12.2.4 Direct digital synthesis (DDS)

This technique, illustrated in Figure 12.12, uses an adder with two n-bit inputs, A and B, together with an n-bit register to accumulate phase. The output of the adder is latched into the register on every cycle of a high-frequency clock. The inputs to the adder are the current register contents (the phase) and an adjustable addend (the phase increment). On every clock cycle, the accumulated phase increases by an amount given by the addend. Since the accumulator has a finite

length, it rolls over, like an automobile odometer, and the sequence of its output values forms a sawtooth wave. The maximum addend value is 2^{n-1}, where n is the number of bits in the adder/accumulator. Therefore, the output frequency of the DDS extends up to one-half the clock frequency. At this maximum frequency, the MSB toggles on every clock pulse and the lower bits remain constant. The output of the accumulator is used to address a ROM (read-only memory) that converts the stairstep digital sawtooth into a stairstep digital sine wave.

Let us consider the operation of the DDS in some detail. Suppose the selected addend is the integer A. Let θ_i denote the number held in the register after the i-th clock pulse. Because the accumulator rolls over when the output value would have reached or exceeded 2^n, we can write $\theta_i = (\theta_{i-1}+A) \bmod 2^n$, a formula which lets us easily simulate the DDS. On average, it will take $2^n/A$ clock pulses to fill the accumulator,[3] so the average period of the sawtooth wave will be $f_{\text{clk}}^{-1}\ 2^n/A$ and the output frequency will be $f_{\text{clk}}\ A/2^n$. This frequency can be changed in very fine increments if the number of bits in the accumulator is large. With a 32-bit accumulator, for example, the frequency resolution will be $f_{\text{clock}}/2^{32}$. For a clock frequency of 100 MHz the resolution will be $10^8/2^{32} = 0.023$ Hz.

---

[3] Consider that, after every 2^nA clock pulses, the accumulator must return to the same value. During that period, the value that would be accumulated without rollover is $A(2^nA)$. Thus the number of rollovers would be A^2. The average time per rollover is therefore $f_{\text{clk}}^{-1}\ (2^nA)/A^2 = f_{\text{clk}}^{-1}\ 2^n/A$.

One might think that, since the most significant bit (MSB) of the accumulator toggles at the desired output frequency, we could use it alone, simply filtering away its harmonics to obtain a sine wave at the desired frequency. However, while the MSB has the right *average* frequency it can be quite irregular. If the addend is a power of 2, the MSB will toggle at uniform time intervals but otherwise the MSB will have a jitter which depends on the value of the addend. A sine wave made from just the MSB would, therefore, contain too much phase noise (FM noise) for most RF applications.

The solution is to use more than just the top bit. If we use the top m bits, then the phase error is never greater than $360/2^m$ degrees. A table-lookup ROM uses these m-bit phase values, θm_i, as address bits to produce an output sequence, $\sin(\theta m_i)$, which has the desired wave shape (except for the roundoff error), together with low phase noise. An analog output can be provided by adding an m-bit D-to-A converter but, in digital radio applications, the digital sine wave is used directly. The more bits used to form the output sine wave, the lower the phase noise. Note that the DDS can incorporate the technique of digital pipelining in the adder/accumulator to achieve simultaneously high output frequencies and fine frequency resolution. The pipe delay is of no consequence for most system applications. Note also that the DDS can easily be modified to produce a chirped frequency by adding another accumulator to produce a sawtooth addend value. A precise FM modulator consists of a DDS whose addend is the digitized audio signal. Clock rates in DDS ICs have reached several GHz.

Output spectrum of the DDS

The exact spectrum of the DDS output can be calculated directly using Fourier analysis. For any value of the addend, the sequence of accumulator values will always repeat after at most 2^n clock pulses. Therefore, the sequence of digital values produced by the lookup ROM also repeats after at most 2^n cycles. This repetitive waveform can be represented as a Fourier series whose components are spaced in frequency by at least $f_{\text{clk}}/2^n$. The squares of the Fourier coefficients at each frequency are proportional to power. A simpler and more instructive approach is to note that the number contained in truncated accumulator bits (the bits below $n - m$) is just the phase error, $\delta\theta_i = \theta_i - \theta m_i$. The output sequence formed by the m-bit numbers can therefore be written as

$$\sin(\theta m_i) = \sin(\theta_i - \delta\theta_i) \approx \sin(\theta_i) - \delta\theta_i \cos(\theta_i), \tag{12.12}$$

where we have assumed $\delta\theta_i$ is small. The term $\sin(\theta_i)$ is the desired output, while the term $\delta\theta_i \cos(\theta_i)$ is the noise. The error sequence, $\delta\theta_i \cos(\theta_i)$, will repeat after, at most, 2^{n-m} clock pulses, so the noise forms a Fourier series with components separated in frequency by at least $f_{\text{clk}}/2^{n-m}$. The nature of the noise will depend on the value of the bottom part of the addend, i.e., the lowest $n - m$ bits of the addend. If that number is a power of 2, the noise components will fall at harmonics of the output frequency, distorting the output waveform slightly, but contributing no phase noise. If the bottom part of the addend contains no factors of 2, the noise may be a grass of components at all multiples of $f_{\text{clk}}/2^{n-m}$. The more factors of 2 in the bottom part of the addend, the wider the spacing between noise components. Thus, the nature of the noise can change dramatically from one output frequency to the next.

12.2.5 Switching speed and phase continuity

Indirect synthesizers cannot change frequency faster than the time needed for their phase lock loops to capture and settle. Direct synthesizers and direct digital synthesizers can switch almost instantly. Sometimes it is necessary to switch frequencies without losing phase continuity. The DDS is perfect for this since the addend is changed and the phase rate changes but there is no sudden phase jump. Other times, when the synthesizer is retuned to a previously selected frequency, the phase must take on the value it would have had if the frequency had never been changed. This second kind of continuity might be called phase memory. A frequency synthesizer that provides the first kind of phase continuity clearly will not provide the second and vice versa. Continuity of the second kind can be obtained with a direct synthesizer that uses only mixers and multipliers (no dividers – which can begin in an arbitrary state).

12.2.6 Phase noise from multipliers and dividers

It is important to see how any noise on the reference signal of a synthesizer determines the noise on its output signal. Let us examine how noise is affected by the operations of frequency multiplication and division. We will assume the input noise sidebands are much weaker than the carrier. Suppose the input signal has a discrete sideband at 60 Hz. (Such a sideband would normally be one of a pair but for this argument we can consider them one at a time.) Let this sideband have a level of −40 dBc, i.e., its power is 40 dB below the carrier power. If this signal drives a times-N frequency multiplier, it turns out that the output signal will also have a sideband at 60 Hz but its level will be $-40 + 20\log(N)$ dBc. The relative sideband power increases by the *square* of the multiplication factor.

Let us verify this, at least for a specific case – a particular frequency tripler. Let the input signal be $\cos(\omega t) + \alpha\cos([\omega+\delta\omega]t)$, i.e., a carrier at ω having a sideband at $\omega+\delta\omega$ with relative power of α^2 or $20\log(\alpha)$ dBc. We assume that $\alpha \ll 1$. Here the tripler will be a circuit whose output voltage is the cube of the input voltage. Expanding the output and keeping only terms of order α or higher whose frequencies are at or near $3f$ we have

$$[\cos(\omega t) + \alpha\cos[(\omega+\delta\omega)t]]^3 \rightarrow \cos^3(\omega t) + 3\alpha\cos^2(\omega t)cos[(\omega+\delta\omega)t] \tag{12.13}$$

$$\rightarrow 1/2\ \cos(\omega t)\cos(2\omega t) + 3/2\ \alpha\cos(2\omega t)\cos[(\omega + \delta\omega)t]$$

$$\begin{aligned} &\rightarrow 1/4\ \cos(3\omega t) + 3/4\ \alpha\cos[(3\omega + \delta\omega)t] \\ &\ = 1/4\ [\cos(3\omega t) + 3\alpha\cos[(3\omega + \delta\omega)t]]. \end{aligned} \tag{12.14}$$

Note that the carrier-to-sideband spacing is still $\delta\omega$ but the relative amplitude of the sideband has gone up by 3, the multiplication factor. The relative power of the sideband has therefore increased by 3^2, the square of the multiplication factor. A continuous distribution of phase noise $S(\delta\omega)$ is like a continuous set of discrete sidebands so, if the noise spectrum of a multiplier input is $S(\delta\omega)$, the noise spectrum of the output will be $n^2 S(\delta\omega)$. Sideband noise enhancement is a direct consequence of multiplication. If the multiplier circuit itself is noisy, the output phase noise will increase by more than n^2. Fortunately, most multipliers contribute negligible additive noise.

Division, the inverse of multiplication, reduces the phase noise power by the square of the division factor. Mixers just translate the spectrum of signals; they do not have a fundamental effect on noise. Additive noise from mixers is usually negligible. If a direct synthesizer is built with ideal components, the relation between the output phase noise and the phase noise of the standard will be as if the synthesizer were just a multiplier or divider, no matter what internal operations are used. The phase noise produced by indirect synthesizers depends on the quality of the internal VCOs and the bandwidths of the loop filters.

Problems

*These more difficult problems could be used as projects.

Problem 12.1. How would you modify the gear train in Figure 12.3 so that the output shaft would turn *N/M* times faster than the input shaft?

Problem 12.2. Show that Equation (12.2) describes the time domain input/output relation for the loop filter circuit of Figure 12.4.

Problem 12.3. Suppose the VCO in the block diagram of Figure 12.5 is noisy and that its noise can be represented as an equivalent noise voltage added at the control input of the VCO. Redraw the block diagram showing a summing block just in front of the VCO. Find the frequency transfer function for this noise input. Show that the loop is able to "clean up" the low-frequency noise of the VCO.

Problem 12.4.* Write a computer program to numerically simulate the PLL shown in Figure 12.5. Use a multiplier type phase detector and investigate the process of lock-up. Let the phase detector output be proportional to $\cos(\theta - \theta_{\text{ref}})$. Use numerical integration on the simultaneous first-order differential equations for $V_1(t)$ and $V_2(t)$.

Problem 12.5.* Invent a phase detector circuit that would have a range of many multiples of 2π rather than the restricted range of the multiplier phase detector.

Problem 12.6.* Derive the formula given for lock-up time, $\tau_{\text{LOCKUP}} \approx 4(\Delta\omega)^2/B^3$, where $\Delta\omega$ is the initial frequency error and B is the loop bandwidth (in radians/sec). Consider the type-II loop of Figure 12.5. Find the ac component on the VCO control input. Assume that $\Delta\omega$ is high enough that the gain of the loop filter for this ac voltage is just $-R_2/R_1$. Find the amplitude of the sidebands caused at the output of the VCO from this ac control voltage component. Use this amplitude to find the dc component at the output of the phase detector caused by product of the reference signal and the VCO sideband at the reference frequency. This dc component will be integrated by the loop filter. Find $\mathrm{d}V/\mathrm{d}t$ at the output of the loop filter. Find an expression for τ_{LOCKUP} by estimating the time for the dc control voltage to change by the amount necessary to eliminate the initial error.

Problem 12.7. Design a direct synthesizer (ad hoc combination of mixers, dividers, multipliers) to produce a frequency of 105.3 MHz from a 10-MHz reference. Avoid multipliers higher than ×5 and do not let the two inputs of any mixer have a frequency ratio higher than 5:1 (or lower than 1:5).

Problem 12.8. Design a direct digital synthesizer with 10-kHz steps for use as the tunable local oscillator in a middle-wave broadcast band (530–1700 kHz) AM receiver with a 455 kHz IF frequency. Assume a high-side L.O., i.e., the synthesizer frequencies range from 530 + 455 to 17800 + 455 An accurate reference frequency is available at 10.24 MHz.

Problem 12.9. Design a synthesizer with the range of 1–2 MHz that has phase memory, i.e., when the synthesizer is reset to an earlier frequency, its phase will be the same as if it had been left set to the earlier frequency. The required step size is 50 kHz and the available frequency reference is 5 MHz. Hint: one approach is to generate a frequency comb with a spacing of 50 kHz and then phase-lock a tunable oscillator to the desired tooth of the comb.

Problem 12.10. Explain why a direct synthesizer that includes one or more dividers will not have phase memory.

Problem 12.11. Draw a block diagram for an FM transmitter in which a phase locked loop keeps the average frequency of the VCO equal to a stable reference frequency.

Problem 12.12. Draw block diagrams for PM and FM generators based on the direct digital synthesizer (DDS) principle.

CHAPTER

13 Coupled-resonator bandpass filters

We saw in Chapter 4 that the straightforward transformation of a prototype lowpass filter to a bandpass filter yields a circuit with alternating parallel resonant circuits and series resonant circuits as shown in Figure 13.1.

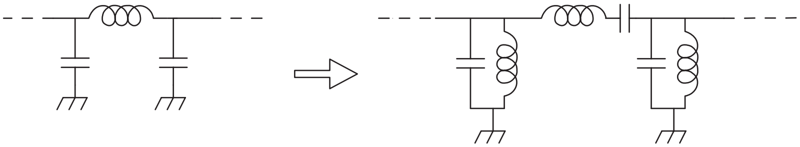

Figure 13.1. Conversion of a lowpass filter to a canonical bandpass filter.

If the prototype lowpass filter has a response $F_{\mathrm{LP}}(\omega)$, the corresponding bandpass filter will have the response $F_{\mathrm{BP}}(\omega)=F_{\mathrm{LP}}(\,|\omega-\omega_{\mathrm{C}}|)$, where ω_{C} is the center frequency. These canonical bandpass filters work perfectly – when simulated with a network analysis program. But usually they call for impractical component values. The inductors in the shunt branches must be smaller than the inductors in the series branches by a factor on the order of the square of the fractional bandwidth. For a 5% bandwidth filter, the ratio of the inductor values would be of the order of 1:400. For a given center frequency we might be lucky to find a high-Q inductor of any value, let alone high-Q inductors with such different values. Low-Q (resistive) inductors make a filter lossy and change its nominal passband shape. The series and shunt capacitor values have the same ratio. Generally Q is not a problem with capacitors, but very small values are impractical when they become comparable to the stray wiring capacitances.

13.1 Impedance inverters

This component value problem can be solved by transforming canonical bandpass filters into *coupled-resonator bandpass filters*, which can be built with identical or almost identical *LC* resonant circuits. The coupled-resonator filters have the same filter shapes, based on prototype lowpass designs, such as Butterworth or Chebyshev. Figure 13.2 shows some coupled-resonator fiter designs.

These filters are based on *impedance inverters*. Three examples of impedance inverters are shown in Figure 13.3, a 90° length of transmission line and two lumped *LC* circuits.

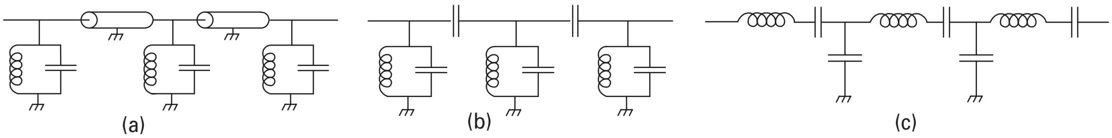

Figure 13.2. Three examples of coupled-resonator bandpass filter circuits.

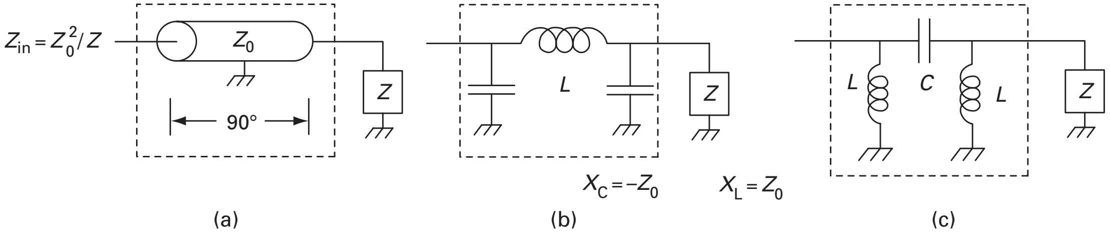

Figure 13.3. Three impedance inverter circuits

In every case, an impedance Z, when seen through the inverter, becomes $Z_0{}^2/Z$ where Z_0 can be called the characteristic impedance of the inverter. For the transmission line inverter, a 90° length of line, Z_0 is just the characteristic impedance of the line. For the *LC* inverters, both the inductor's reactance, X_L, and the capacitor's reactance, X_C, must be equal to the desired Z_0. Like the 90° cable, the lumped element circuits are perfect inverters only at one frequency but, in practice, they are adequate over a considerable range. An inverted capacitor is an inductor. An inverted inductor is a capacitor. Figure 13.4 shows an inverter (in this example, a 90° transmission line) used to invert a parallel circuit, making an equivalent series circuit.

The mathematics of this inversion is just

$$Z_{in} = Z_0{}^2 Y = Z_0{}^2\left(\frac{1}{j\omega L_p} + j\omega C_p + \frac{1}{R_p}\right) = \frac{1}{j\omega(L_p/Z_0{}^2)} + j\omega(Z_0{}^2 C_p) + \frac{Z_0{}^2}{R_p}. \tag{13.1}$$

Let us look at four inverters which include inductors or capacitors with negative values. For these inverters, shown in Figure 13.5, $X_C = Z_0$ or $X_L = Z_0$.

Figure 13.6 verifies the inverter action of the all-capacitor T-section inverter. You can use this kind of reasoning to verify the inverter action of the other circuits:

$$Z_1 = \frac{1}{j\omega(-C)} + Z \tag{13.2}$$

$$Y_2 = j\omega C + \frac{1}{Z_1} = \frac{j\omega CZ}{Z - 1/j\omega C} \tag{13.3}$$

$$Z_{in} = \frac{1}{j\omega(-C)} + \frac{1}{Y_2} = \frac{1}{\omega^2 C^2 Z} = \frac{Z_0^2}{Z}. \tag{13.4}$$

Because they contain negative capacitances or negative inductances, the four inverters in Figure 13.5 might seem to be only mathematical curiosities. Not at

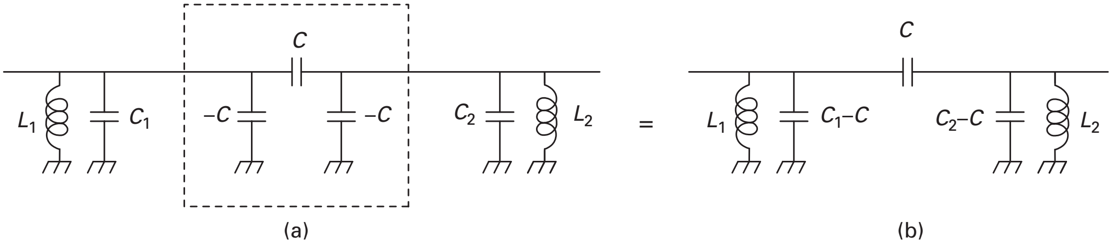

Figure 13.7. Negative capacitors absorbed into adjacent positive capacitors.

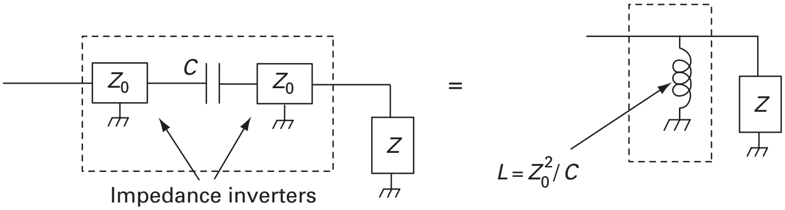
all; the negative elements can be absorbed by positive elements in the adjacent circuitry as shown in Figure 13.7, where a π-section capacitor inverter is placed between two parallel *LC* "tanks."

13.2 Conversion of series resonators to parallel resonators and vice versa

Ladder network filters have alternating series and shunt branches. Let us see how inverter *pairs* are used in ladder filters. Suppose we embed a series capacitor between a pair of inverters at some point along a ladder network.

Figure 13.8. A series capacitor between inverters is equivalent to a shunt inductor.



The combination of the capacitor and the inverter pair is equivalent to a shunt inductor, as shown in Figure 13.8.

You can show just as easily that any series impedance, Z_s, together with a pair of bracketing inverters of characteristic impedance Z_0 is equivalent to a shunt admittance $Y_p = Z_0^{-2} Z_s$. Likewise, the combination of any shunt admittance Y and a pair of bracketing inverters is equivalent to a series impedance $Z = Z_0^2 Y$. Figure 13.9 illustrates this, showing how a series resonant series branch in an ordinary bandpass filter can be replaced by a parallel resonant shunt branch imbedded between a pair of inverters.

Likewise, a parallel resonant shunt branch can be realized as a series resonant series branch imbedded between a pair of inverters, as shown in Figure 13.10.

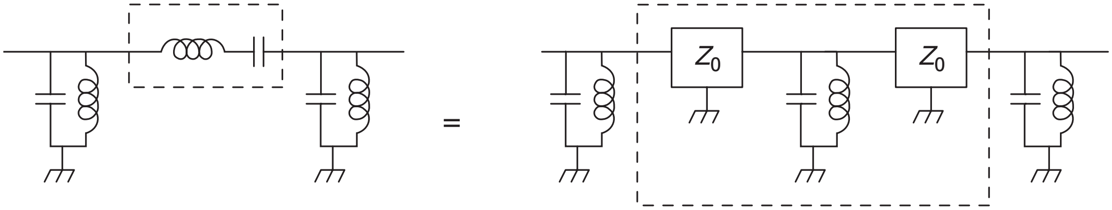


Figure 13.9. A shunt resonator between inverters is equivalent to a series resonator.

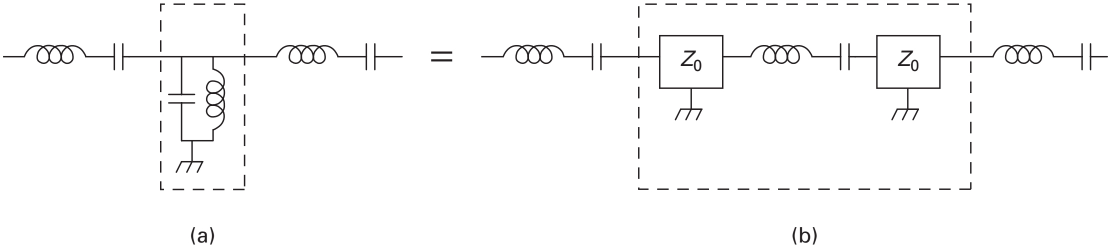

Figure 13.10. A series resonator between inverters is equivalent to a shunt resonator.

13.3 Worked example: a 1% fractional bandwidth filter

Consider a 50-ohm, 1-dB Chebyshev filter with a 10-MHz center frequency and a bandwidth of 100 KHz between the 1-dB points. The filter, which results from the straightforward lowpass to bandpass transformation (Chapter 4) is shown in Figure 13.11 and its response is shown in Figure 13.12.

We might find 86-μH inductors with high Q at 10 MHz but the 3.728 nH and 2.645 nH inductors would be tiny single turns of wire with very poor Q. To get around these component limitations, we will convert this filter into a coupled-resonator filter. Suppose we have in hand some adjustable 0.3 to 0.5 microhenry

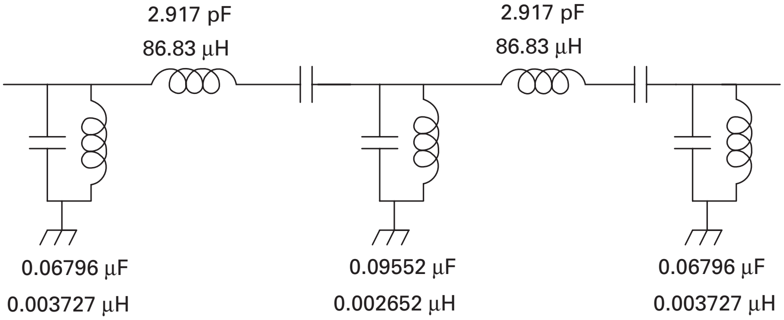

Figure 13.11. A straightforward (but impractical) bandpass filter. The calculated response of this filter is shown in Figure 13.12.

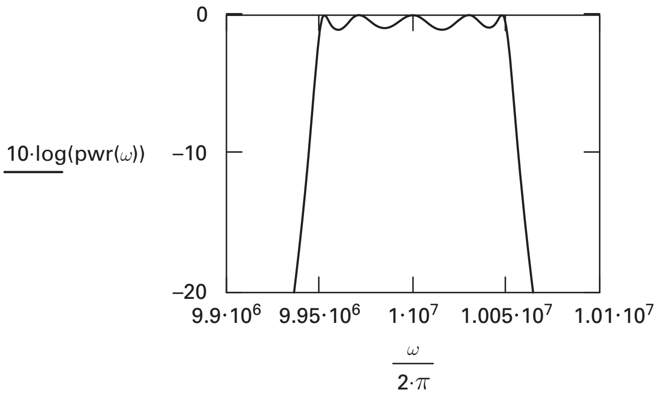

Figure 13.12. Calculated response for filter of Figure 13.11.

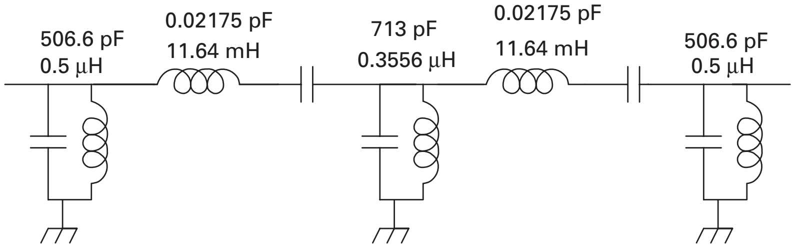

Figure 13.13. Filter of Figure 13.11, scaled from 50 to 6705 ohms.

inductors which, at 10 MHz, have very high Q (we will see later just how much Q is required). Let us first change the working impedance of the filter so that the parallel resonators at the end will use 0.5 μH, which is 134.1 times the original end inductors and implies that the filter will be scaled to 50 × 134.1 = 6705 ohms. We multiply the other inductors by 134.1 and divide the capacitors by 134.1 to get the circuit of Figure 13.13.

The parallel resonators now use the desired inductors but the series resonators call for inductors of 11.6 mH, a very large value for which we surely will not find high Q components. Moreover, the series capacitors are only 0.02 pF, a value far too small to be practical. We can solve this problem by using impedance inverters to convert the series resonators into parallel resonators. Let us use the all-capacitor π-section inverters of Figure 13.5(b) and the same parallel resonators we used for the end sections. Figure 13.14 shows how two inverters and the parallel resonator replace each series resonator.

We can calculate the inverter's characteristic impedance, Z_0, as follows:

$$Z_0{}^2 Y = Z;\; Z_0{}^2(\mathrm{j}\omega C_\mathrm{p} + 1/\mathrm{j}\omega L_\mathrm{p}) = \mathrm{j}\omega L_\mathrm{S} + 1/\mathrm{j}\omega C_\mathrm{S} \qquad (13.5)$$

$$Z_0{}^2 = L_\mathrm{p}/C_\mathrm{S} = 0.5\times10^{-6}/0.02175\times10^{-12} = 4796^2. \qquad (13.6)$$

Figure 13.16. Finished coupled-resonator filter.

For this type of inverter, we had seen that $Z_0 = X_C$, so $C = 3.32$ pF. We now have our coupled-resonator filter but since it works at 6705 ohms we will add L-section matching networks at each end to convert it back to 50 ohms. The filter, at this point, is shown in Figure 13.15. All the resonators are now parallel resonators. (In other situations we might use inverters to convert series resonators into equivalent parallel resonators to make an all-series-resonator filter – see Figure 13.1.)

The final clean-up step is to absorb the -3.32 pF capacitors into the resonator capacitors and combine the matching section inductors with the end-section resonator inductors as shown in Figure 13.16.

The response of the finished filter is shown in Figure 13.17 and is almost identical to the response of the prototype filter of Figure 13.11. The difference, a fraction of a dB, occurs because the inverters work perfectly only at the center frequency.

13.4 Tubular bandpass filters

A popular bandpass filter design, the “tubular filter” is produced by many filter manufacturers. Figure 13.18 shows the construction of a three-resonator tubular filter.

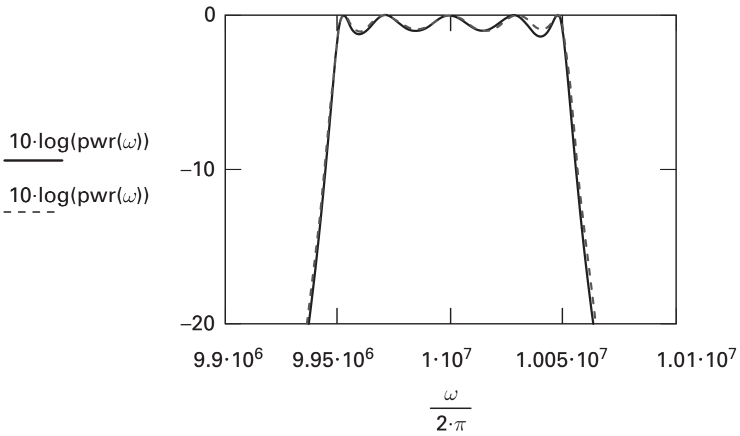

Figure 13.17. Calculated response of the filters of Figure 13.16 (pwr) and Figure 13.11 (pwr).

The only standard electronic components are the coaxial connectors at the ends. There are also (in this example) three inductors (wire coils), four metal cylinders, two dielectric spacers, two (or one long) dielectric sleeves, and a tubular metal body. Figure 13.19 shows how a coupled-resonator filter design, of the type we have discussed, is transformed into the tubular filter design. You can verify that Figure 13.19(d) is the circuit diagram of the tubular filter. The three-capacitor π-sections are formed by the capacitance between the adjacent faces of the metal cylinders and the capacitors are formed between the outside surfaces of the cylinders and the tubular body.

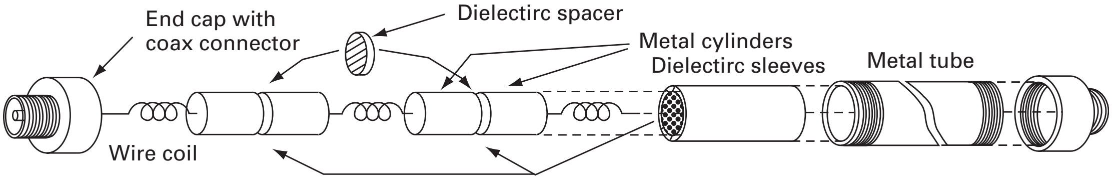

Figure 13.18. Tubular bandpass filter.

Beginning with Figure 13.19(a), we have a standard coupled-resonator bandpass filter using series resonators. In the canonical prototype for this filter, the middle section is a parallel resonator, but this has been replaced by a series resonator sandwiched between two impedance inverters. In (b), the center capacitor has been replaced by two capacitors (each of twice the value of the original capacitor so that, in series, the total series capacitance is the same). The capacitors have been shifted slightly in (c) to identify a T-section capacitor network at each side of the central inductor. Finally, in going from (c) to (d), these T-networks are replaced by equivalent π-networks, to arrive at the circuit of the tubular filter. Any

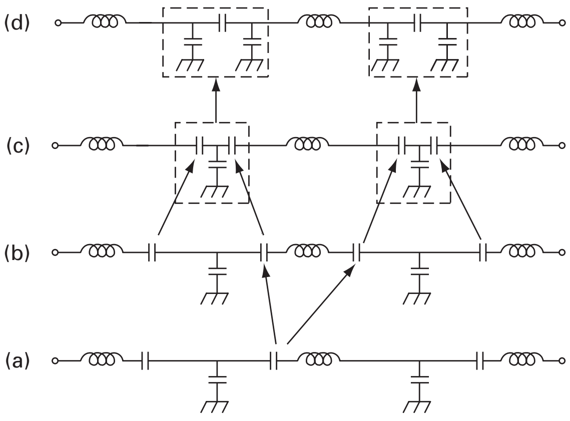

Figure 13.19. Tubular bandpass filter evolution.

Figure 13.20. Equivalent π-section and T-section networks.

T-network has an equivalent π-network and vice versa (Problem 13.5). These transformations, also known as T–π and π–T are shown in Figure 13.20. Formulas are given for one element in each network; the others follow from symmetry.

13.5 Effects of finite *Q*

These calculated filter responses assume components of infinitely high *Q*. We can calculate the effects of finite *Q* by paralleling the (lossless) inductors in our model with resistors equal to *Q* times the inductor reactances at the center frequency. If, for example, the *Q* is 500 (quite a high value for a coil), we would parallel the inductors in the filter of Figure 13.15 with resistors of about 15 000 ohms. Reanalyzing the circuit response, we would find that the filter will have a midband insertion loss of 7 dB and that the flat (within 1 dB) passband response becomes rounded. The effect will be somewhat less for a filter with more gradual skirts, e.g., a 0.01 dB Chebyshev or a Butterworth filter. But the real problem is still the small fractional bandwidth. For a filter with small fractional bandwidth to have the ideal shape of Figure 13.17, the resonators must be quartz or ceramic or other resonators with Qs in the thousands. An approximate analysis predicts that the midband loss per section in a bandpass filter will be on the order of

$$\frac{\text{power transmitted}}{\text{power incident}} = \left(1 - \frac{L_0/2}{Q \cdot \text{fractional bandwidth}}\right) \tag{13.7}$$

where L_0 represents the inductor value in the normalized lowpass prototype filter. For our five-section filter we can take L_0 to be about 1.5 henrys. If the inductor Q is 500, the predicted transmission of the five-section filter is $5 \times 10 \log[1-(1.5\ /2)/(500\cdot(1/100))] = -10$ dB, which is roughly equal to the actual value of −7 dB.

13.6 Tuning procedures

Filters with small fractional bandwidths and sharp skirts are extremely sensitive to component values. In the filter of Figure 13.16, for example, the resonators must be tuned very precisely or the shape will be distorted and the overall transmission will be lowered. (The values of the small coupling capacitors – all that remains of the impedance inverters – are not as critical.) Usually each resonator is adjustable by means of a variable capacitor or variable inductor. All the adjustments interact and, if the filter is totally out of tune, it may be hard to detect any transmission at all. A standard tuning procedure is to monitor the input impedance of the filter while tuning the resonators, one-by-one, beginning at input end. While resonator N is being adjusted, resonator N+1 is short circuited. The tuning of one resonator is done to produce a maximum input impedance while the tuning of the next is done to produce a minimum input impedance. The procedure must sometimes be customized to account for matching sections at the ends.

13.7 Other filter types

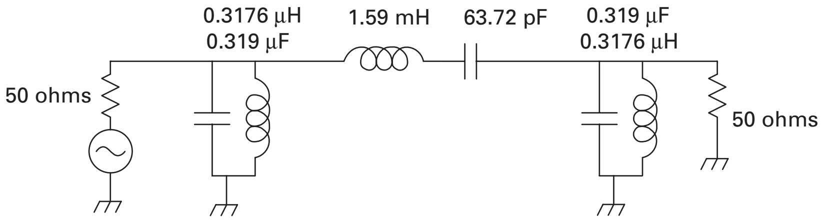
The coupled-resonator technique is used from HF through microwaves. Not all RF bandpass filters, however, use the coupled-resonator technique. The IF bandpass shape in television receivers is usually determined by a SAW (surface acoustic wave) bandpass filter. SAW filters are FIR (finite impulse response) filters, whereas all the *LC* filters we have discussed are IIR (infinite impulse response) networks. This classification is made according to the behavior of the output voltage following a delta function (infinitely sharp impulse) excitation. Digital filters can be designed to be either FIR or IIR filters.

Problems

Problem 13.1. Use your network analysis program to verify that the filter of Figure 13.16 does indeed give the response shown in Figure 13.17.

Problem 13.2. Verify that the two *LC* circuits in Figure 13.3 are impedance inverters.

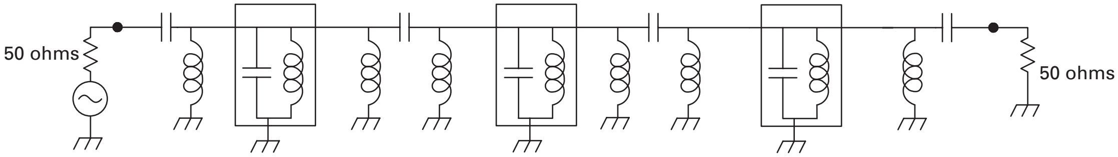
Problem 13.3. The filter shown below was developed in Chapter 4 as an example of the straightforward conversion from a prototype lowpass filter to a bandpass filter. This Butterworth (maximally flat) filter has a bandwidth of 10 kHz and a center frequency of 500 kHz. Suppose you have available some 30 μH inductors with a *Q* of 100 at 500 kHz. Convert the filter into a coupled-resonator filter that uses these inductors. Use your ladder network analysis program to verify the performance of your filter.



Problem 13.4. A bandpass filter is to have the following specifications:

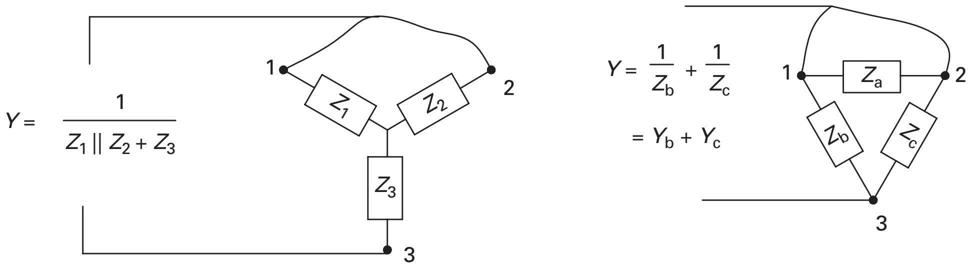
Center frequency: 10 MHz; shape: three-section 1-dB Chebyshev; bandwidth: 3 KHz (between outermost 1-dB points); source and load Impedances: 50 ohms. Since the loaded *Q* of this filter is very high, $10^6/3000 = 333$, it is important to use very high-*Q* resonators. Suppose you have located some resonators (cavities, crystals, or whatever) with adequate *Q*. These resonators are all identical. At 10 MHz they exhibit a parallel resonance, equivalent to a parallel *LC* circuit. At 10 MHz, they have a susceptance slope of 10^{-6} (1 mho/MHz).

(a) Find the *LC* equivalent circuit for these resonators (in the vicinity of 10 MHz).
(b) Design the filter shown below around these resonators.
(c) Use your ladder network analysis program to verify the frequency response of your design.



Problem 13.5. Derive expressions for Z_a, Z_b, and Z_c in terms of Z_1, Z_2, and Z_3 for the equivalent *T* and *π* networks shown in Figure 13.19. Hint: consider the connections

shown below. The sketched-in wires show that $Y_A + Y_B = (Z_3 + Z_1 \| Z_2)^{-1}$. If you write the corresponding $Y_B + Y_C$ and $Y_C + Y_A$ equations, then add the first two and subtract the third, you will have the formula for Y_B. A similar technique yields the expressions for Z_1, Z_2, and Z_3.



$Y = \dfrac{1}{Z_1 \| Z_2 + Z_3}$

Problem 13.6. The bridge circuit shown below in (a) is the simplest network whose resistance cannot be found immediately by series and parallel reduction. Rather than resorting to loop or node equations, note that the circuit contains two πs and two Ts. Replace a π by its equivalent T or a T by its equivalent π. Now find the resistance of the network by simple reduction. The circuit at the right shows how one of the π's can be replaced by a T.

CHAPTER

14 Transformers and baluns

Transformers are harder to understand than resistors, capacitors, and single inductors. First, transformers have two terminal pairs rather than one, so we must deal with two voltages and two currents. Second, we can be misled by the deceptive simplicity of the simplest mathematical model, the "ideal transformer." In this chapter we discuss the conventional transformers used in power supplies, switching power supplies, amplifiers, and RF matching networks. We will then examine transmission line transformers, which work to higher frequencies, and *baluns*, which are devices used to connect *bal*anced circuits to *un*balanced circuits.

Figure 14.1(a) shows two inductors (here, wire coils) with arbitrary placement. The region does not have to be otherwise empty; it can contain any distribution of clumped and/or continuous magnetic materials.

The inductance values ("self-inductances") of these coils are L_1 and L_2, each measured with the other coil open circuited, so that it carries no current. We will refer to these coils as L_1 and L_2. Two representative magnetic flux lines are shown, corresponding to a current in L_1. Note that one of these flux lines is encircled by three turns of L_2. Therefore, when L_1 carries an ac current, by Faraday's law there will be an ac voltage induced in L_2, proportional to the time derivative of the encircled magnetic flux. We can write Faraday's law for this situation as

$$V_2 = \mathrm{j}\omega t M I_1 + \mathrm{j}\omega t L_2 I_2, \tag{14.1}$$

where the constant M is known as the "mutual inductance." The jω factor represents the time derivative since we are using standard ac circuit analysis, where the time dependence is contained in an implicit factor $\mathrm{e}^{\mathrm{j}\omega t}$. The second term, containing the self-inductance, L_2, is a voltage induced by the current, if any, flowing in L_2 itself. Note that we have assumed that the wires have negligible resistance – no IR voltage drop.[1] The directions of the currents are

---

[1] To take account of the winding resistances, we would add a term I_2R_2 to the right-hand side of Equation (14.1) and a term I_1R_1 to the right-hand side of Equation (14.2). The effect of the resistance distributed in the windings is the same as if the resistance were consolidated into two external resistors, R_1 and R_2, in series with the windings.

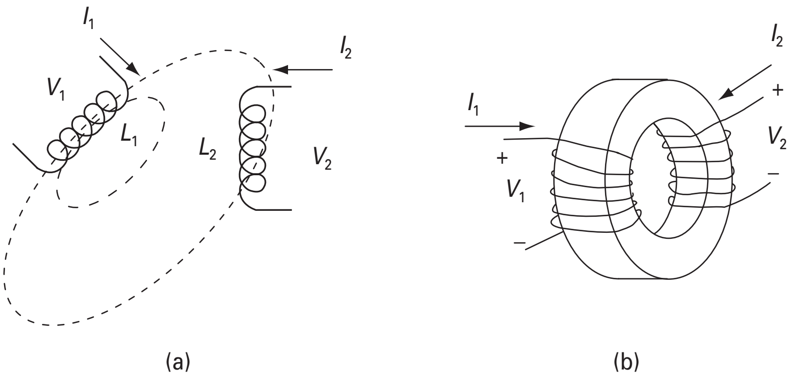

Figure 14.1. (a) Coupled inductors; (b) prototype transformer.

defined by arrows in Figure 14.1 as entering the positive end of each coil. This symmetric assignment produces a symmetric equation for V_1:

$$V_1 = \mathrm{j}\omega t L_1 I_1 + \mathrm{j}\omega t M I_2. \tag{14.2}$$

Note that both equations contain the same constant M. There is no need to write M_{12} and M_{21}, since the mutual inductances are always equal. This can be seen quite easily for the arrangement of coupled coils shown in Figure 14.1(b). This a conventional transformer, in which a toroid of iron or other magnetic material effectively contains all the field lines, forcing them to thread through every turn of both L_1 and L_2. An ac current in L_1 produces a flux proportional to N_1, the number of turns in L_1. The ac voltage induced in L_2 is proportional to N_2 times the flux. Hence M_{21} is proportional to the product N_1N_2. Likewise the ac current in L_2 produces an ac voltage in L_1 with the same proportionality to N_1N_2, so M_{12} and M_{21} are equal.[2]

If all the flux lines thread both windings, the transformer is said to be *perfectly coupled*. A *coupling coefficient*, k, is defined by $M = k(L_1\ L_2)^{1/2}$. The value of k ranges from zero, for inductors with no coupling, to unity, for perfect coupling. In the transformer of Figure 14.1(b), perfect coupling is approached by using a core material of extreme magnetic permeability. For such a transformer, it makes no difference whether the windings are side-by-side, as shown, or wound one on top of the other. Nor is it necessary that they be wound tightly around the core; loose windings can be used to allow circulation in an oil-cooled power transformer.

14.1 The "ideal transformer"

If a transformer is perfectly coupled and the windings have negligible resistance, then the ratio of primary-to-secondary[3] voltages is equal to the turns ratio and these voltages have the same phase. This strict proportionality of voltages follows directly from Faraday's law, since the time derivative of the magnetic flux is equal in both windings. The situation with the currents is not as simple. The primary and secondary currents are not strictly proportional. This follows from the transformer's ability to store magnetic energy. If the transformer could *not* store energy, the instantaneous net power into the transformer would have to be zero. The proportionality of primary and secondary voltages would demand that the currents be proportional, i.e., setting $V_pI_p = V_sI_s$, we would have $I_s/I_p = V_p/V_s = \text{constant} = n_P/n_S$, the effective turns ratio. This hypothetical transformer, which stores no energy, is known as the *ideal transformer* and is a useful abstraction. We will discuss below a circuit with two inductors and an ideal transformer which together, are equivalent to a real transformer. But first let us emphasize how the ideal transformer, by itself, is an unrealistic model.

---

[2] The equality of M_{12} and M_{21} is a general reciprocity relation that holds true for any passive two-port network, e.g., any network made from resistors, capacitors, inductors, and transformers.

[3] The names "primary" and "secondary" are arbitrary and refer only to the way the transformer is used; power usually flows into the primary and out of the secondary.

Consider an ideal transformer with an effective turns ratio n_1/n_2. If an impedance Z_{load} is connected to the secondary, the ratio of primary voltage to primary current will be $(n_1/n_2)\ V_2/[(n_2/n_1)I_s] = (n_1/n_2)^2\ V_s/I_s = (n_1/n_2)^2Z_{\text{load}}$ times the secondary current. The primary will therefore present an impedance of $(n_1/n_2)^2Z_{\text{load}}$, a simple impedance multiplication. If Z_{load} is infinite (an open circuit), the impedance looking into the primary of the ideal transformer is also infinite. But inspection of Equation (14.2) shows that, in this case, the impedance looking into a real transformer is $j\omega L_1$. Another "unreal" feature of an ideal transformer is that it contains no magnetic field! The field (or flux) from the primary winding is exactly cancelled by the field from the secondary winding. And with no magnetic field there would be no $d\Phi/dt$ and therefore no voltage across either winding. A real transformer approaches the ideal transformer model only when the number of turns approaches infinity and the magnetic coupling approaches 100%. Transformers used in practice are usually far from ideal. This is in contrast to resistors and capacitors which, at least at low frequencies, are almost ideal components obeying the relations $Z_R = R$, $Z_C = 1/j\omega C$, and $Z_L = j\omega L$.

14.2 Transformer equivalent circuit

An equivalent circuit for a real transformer is shown in Figure 14.2(b).

This model circuit consists of two inductors plus an ideal transformer having an equivalent turns ratio n_1/n_2. The shunt inductor at the left is known as the *magnetizing inductance* and its value is L_1, the inductance of the primary. Note that, even if the secondary is left open, a voltage V applied to the primary will produce a primary current $I = V/(j\omega L_1)$. The series inductor at the right is known as the *leakage inductance*. Its value is $L_2\ (1-\ k^2)$, so a perfectly coupled transformer ($k = 1$) has no leakage inductance. In practice, maximum coupling is limited to maybe 98% at low frequencies and less at RF frequencies. The useful frequency range of a transformer is determined by these two inductances. Suppose we put a transformer between a resistive load and a signal generator.

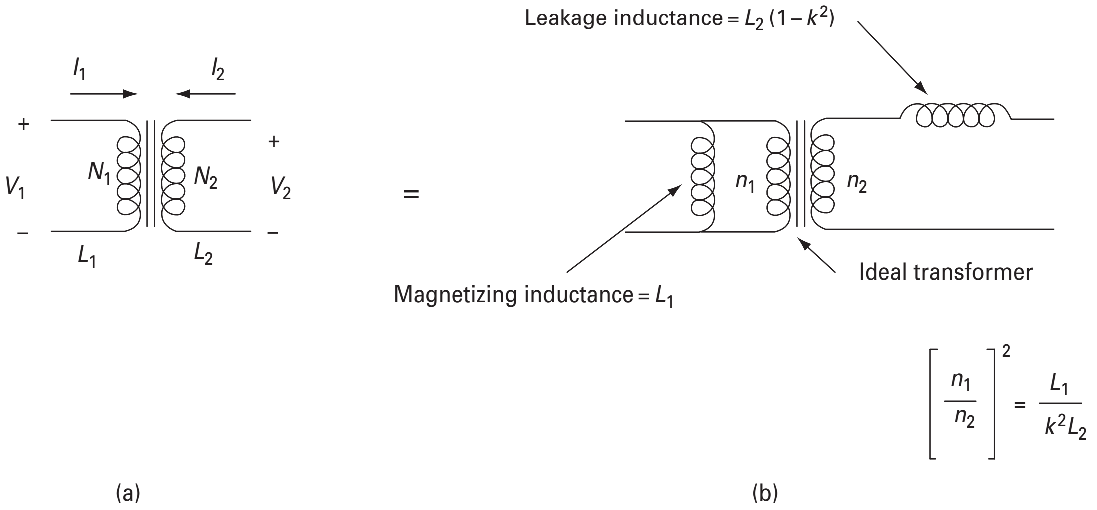

Figure 14.2. (a.) Transformer symbol with voltage and current assignments; (b.) an equivalent circuit.

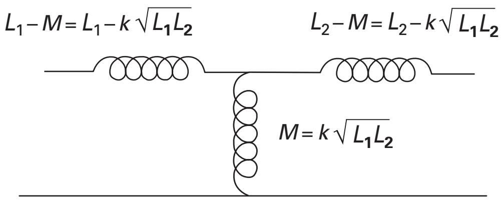
Below the useful frequency range, the magnetizing inductance becomes a short circuit across the generator. Above the useful range, the leakage inductance becomes a high impedance in series with the load. In both extremes, the power delivered to the load becomes negligible.

Let us demonstrate that the model circuit of Figure 14.2(b) does, indeed, agree with the fundamental equations (14.1) and (14.2), i.e., that it really is an equivalent circuit. We have already seen that the value of the magnetizing inductance must be L_1, the inductance value of the primary winding. Leaving the secondary open, so that $I_2 = 0$, the fundamental equations (14.1) and (14.2) produce the relation $V_2/V_1 = M/L_1 = k\sqrt{L_1 L_2}/L_1 = k\sqrt{L_2/L_1}$. In this situation, the model circuit gives $V_2/V_1 = n_2/n_1$. For the model to agree with the fundamental equations, $n_2/n_1 = k\sqrt{L_2/L_1}$. Finally, consider the situation in which the primary is shorted, so that $V_1 = 0$. The secondary current given by Equations (14.1) and (14.2) must be the same as the current predicted by the model. Equation (14.1) produces $I_1 = -I_2 M/L_1$. Putting this into Equation (14.2) gives $V_2/I_2 = \mathrm{j}\omega\ (L_2/M - M^2\ /L_1) = \mathrm{j}\omega L_2(1-k^2)$. Looking at the model, the impedance at the secondary, with the primary shorted, is just $\mathrm{j}\omega$ time the leakage inductance, so the leakage inductance must be assigned the value $L_2(1- k^2)$. With these assignments for the values of the magnetization and leakage inductances, the model correctly reproduces Equations (14.1) and (14.2).

This is not the only possible equivalent circuit. We could just as well have constructed this equivalent circuit with the magnetizing inductance on the right side and the leakage inductance on the left side. Or we could "push" either the magnetizing inductance or the leakage inductance through the transformer, correcting the inductance by a factor $(n_1/n_2)^2$ or $(n_2/n_1)^2$, so that they are both on the same side. Another equivalent circuit, is shown in Figure 14.3. Using arguments like those presented above, you can show that this circuit also



$L_1 - M = L_1 - k\sqrt{L_1L_2}$
$L_2 - M = L_2 - k\sqrt{L_1L_2}$
$M = k\sqrt{L_1L_2}$

Figure 14.3. An all-inductor equivalent circuit.

satisfies Equations (14.1) and (14.2). This circuit contains no unphysical ideal transformer (and therefore has no dc isolation between primary and secondary, making it not quite as equivalent). But you can see from the labels in the figure that, in general, one of the inductors must have an unphysical negative inductance. However, note that if $k < L_1/L_2$ and $k < L_2/L_1$ all the inductors are positive. As the turns ratio becomes close to unity, the inductors all remain positive as the coupling is increased. In the case of a 1:1 transformer with perfect coupling, the values of the series inductors go to zero and the equivalent circuit is just a single shunt inductor, the magnetizing inductance. (You could put a 1:1 ideal transformer on each side of this inductor to produce a symmetric equivalent circuit that preserves dc isolation.) And, of course, the circuit of Figure 14.3 could be converted from the T configuration to an equivalent pi configuration.

To approach the ideal, a transformer must have a very high magnetizing inductance and a very small leakage inductance. You can increase the magnetizing inductance by increasing the number of turns (keeping the turns ratio constant) but, in practice, this only increases the leakage inductance and the ohmic resistance of the windings. You can decrease the leakage inductance by using fewer turns, but this lowers the magnetizing inductance. A compromise is generally needed. However, we will see that there are applications in which the leakage and/or magnetizing inductances become useful circuit components.

14.3 Power transformer operation

Power transformers are usually iron-core transformers with high coupling. The best power transformer would be an ideal transformer; its stored energy, excitation current and leakage inductance would all be negligibly small. The primary is connected to the ac line, which can be regarded as a perfect voltage source with negligible source impedance. If the coupling is high enough to make the leakage inductance negligible and the winding resistances are low, the secondary voltage will be constant, $V_2 = (n_2/n_1)V_1$, independent of the load. The magnetizing inductance will draw a constant "magnetizing" current from the line, $I_M = V/(j\omega L_1)$. Since this current is 90° out of phase with respect to the primary voltage, it consumes no average power, but does cause "excitation" energy to slosh in and out of the transformer. When a resistive load is connected to the secondary, additional "working" currents flow in both the primary and the secondary. These currents have the ratio n_2/n_1. They are in phase with the primary voltage and transfer power from the source to the load. Sometimes a capacitor is placed across the primary to resonate with the magnetizing inductance. The excitation energy will then slosh back and forth between the capacitor and the magnetizing inductance. This corrects the power factor; the power line now only has to supply the component of current that is in phase with the voltage. In practice, the magnetizing current may be comparable to the maximum working current. In a power transformer, the magnetic core is used close to saturation. When the magnetizing current is at its maximum, the inductance of the core is reduced. This nonlinear behavior of the core distorts the otherwise sinusoidal waveform of the magnetizing current. Nevertheless, the voltages on the primary and secondary remain proportional and sinusoidal, because of the low source impedance of the power line, low *IR* drops in the windings, and negligible leakage inductance.

14.4 Mechanical analogue of a perfectly coupled transformer

A transformer transfers ac power, usually with a step-up or step-down in voltage. Figure 14.4 shows how a lever could be used to step down the velocity of a sinusoidally reciprocating arm. The resistive load on the right-hand side is a dashpot (damper), which produces a reaction force proportional to velocity. A voltage step-down transformer increases current. This lever steps down velocity (and amplitude) and provides increased force. For an ideal transformer (infinite magnetizing inductance) or an ideal lever (zero mass) the input power (primary voltage times primary current or primary velocity times primary force) is equal to the output power at every instant. But, for a real transformer with finite magnetizing inductance, there is also the "excitation" current, lagging the voltage by 90°, pumping energy in and out of the core. Likewise, for a real lever, with nonzero mass, there is an additional component of input force, leading the velocity by 90°, that pumps mechanical kinetic energy in and out of the lever. For both the transformer and the lever the average reactive power is zero but the excitation current or force can be considerable.

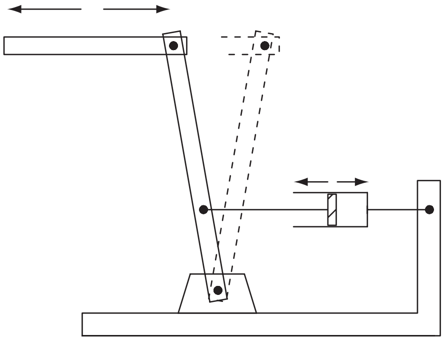


Figure 14.4. Mechanical analogue of a transformer.

14.5 Magnetizing inductance used in a transformer-coupled amplifier

In Chapter 3 we saw a circuit whose operation cannot be explained if its transformer is modeled as an ideal transformer. That circuit, a transformer-coupled class-A amplifier, is shown in Figure 14.5. Since the transformer windings have almost no dc resistance, the average voltage at the collector must be V_{cc}. Under maximum signal conditions the collector voltage swings between 0 and $2V_{dc}$, applying a peak-to-peak voltage of $2V_{dc}$ to the transformer primary.

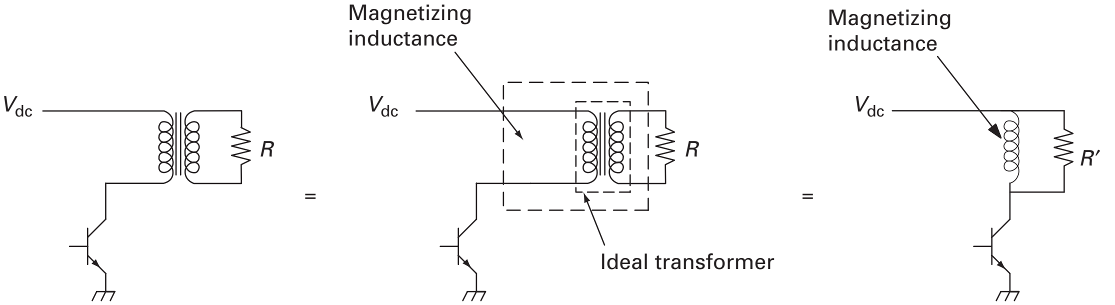

Figure 14.5. Transformer-coupled amplifier.

If we do not include the magnetizing inductance, the transformed load is a pure resistance. We would mistakenly conclude that the quiescent collector voltage must be $V_{cc}/2$ rather than V_{cc} and that the largest peak-to-peak collector signal would be V_{cc} rather than $2V_{cc}$. We would also conclude incorrectly that the frequency response would be unlimited, rather than being limited at low frequencies by the magnetizing inductance and limited at high frequencies by leakage inductance.

14.6 Double-tuned transformer: making use of magnetization and leakage inductances

Leakage inductance and magnetizing inductance limit the performance of transformers used in audio and other baseband applications. But in RF work these parasitic inductances can be tuned out with capacitors. Sometimes the leakage and magnetizing inductance can be intentionally used as in the band-pass filter of Figure 14.6(a).

To see how this circuit works, consider Figure 14.6(b), where the transformer has been replaced by its equivalent circuit. Only the leakage and magnetizing inductances are shown; the ideal transformer in the equivalent circuit of the transformer is either one-to-one or the resistor and capacitor on the right-hand side have been multiplied by its ratio. This equivalent circuit, with its vertical

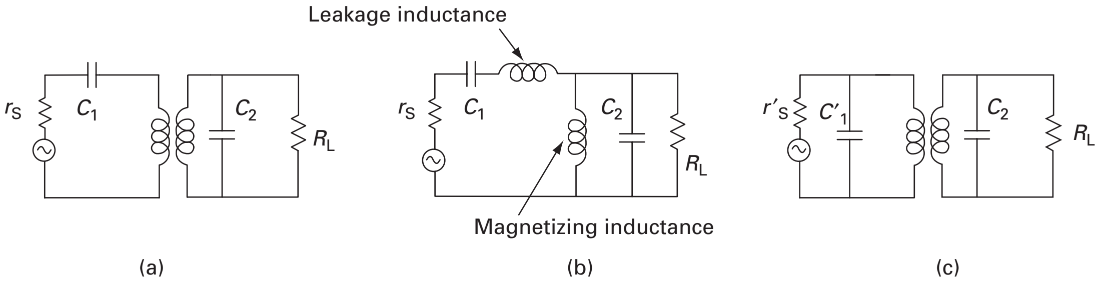

Figure 14.6. (a) Bandpass filter made with a loosely-coupled transformer; (b) equivalent circuit; (c) alternate circuit with two shunt capacitors.

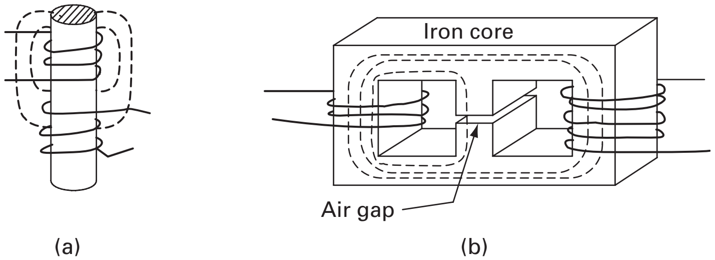

Figure 14.7. Loosely coupled transformers: (a) with powdered iron core; (b) with iron core for low frequencies.

parallel resonator and its horizontal series resonator, is a canonical two-section bandpass filter, as discussed in Chapter 4. The transformer, to have enough intentional leakage inductance, may be air-wound or may be wound on a permeable rod as shown in Figure 14.7(a). The alternate circuit of Figure 14.6(c) uses a parallel capacitor on each side of the transformer. The values of r'_S and C'_1 can be determined from the values of r_S and C_1 by noting that the equivalent Thévenin generator containing r'_S and C'_1 must have an impedance equal to the impedance of $r_S + jC_1$. (Note: whenever you see capacitors across both windings of a transformer, you can guess that the coupling is less than unity – otherwise the two capacitors would be effectively in parallel, and a single capacitor could be used.)

Power transformers are sometimes designed to have intentional leakage inductance to provide short-circuit protection (the leakage inductance limits the current). One way to build an iron core transformer with leakage inductance is shown in Figure 14.7(b). The magnetic path containing the air gap effectively shunts some of the flux generated by one winding from reaching the other winding. This design also provides magnetic shielding, in that the fringing fields are contained within the body of the transformer.

14.7 Loss in transformers

Large power distribution transformers are designed to have efficiencies around 99%. Inexpensive transformers are designed with enough efficiency to avoid premature burn-out. (Plug-in “wall-wart” transformers can be hot to the touch even without a load.) High-frequency transformers have efficiency limits set by core materials and the “skin effect” that excludes high-frequency currents from the interior of conductors, thus increasing the effective resistance of the windings.

Resistance of the windings (“copper loss”) is an obvious loss mechanism. We have seen that this can be included easily in a transformer equivalent circuit by simply putting a resistor in series with the primary and another in series with the secondary.

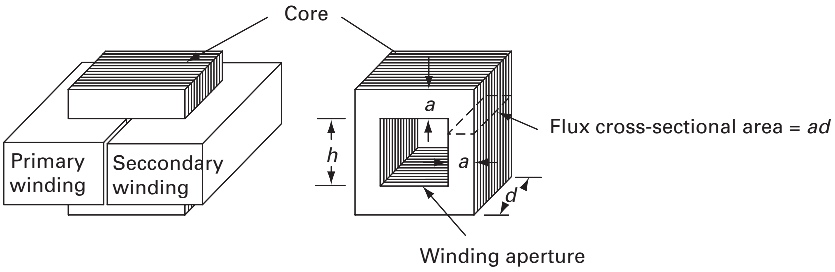
A magnetic core made of a conductive material such as iron will dissipate energy as ordinary I^2R loss since closed paths in the iron core will act as shorted turns around magnetic flux lines. To minimize these *eddy current* losses, any such closed paths are kept short by making the core a stack of thin sheet iron laminations separated by insulating varnish or oxide. The core of a toroidal transformer can be a bundle of insulated iron wire rings, a stack of varnished sheet metal toroids, or a toroid wound of varnished thin metal tape. High-frequency transformers use cores made of magnetic particles, held together in an inert binder material. Eddy current losses can be included in the transformer equivalent circuit as a resistor in parallel with the ideal transformer.

The final loss mechanism comes from magnetic hysteresis in the core. Ideally, the magnetic flux density is proportional to the magnetic force, $B = \mu H$, where μ is the permeability. But B often lags H, as magnetic domains exhibit a kind of static friction before they break loose and reverse their direction. As a result, B vs. H through the ac cycle forms a closed curve whose included area is the energy loss per unit volume per cycle. Hysteresis loss is associated with the magnetizing current, since it is the magnetizing current that produces H, which induces B. We can therefore include hysteresis loss in the equivalent circuit as a resistor in parallel with the magnetizing inductance. This is satisfactory for a power transformer, where the magnetizing current is constant and the frequency is constant. But note that the hysteresis loss is proportional to frequency, since the B-H loop is traversed once per cycle. It also has a nonlinear amplitude dependence. Thus a simple resistor is not adequate to model hysteresis loss in a wideband transformer or a transformer operating over a range of input voltages.

14.8 Design of iron-core transformers

A transformer designer usually strives to find the smallest, lightest, and least expensive (usually synonymous) transformer that conforms to a set of electrical specifications. To see the issues involved, let us consider the design of a 60-Hz

Figure 14.8. Iron-core transformer geometry.



power transformer. Suppose the primary voltage is 220 volts rms and the power delivered to the load is 500 watts. The efficiency is to be 96% and the magnetizing current must be no greater than the "working" (in-phase) current.

We will pick a silicon-steel core material for which the maximum flux density before saturation, $B_{\max}$, is 1.5 webers/m^2. The core, a square toroid, is shown in Figure 14.8. For minimum copper loss (neglecting the excitation current) the primary and secondary windings will have equal loss and will each occupy half of the winding aperture.

The transformer will be specified by four parameters: the number of turns on the primary, N, and the three linear dimensions of the core, a, h, and d. To determine these four parameters we must write equations for the maximum B field, the loss, and the inductance of the primary winding. Faraday's law of induction gives us the maximum B field:

$$V_{\max} = N\frac{\mathrm{d}\phi}{\mathrm{d}t} = N\omega a d B_{\max}. \tag{14.3}$$

Since the rms primary voltage is 220, $V_{\max} = 220\sqrt{2}$ and we have

$$B_{\max} = \frac{220\sqrt{2}}{\omega N a d} < 1.5\,\text{webers/m}^2. \tag{14.4}$$

The copper loss in the primary winding will be I^2R_{p} where I is the rms current in the primary and R_{p} is the resistance of the winding. The number of turns on the primary, N, is given by

$$N = \frac{(h^2/2)}{\sigma} \tag{14.5}$$

where $h^2/2$ is the winding area for the primary and σ is the cross-sectional area of the wire. The mean length per turn is given by $2(a+d+h)$ so the primary resistance is found to be

$$R_{\mathrm{p}} = \rho\frac{\text{length}}{\sigma} = \frac{4\rho N^2(a+d+h)}{h^2}. \tag{14.6}$$

As for core losses, the 60-Hz loss for the selected core material (when $B_{\max}$= 1.5) is 0.6 watts/lb = 11 000 watts/m^3. The overall loss is the sum of the winding losses and the core loss. Since this loss is to be 500(1−0.96) = 20 watts, we can write

$$\text{Loss}_{\text{watts}} = 11\,000(4ad(a+h)) + \left(\frac{500}{220}\right)^2 \frac{4\rho N^2(a+d+h)}{h^2} = 20. \quad (14.7)$$

Finally, the specification on the magnetizing current is equivalent to specifying that the reactance of the primary, ωL, is greater than the equivalent input load resistance, or

$$\omega L \geq \frac{220^2}{500}. \quad (14.8)$$

The inductance of the primary, L, can be written as

$$L = \frac{\mu N^2(\text{flux area})}{\text{mean flux path length}}. \quad (14.9)$$

The mean flux path length, from Figure 14.8, is $4(h+a)$, so

$$L = \frac{\mu N^2 ad}{4(h+a)}. \quad (14.10)$$

We must use Equations 14.4, 14.7, and 14.8 to find transformer parameters, a, d, h, and N that will satisfy the given specifications and minimize the size of the transformer. This is not quite as simple as solving four equations in four unknowns. The equations are really inequalities and, in general, there will not be a solution that simultaneously produces the maximum allowable flux density, the maximum allowable loss, and the minimum allowable inductance. Instead, this problem in linear programming is most often solved by cut-and-try iterative methods, conveniently done using a spreadsheet program. In this particular example, such a procedure led to the set of parameters: $d = 5$ cm, $a = 2$ cm, $h = 5$ cm and $N = 580$ turns. These dimensions give a core weight of 5.1 lbs, a loss of 19.3 watts and B_{max} of 1.42. The reactance of the primary, assuming a relative permeability of 1000, is 5.9 times the input load resistance – five times more than the minimum required reactance. Note: in the equations presented above, no consideration was made for the space occupied by wire insulation and lamination stacking but these can be accounted for by simply increasing the value of the winding wire resistivity, ρ, and decreasing the permeability.

14.8.1 Maximum temperature and transformer size

The heat generated by a transformer makes its way to the outside surface to be radiated or conducted away. The interior temperature buildup must not damage the insulation or reach the Curie temperature where the ferromagnetism quits (a consideration with high-frequency ferrite cores). “Class-A” insulation materials

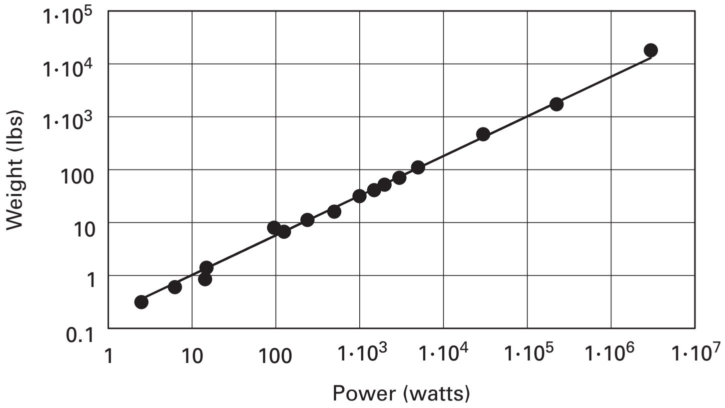


Figure 14.9. Weight vs. power rating for 16 commercial 60-Hz power transformers. The data points fit the solid line, for which (weight in lbs) = 0.18 (power in watts)$^{3/4}$.

(cotton, silk, paper, phenolics, varnishes) are limited to a maximum temperature of 105 °C. If reliable theoretical or empirically determined equations are available to predict internal temperatures, they can be included in the iterative design procedure described above. Rules of thumb can be used, at least as a starting point to determine core sizes for conventional transformers. One such rule for transformers up to, say, 1 kW is that the flux cross-sectional area of the core ($a \times d$ in Figure 14.8) in square inches should be about $0.25\sqrt{\text{Power in watts}}$. Transformer weight vs. power rating (from catalog specifications) is plotted in Figure 14.9 for sixteen 60-Hz power transformers, ranging from 2.5 watts to 3 megawatts.

The solid line, which fits the data, shows that the weight is proportional to the power raised to the exponent 3/4. Transformer manufacturers seem to use the rule-of-thumb that makes core area proportional to power$^{1/2}$ since this results in the volume and weight being proportional to power$^{3/4}$.

14.9 Transmission line transformers

Leakage inductance and distributed capacitance eventually determine the high-frequency limit of conventional transformers. For wideband applications we cannot simply resonate away these parasitics. Wideband *transmission line transformers* [3] are built like ordinary core-type transformers except that the windings are made with transmission line – either a coaxial cable, as shown in Figure 14.10, or a bifilar winding. The core must have high permeability but modest loss is acceptable (cores in chokes and transformers store little energy so high Q is not necessary). The effect of the core is to choke off any common-mode current in the transmission line, leaving only differential currents. When the transformer is wound with a piece of coaxial cable, as shown in Figure 14.10, the core suppresses current flowing on the outside of the shield,

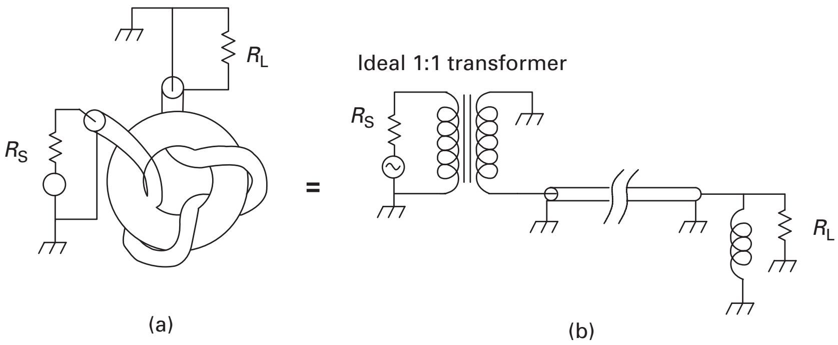

Figure 14.10. Transmission line reversing transformer.

leaving only the equal and opposite currents on the inside of the shield and the inner conductor.

This circuit is a reversing transformer, i.e., $V_{\text{out}} = -V_{\text{in}}$. The polarity flip is achieved by reversing the transmission line connections at the load end where the center conductor is grounded. Normally this would simply short the generator, but the inductance provided by the magnetic core chokes off the otherwise short-circuit current. An equivalent circuit model is shown in (b). Here the reversal is done with an ideal transformer. The length of the coax is the same, to duplicate the additional phase shift between the generator and the load. The inductor in parallel with the load represents the inductance of the cable winding around the core. At the lowest frequencies, this inductor diverts current from the load, just as the magnetization inductance limits the low-frequency response of a conventional transformer. At high frequencies, however, the circuit becomes just a piece of transmission line and its response does not fall off. There is effectively no leakage inductance nor stray capacitances. The time lag through the transmission line, however, will shift the phase from the nominal 180° as the frequency increases. Nevertheless, if an application calls for a pair of signals, identical except for polarity, the "reference" signal can be provided by using an identical piece of transmission line to provide an identical delay.

Transmission line transformers extend the range of ordinary transformers by two octaves or more. In addition to this reversing transformer, many other transformers can be made with the transmission line technique [3, 4]. Commercial hybrids good from 0.1 MHz to 1000 MHz use transmission line transformers. Miniature transmission line transformers are commercially available as standard components.

14.10 Baluns

A balun is any device that converts a *bal*anced (double-ended symmetric) signal into an *un*balanced (single-ended) signal. Baluns are commonly used to feed

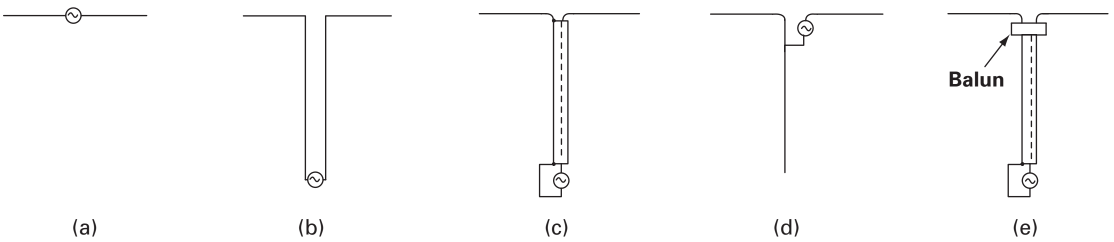

Figure 14.11. A symmetric dipole antenna fed (a) at the antenna feed point, (b) with a balanced feedline, (c) with an unbalanced coaxial feedline, (d) equivalent circuit for (c) showing how the antenna is modified by current on the feedline, (e) Balun provides symmetric feed.

symmetric antennas (e.g., dipoles) from unbalanced coaxial feed lines. Figure 14.11 shows what happens if we feed a dipole directly with a coaxial transmission line. In (a), the generator is at the feed point of the dipole so there is no question of balance or imbalance. In (b), a balanced feedline is used. Everything is still symmetric. At any point along the feedline, the current in one side is equal and opposite to the current in the other side. The spacing between the conductors is very small compared to the wavelength, so “cancellation” assures there is negligible radiation from the line. In (c) a coaxial line feeds the dipole improperly; the shield of the coax tied to the left-hand element of the dipole. An equivalent circuit (d) shows how the outer conductor of the coax becomes part of the left-hand dipole element. The antenna now has one straight element and one L-shaped element. The radiation pattern will not be the intended dipole pattern and there will be RF current flowing on the outside of the feedline. In (e) a balun at the end of the coaxial feedline provides equal and opposite voltages to each side of the dipole and eliminates any current from the outside of the feedline.

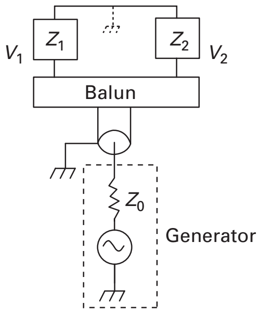

Figure 14.12. Balun operation: unbalanced-to-balanced.

Figure 14.12 illustrates the requirement for a balun; with equal Z_1 and Z_2, i.e., a load structure symmetric with respect to ground, we want V_1 and V_2 to be equal and opposite with respect to ground.

The dotted ground symbol indicates that this point of symmetry will have zero voltage (when $Z_1 = Z_2$) and can be grounded if necessary or desirable. Figure 14.13 shows the equivalent situation with the load at the unbalanced side. When V_1 and V_2 are in phase (common mode) there must be no excitation of Z. But when V_1 and V_2 are 180° apart (differential mode) the load, Z, is fully excited. Baluns are normally reciprocal devices so the name “Unbal” is not needed.

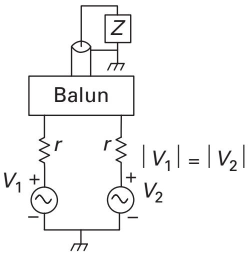

Figure 14.13. Balun operation: balenced-to-unbalanced.

From a transmitting standpoint, the balun eliminates common mode current on the feedline which otherwise would radiate and affect the pattern of the antenna. Figure 14.14(a) shows a reversing transformer used as a balun for this application. Note that this balun is also a 4-to-1 impedance transformer since the voltage across the dipole is $2V$. In Figure 14.14(b), the reversing transformer is replaced by a half-wave length of transmission line. The phase shift through this piece of line transforms V into $-V$ just as the transformer did, but the reversal is only correct over a narrow frequency band. (Note that the half-wave line can have any value for Z_0.)

The simple reversing transformer in Figure 14.14(a) can be replaced by the wideband transmission line transformer of Figure 14.10. The phase shift this transformer picks up at increasing frequencies is compensated by using a

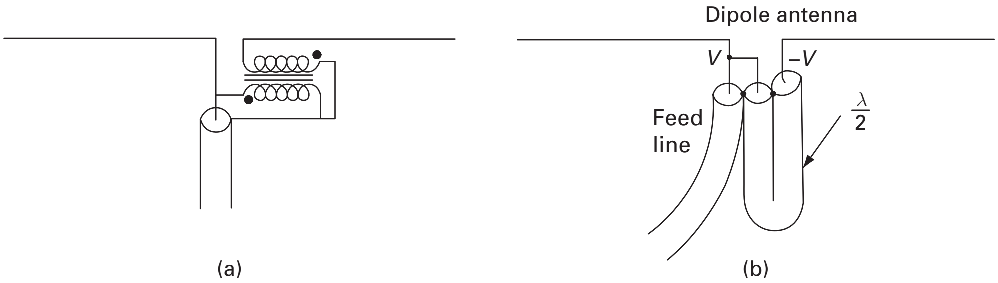

Figure 14.14. 4:1 baluns.

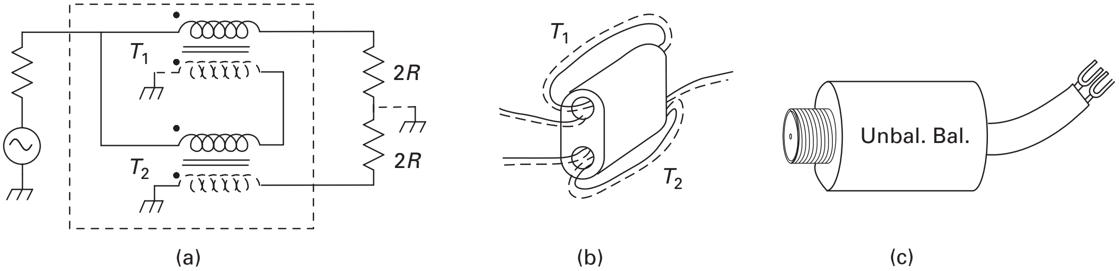

Figure 14.15. Wideband 4:1 balun made from two 1:1 transmission line transformers.

second transformer, identical except with no reversal, to provide an equal frequency-dependent phase shift. The combination of these transformers, connected in parallel at one end and in series at the other end, as shown in Figure 14.15(a), makes a very wideband 4-to-1 balun.

This is the circuit most often found in the television balun of Figure 14.15(c). The transformers are often wound on a “binocular core” (Figure 14.15b). This core operates as two separate cores, i.e., there is nominally no magnetic coupling between the two transformers, T_1 and T_2. For clarity, the figure shows the transformers wound with only two turns; in practice several turns are used.

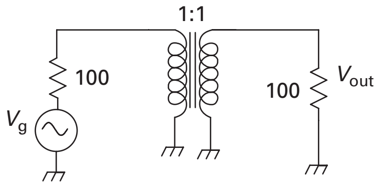
Problems

Problem 14.1. Use Equations (14.1) and (14.2) to show that when the primary and secondary windings of a transformer are connected in series the total inductance is given by $L = L_1 + L_2 \pm 2M$ where M, the mutual inductance, is given by $M = k\sqrt{L_1 L_2}$ and the ± changes when one of the windings is reversed. (This is a standard method for measuring mutual inductance.)

Problem 14.2. Consider the following transformer: $L_1 = 0.81\,\text{H}$ (inductance of the primary winding), $L_2 = 1\,\text{H}$ (inductance of the secondary winding), $k = 0.9$ (coupling coefficient).

(a) If the secondary is open circuited and 1 volt (ac, of course) is applied to primary, show that the secondary voltage is 1 V. (b) If the primary is open circuited and 1 volt is applied to the secondary, show that the primary voltage is 0.81 V.

Problem 14.3. Calculate the low-frequency cutoff (half-power frequency) for a resistive load coupled by a particular transformer to a generator. The transformer has perfect coupling and a 1:1 turns ratio. The source and load impedances are both 100 ohms and the reactance of the transformer primary is 50 ohms at 20 Hz.



Problem 14.4. Upgrade your ladder network analysis program (Problem 1.3) to handle conventional transformers. Let the transformer be specified by its primary inductance, secondary inductance, and coupling coefficient.

Example answer: For the MATLAB example solution given in Problem 1.3, add the element, “XFRMR” by inserting the following sequence of statements in the “elseif chain”:

```
elseif strcmp(component,‘XFRMR’)==1
ckt_index=ckt_index+1; Lpri=ckt{ckt_index}; %primary inductance
ckt_index=ckt_index+1; Lsec=ckt{ckt_index};% secondary inductance
ckt_index=ckt_index+1; k =ckt{ckt_index}; %coupling coefficient
V=V+I*(1j*w*Lsec*(1-k^2));
ratio= sqrt(Lpri/(k^2*Lsec));
V=V*ratio; I=I/ratio;
I=I+V/(1j*w*Lpri);
```

Problem 14.5. A lossless transformer is placed between a 50-ohm signal generator and a 4.5-ohm load. (a) Use your ladder network analysis program (or an equivalent program) to plot the relative power at the load vs. frequency. Use the following parameters: primary inductance=100 μH, secondary inductance=10 μH, coupling coefficient k=0.9. (b) Find the values of a capacitor to be shunted across the primary (i.e., in parallel with the magnetizing inductance) and another capacitor to be placed in series with the secondary (i.e., in series with the leakage inductance) so that the magnetizing and leakage inductances will be cancelled (resonated out) at 0.5 MHz. Plot the resulting frequency response to verify that the transmission is now perfect at 0.5 MHz.

Problem 14.6. When a power transformer is first turned on, i.e., connected to the line, there is sometimes an initial inrush of current strong enough to dim lights on the same circuit and produce an audible “grunt” from the transformer itself. Decide whether this effect is strongest when the circuit is closed at a zero crossing of the line voltage or at a maximum of the line voltage. (This involves the magnetizing inductance of the transformer so simply analyze the transient when an inductor is connected to an ac line.)

Problem 14.7. (a) Suppose you have a power transformer designed to be fed from 220 V, 60 Hz but you want to use it in a country where the power line supplies 220 V, 50 Hz. Why is the transformer likely to overheat when fed with 50 Hz power? Consider the magnetizing current, copper losses, and core losses. (b) Consider the reverse situation. Would there be any mechanism to cause extra power dissipation if a 50 Hz transformer is used on a 60 Hz line?

Problem 14.8. Two identical perfectly coupled 1:1 transformers are connected in series, i.e., the secondary of the first is connected to the secondary. The primary and secondary inductances of each transformer are L. Show that this combination is equivalent to a single transformer and find its magnetizing inductance L'. If you enjoy algebra, assume the transformers are not perfectly coupled and find L' and k'.

Problem 14.9. Consider a lossless transformer with primary and secondary inductances L_1 and L_2. Suppose the coupling coefficient has a value that results in a 1:1 ideal transformer in the transformer's equivalent circuit. Find the values of the magnetizing inductance and the leakage inductance.

Problem 14.10. The transformer in the figure has a turns ratio of 1:1. The primary and secondary inductances are both L. The amplitude of the sine wave from the generator is V_0. Assume the transformer has no leakage inductance. Find an expression for the current in the resistor. Hint: use the equivalent circuit for the transformer: an inductor together with an ideal transformer.

CHAPTER

15

Hybrid couplers

Hybrid couplers, also known as hybrid junctions or simply "hybrids," are lossless passive four-port devices used to make interconnections between circuit elements. Hybrids are used as power dividers ("signal splitters") and combiners. They are also used in mixers and TR (transmit/receive) switches. A useful schematic representation for a hybrid, Figure 15.1, shows the four connection points (ports).

RF hybrids usually have unbalanced ports designed for coaxial transmission lines, so all four ports share a common ground, indicated in Figure 15.1 by a dotted ground symbol (usually not shown). Each port has a characteristic impedance. Most packaged RF hybrids with coaxial ports are made so that the characteristic impedance of all four ports is 50 or 75 ohms. The symbol in Figure 15.1 shows signal flow paths; power incident on Port 1 splits and exits through Ports 2 and 3. If both of these ports are properly terminated there will be no reflections and the impedance seen looking into Port 1 will be equal to the characteristic impedance of that port. In this case no power will reach Port 4 as opposite ports are isolated. But if Port 2 and/or Port 3 are not terminated in their own characteristic impedances, the power exiting these ports will be partially or completely reflected back into the hybrid. The reflection, which depends on the mismatch, is calculated exactly as if the power had exited from a transmission line whose impedance is equal to that of the respective port. Any power reflected back into the hybrid splits and follows the signal paths, just as if it had come from an external source. You can see that, with arbitrary terminations and arbitrary signals, the situation could become complicated. But usually we deal with continuous wave (cw) sinusoidal signals so, rather than analyze multiple reflections in the time domain, we only have to solve for the forward and reverse wave amplitudes on each of the four internal paths. In most applications, things are even simpler; hybrids usually have proper terminations and the signal flows are simple and can be determined by inspection of the signal flow diagram.

15.1 Directional coupling

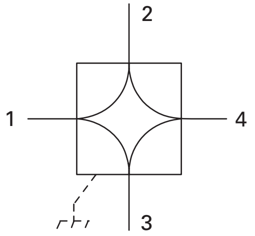

Figure 15.1. Schematic symbol for a hybrid coupler.

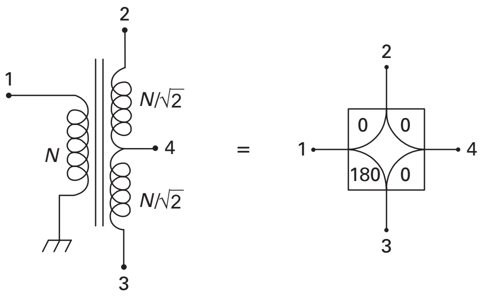
From inspection of the signal paths in Figure 15.1, we see that with the ports matched and with power flowing from Port 1 to Port 2 there will also be power flowing out of Port 3 but none out of Port 4. If the power is now reversed, to flow from Port 2 to Port 1, there will be power flowing out of Port 4 but none from Port 3. Port 3 is therefore coupled to power flowing from 1 to 2. Likewise, Port 4 is coupled to power flowing from 2 to 1. Therefore, a hybrid is a *directional coupler*, and can be used to determine how much power is flowing in each direction on a transmission line. Here we will use the term *hybrid* only for 3-dB directional couplers, i.e., directional couplers that split the incident power in half.

15.2 Transformer hybrid

The name *hybrid transformer* was first applied around 1920[1] to the simple center-tapped transformer shown in Figure 15.2. The primary winding has N turns while each half of the secondary winding has $N/\sqrt{2}$ turns. For this transformer hybrid (hybrid composed of a transformer), the characteristic impedances of Ports 1, 2, and 3 are equal and are twice the impedance of Port 4. (Here the port impedances are R, R, R, and $R/2$, where the value of R is arbitrary, as long as the transformer behaves as an ideal transformer, i.e., its magnetizing inductance has a reactance substantially larger than R.)

Let us confirm that this circuit has the power splitting and isolation characteristics of a hybrid. First consider a signal connected to Port 1. If Ports 2 and 3 have identical terminations, they will have equal and opposite voltages. The voltage at Port 4, since it is midway between the voltages at Ports 2 and 3, must be zero and Port 4 is indeed isolated from Port 1. Next note that a signal applied to Port 4 will appear unchanged at Ports 2 and 3 but will not appear at Port 1. (The currents to Ports 2 and 3 are in opposite directions so there is no net flux in the transformer to provide a voltage at Port 1 or produce an IX_L drop.) You can verify that Ports 2 and 3 are also isolated from each other (see Problem 15.1). Figure 15.2 also shows the symbol appropriate

Figure 15.2. Transformer hybrid.



---

[1] The origin of the term seems to be lost – a hybrid of what? – but it came from the telephone industry, where the terms *hybrid transformer* and *hybrid coil* were both common.

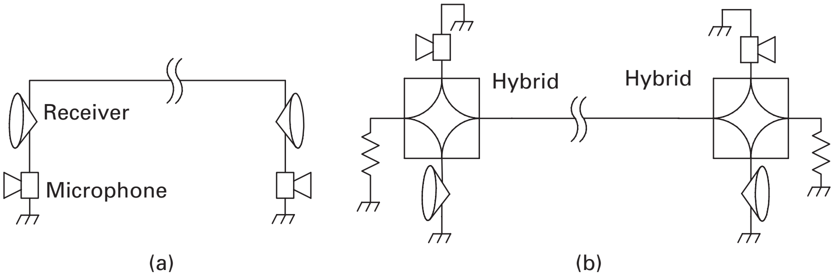


Figure 15.3. Hybrids allow full-duplex communication over a single line.

for this hybrid. The labels 0, 0, 0, and 180 indicate the phase shifts through the respective branches. A signal incident on Port 1, for example, appears at Port 2 with the phase unchanged (shifted 0°) and at Port 3 with its polarity inverted (shifted 180°). Any hybrid with these four phase shifts is called a *180° hybrid*.

15.2.1 Applications of the transformer hybrid

In telephony or other wired communication, hybrids allow a transmission line to carry independent signals in each direction. Figure 15.3 shows two telephone circuits. In the simple series circuit of Figure 15.3(a), each user hears his own voice as well as the voice from the other end. In the circuit of Figure 15.3(b), hybrids isolate each receiver from its own microphone.

If we are using the transformer hybrid of Figure 15.2, we would terminate Port 4 with a resistor of value $Z_0/2$, where Z_0 is the characteristic impedance of the phone line. The microphones and receivers must have impedances equal to Z_0. This arrangement provides two-way signaling , "full duplex," over a single cable.[2]

The circuit of Figure 15.4 uses two hybrids and two amplifiers to make a bidirectional repeater for a long (lossy) line. Here the hybrids let the signals in each direction be independently amplified without feedback and consequent oscillation.

It is convenient to make the characteristic impedances be the same for all four ports of a general-purpose hybrid. The transformer hybrid, fixed up to have equal impedances, is shown in Figure 15.5. This is the kind of circuit found inside an off-the-shelf wideband 3-dB hybrid. Transformer hybrids made with toroidal cores (ferrite beads) can work over large bandwidths, e.g., 10 KHz to 20 MHz and 1 MHz to 500 MHz.

---

[2] In telephony, the circuit is deliberately unbalanced – just enough so that the users, hearing their own voices or ambient noise, will sense that the call is connected, but not enough that the users hold the receiver (and hence the microphone) away from their heads. Of course cancellation should be as great as possible when this kind of full-duplex circuit carries two-way digital data.

Figure 15.5. Two-transformers make a hybrid with the same impedance at all four ports.

Hybrids are often used in circuits like those illustrated above, as well as signal splitting and combining, where one port is terminated in its characteristic impedance. An easy way to terminate Port 1 of the hybrid of Figure 15.5 is to put a resistor of value $2Z_0$ between Ports 2 and 3. When this is done, the Port 1 winding on the hybrid transformer can be eliminated. The resulting circuit, shown in Figure 15.6a, is

commonly found in the signal splitters used to connect two receivers to a single antenna (c) and in other packaged 2:1 splitter/combiners. When it is acceptable for the impedance of Port 4 to be $Z_0/2$, the right-hand transformer can be omitted, and the hybrid consists only of the center-tapped *hybrid coil*.

15.3 Quadrature hybrids

The transformer hybrid is naturally a 180° hybrid. Other circuits are natural 90° hybrids, the symbol for which is shown in Figure 15.7.

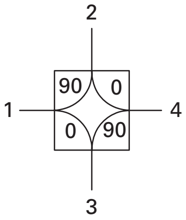

Figure 15.7. Symbol for a 90° hybrid.

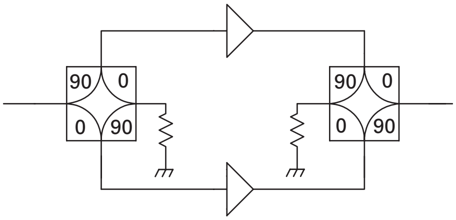
Let us look at an interesting application of the 90° hybrid (often called a *quadrature hybrid*). Here the internal phase paths are zero and 90°. A 90° path means a phase shift equal to that produced by a quarter-wave length of cable. For circuit analysis, one deals with hybrids in terms of voltages. We will consider the hybrid to be connected to transmission lines (of the same impedance as the hybrid) in order to describe the signals in terms of incident and reflected waves. A signal incident at Port 1 will be split equally into signals exiting Ports 2 and 3. Since the power division is equal, the magnitudes of the voltages of the signals exiting Ports 2 and 3 will be $1/\sqrt{2}$ times the magnitude of the incident voltage. The phases of the exiting signals will be delayed as indicated on the symbol for the hybrid. For the hybrid of Figure 15.7, the signal exiting Port 3 has no additional phase shift but the signal exiting Port 2 is multiplied by $e^{-j\pi/2}$. Suppose a signal is also incident at Port 4. It will also split into signals exiting from Ports 2 and 3. The total voltage of the waves exiting Ports 2 and 3 is just the superposition of the waves originating from Ports 1 and 4.

15.3.1 Balanced amplifier

A common application for 90° hybrids is the balanced amplifier circuit shown in Figure 15.8. As long as the two amplifiers are identical they can have arbitrary input and output impedances but the overall circuit will have input and output impedances of Z_0.

To see how this happens, suppose that the hybrids are 50-ohm devices but that the input impedance of the amplifiers is not 50 ohms. Imagine that the interconnections are made using 50-ohm transmission line. The input lines have equal lengths and the output lines have equal lengths. The amplifiers are identical so the two signals have equal phase changes upon reflection. An input signal is split by the input hybrid; half the power will be incident on the top amplifier and half on the bottom amplifier. But reflections from the amplifiers will be out of phase by 180° when they arrive back at the input of the hybrid because the signal on the upper path will have made a round trip through the 90° arm of the hybrid. The two reflections therefore cancel and there is no net

Figure 15.8. A balanced amplifier has constant input and output impedances.

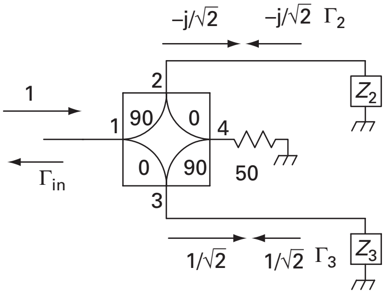


reflection. The input impedance of the overall amplifier will be the characteristic impedance of the hybrid (the value of the resistors, if transformer hybrids are used). The output side works the same way, and this combination of two arbitrary but identical amplifiers produces an amplifier with ideal constant input and output impedances.

15.4 How to analyze circuits containing hybrids

Let us work out an example problem to illustrate the way voltages are added in the manner of transmission line analysis. In Figure 15.9, a 50-ohm hybrid has arbitrary impedances, Z_2 and Z_3 terminating Ports 2 and 3. Port 4 is terminated in 50 ohms, so no power exiting Port 4 will be reflected back into the hybrid. We want to find the impedance seen looking into Port 1. Rather than work directly with impedances, we work with the equivalent reflection coefficients, $\Gamma = (Z - Z_0)/(Z+Z_0)$. Once we have found Γ_{in}, it can be converted to Z_{in}. The input signal is denoted by the forward arrow at Port 1. We will give it unity amplitude.

Figure 15.9. An example circuit problem: finding the impedance looking into Port 1.



The signal incident on Z_2 is therefore $(1/\sqrt{2})e^{-\mathrm{j}\pi/2} = -\mathrm{j}/\sqrt{2}$ where $1/\sqrt{2}$ is the reduction in amplitude due to the equal power split and $-\pi/2$ is the phase shift of the 90° path between Ports 1 and 2. The signal reflected back into Port 2 is $[-\mathrm{j}\sqrt{2}]\Gamma_2$, i.e., the signal incident on Z_2 multiplied by the reflection coefficient of Z_2. This reflected signal will split as it enters Port 2 and its contribution to the wave leaving Port 1 will be its amplitude multiplied by $(1/\sqrt{2})e^{-\mathrm{j}\pi/2}$ as it is split and phase shifted by the 90° path or $[\,-\mathrm{j}(\sqrt{2})]\Gamma_2 \times -\mathrm{j}(\sqrt{2}) = -\Gamma_2/2$.

Figure 15.10. A balanced amplifier built with 180° hybrids.

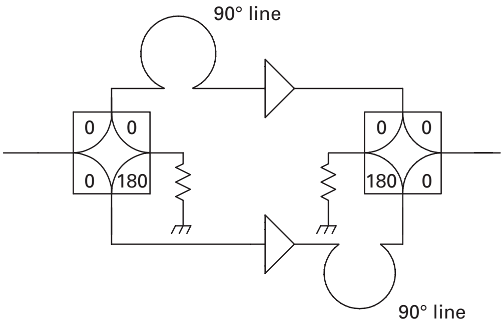


Figure 15.11. Conversions between 90° and 180° hybrids

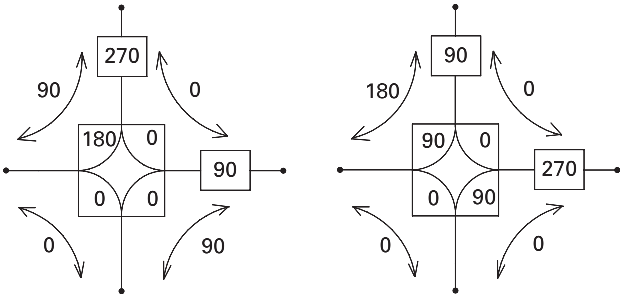


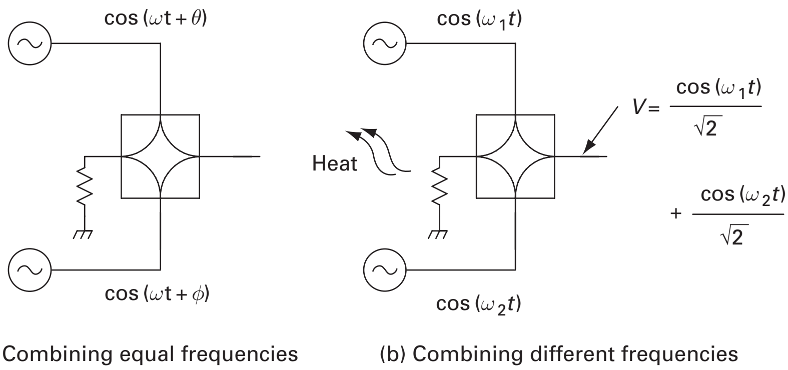
Similarly, the contribution to Γ from the reflection at Z_3 is Γ_3 /2, and the overall reflection is given by $\Gamma = -\Gamma_2/2 + \Gamma_3/2$, which solves the problem. The reader can work out the general case where Port 4 is also terminated by an arbitrary impedance, Z_4. Hint: let V_2, V_3, and V_4 be the wave amplitudes flowing out of Ports 2, 3, and 4. The waves flowing into these ports will therefore have amplitudes $\Gamma_2 V_2$, $\Gamma_3 V_3$, and $\Gamma_4 V_4$. By examination of the circuit, write three equations for V_2, V_3, and V_4, the three unknowns.

A balanced amplifier can also be built with 180° hybrids if two 90° lines are added as shown in Figure 15.10.

This use of cables to allow substitution of 180° hybrids for 90° hybrids in this circuit can be taken much farther; any hybrid can be converted to any other hybrid by adding lengths of transmission line to the ports. Figure 15.11 shows how to convert a 180° hybrid into a 90° hybrid and vice versa.

15.5 Power combining and splitting

An obvious way to power N loads from a single 50-ohm source is to transform the impedance of each load to $50N$ +j0 ohms and then connect the transformed



cos (ωt + θ)

(b) Combining different frequencies

Figure 15.12. Hybrids used as power combiners.

loads in parallel across the generator. However, if any load changes, the power delivered to the other loads will change. A similar argument applies to combining the power from several sources: if any source changes amplitude or phase, the combined output will change. Hybrids provide a way to combine or split power without using impedance transformation and in a way that isolates multiple sources or multiple loads from each other.

To use a hybrid as a two-input power combiner, the unused port is terminated, either externally, as shown in Figure 15.12 or internally, as shown in Figure 15.6. The two signals to be combined should have equal amplitudes, as well as the correct phase relationship, to steer the total available power into the desired port. If the phase difference is changed by 180°, all the power will flow into the terminated port. Note that if one source fails, the other source will not know it; it still sees a matched load. This provides a fail-safe circuit, although the power output will drop by 75%.

When a hybrid is used to combine two signals of different frequencies, as in Figure 15.12(b), half the power of each signal will always be lost in the terminated port. Circuits to combine signals of different frequencies without loss are known as diplexers. (How would you make one?)

Power splitting is, of course, just time-reversed power combining. When hybrids are used as splitters and the source impedance is equal to the port impedance, the signal at any output port will remain constant when the loads on the other output ports are removed, shorted, or changed in any way.

15.5.1 Hybrid trees

Trees of hybrids are often used to make multi-input combiners or multiple-output splitters, as shown in Figure 15.13. High-power transmitters often use such tree structures to combine the power of many low-power solid-state amplifiers.

These trees have the same advantages as single hybrids, when used for power combining or splitting. A 2^N-to-1 combiner/splitter has $2^N - 1$ internal hybrids.

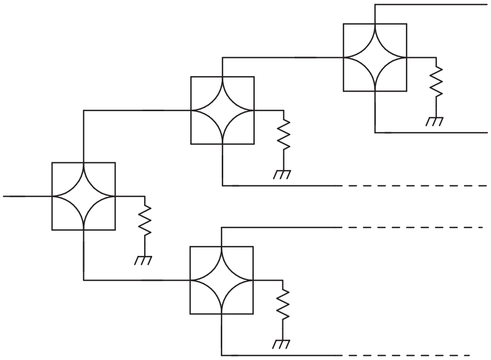

Figure 15.13. A tree of hybrids.

If you buy a three-way TV antenna splitter, you may find that each output provides only one quarter, rather than one third of the input power. What would have been a fourth output port is internally terminated. Or, if the splitter contains two hybrids, one output port can supply half the input power while the other two output ports can each supply one quarter of the input power.

15.6 Other hybrids

There are many ways to make hybrids without transformers. Most of them are circuits whose elements are transmission lines or capacitors and inductors. Unlike the ideal transformer hybrid, these hybrids are all frequency dependent – perfect hybrids only at their center frequency. However, most have a useful bandwidth of about an octave, which is usually sufficient for RF and microwave applications. You can use straightforward circuit analysis to analyze these hybrids.

15.6.1 Wilkinson power divider (or combiner)

This hybrid, shown in Figure 15.14 (in a 50-ohm version), uses two quarter-wave pieces of 70.7 $(50\sqrt{2})$ ohm transmission line. It has only three external ports; the fourth port is internally terminated, that is, connected to a load equal to its characteristic impedance.

It is easy to see that power applied to Port 1 will divide between Ports 2 and 3. By symmetry, the voltages at Ports 2 and 3 must be identical so no power is dissipated in the internal termination. Fifty-ohm loads at Ports 2 and 3 are transformed by the 90° cables to 100 ohms. The parallel connection of 100 ohms and 100 ohms at Port 1 produces the desired 50-ohm input impedance. The Wilkinson divider is usually classified as a 180° hybrid since its outputs have the same phase, even though this phase is 90° rather than 0°.

15.6.2 Ring hybrid

The ring hybrid, shown in Figure 15.15, uses four pieces of transmission line. To have 50-ohm ports, the hybrid must be built from 70.7-ohm transmission line.

Branch-line hybrids

These are ladder networks made of quarter-wave lengths of transmission line. The simplest is shown in Figure 15.16. More complicated versions have more branches and provide more bandwidth.

15.6.3 Lumped element hybrids

Two examples of 50-ohm lumped element hybrids are shown in Figure 15.17. These two circuits are obtained by replacing the Z_0 and $Z_0/\sqrt{2}$ arms of the simple branch line hybrid with the pi (or T) lumped circuit impedance inverters discussed in Chapter 13.

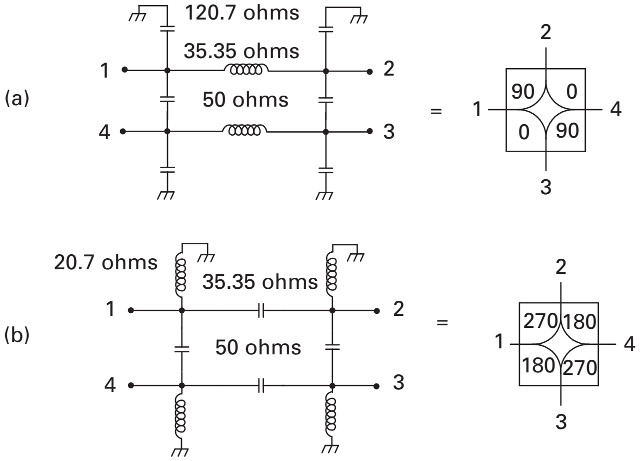

Figure 15.17. Two lumped-element hybrids.

15.6.4 Backward coupler

The *backward coupler* is shown in Figure 15.18 in shielded pair and stripline versions. The coupled transmission lines have both electric and magnetic coupling. When power flows from left to right, between Ports 1 and 2, coupled power flows left (backwards) out of Port 3. This type of coupler can be designed so that the voltage coupling coefficient, c, between Ports 1 and 3 is anywhere between 0 and 1. If designed for $c = 1/\sqrt{2}$, the coupler is a hybrid (a 3-dB directional coupler). This coupler can be analyzed in terms of its common mode and differential characteristic impedances, Z_{CM} and Z_{DIFF}, which are defined as follows. If the two inner conductors are driven together as a single (though split) center conductor, the characteristic impedance of the line is Z_{CM}. When the two inner conductors are regarded as a balanced shielded transmission line, its characteristic impedance is Z_{DIFF}. Two equivalent parameters are defined: $Z_{\mathrm{EVEN}} = 2\ Z_{\mathrm{CM}}$ and $Z_{\mathrm{ODD}} = Z_{\mathrm{DIFF}}/2$. Analysis using simultaneous forward and reflected common mode and differential mode signals (see Problem 15.8) produces the formulas:

$$Z_{\mathrm{ODD}} = Z_0([1-c]/[1+c])^{1/2} \text{ and } Z_{\mathrm{EVEN}} = Z_0([1+c]/[1-c])^{1/2} \quad (15.1)$$

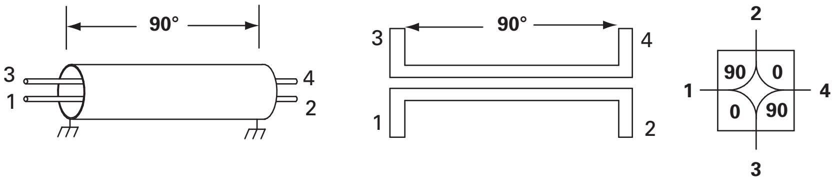

Figure 15.18. Backward couplers (coupled transmission line hybrids).

where Z_0 is the desired port impedance. However, these are only indirect design formulas, since electromagnetic analysis is needed to find physical dimensions to produce the required values for Z_{ODD} and Z_{EVEN}.

The *magic-T* of Figure 15.19 is a four-port waveguide junction that combines an *E*-plane tee junction with an *H*-plane tee junction. This waveguide hybrid, whose operation is surprisingly simple, is discussed in Chapter 16.

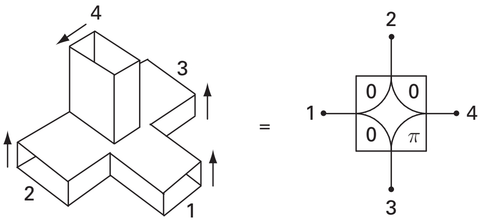

Figure 15.19. Waveguide magic-T hybrid.

Problems

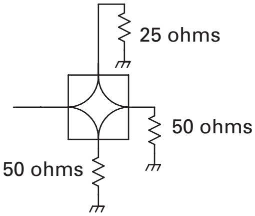
Problem 15.1. Verify for the transformer hybrid of Figure 15.2 that Port 2 is isolated from Port 3, i.e., show that with a generator connected to Port 3, the voltage at Port 2 will be zero provided the impedance terminating Port 1 is twice the impedance terminating Port 4.

Problem 15.2. Explain why the duplex telephone circuit and the two-way telephone repeater could be built with either 90° or 180° or any other hybrids.

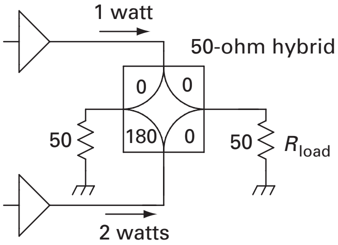
Problem 15.3. (a) Calculate the overall gain of the balanced amplifier of Figure 15.8 if the (identical) individual amplifiers each have gain G_0. (Answer: G_0)

(b) Calculate the overall gain if one of the interior amplifiers is dead, i.e., has zero gain. (Answer: $G_0/4$.)

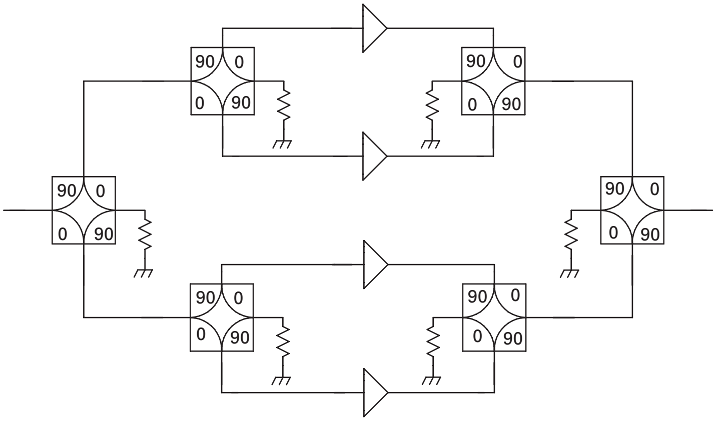
Problem 15.4. The 50-ohm hybrid shown below is properly terminated by 50-ohm resistors on two of its ports. The third port is terminated by a 25-ohm resistor. If a 50-ohm generator is connected to the remaining port, what fraction of the incident power will be reflected back into the generator? (Answer: 1/36.)



Problem 15.5. In the figure below, a 50-ohm hybrid is fed power from two amplifiers. The signals from these amplifiers have the same frequency and the same phase but the upper amplifier supplies 1 watt while the lower amplifier supplies 2 watts. In this seemingly unbalanced configuration, how much power reaches the load resistor? (Answer: 2.91 watts.)



Problem 15.6. Four identical 1-watt amplifiers and six hybrids are used to make a 4-watt amplifier. If one of the interior amplifiers fails, how much power will be delivered to the load? (Answer: 2.25 watts.)



Problem 15.7. Design an op-amp circuit to replace the telephone hybrids in Figure 15.3(b). Put a low-value resistor in series with the line so that a differential

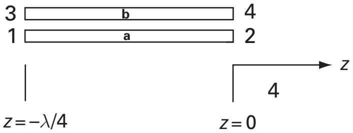
amplifier will produce a voltage proportional to the current × Z_0. Use op-amps to produce signals that are the sum and difference of this voltage and the line voltage.

Problem 15.8. Analyze the coupled-line hybrid to derive Equations (15.1) and (15.2). Let $V_a(z)$ and $V_b(z)$ denote respectively the voltages on the bottom conductor and top conductors. You can write these voltages as the superposition of a common-mode ("even") wave and its reflection plus a differential-mode ("odd") wave and its reflection. Putting $z = 0$ at the right-hand end, confirm that these voltages take the form

$$V_a(x) = \mathrm{V_e e^{-j\mathit{kx}} + V_e \Gamma_e e^{j\mathit{kx}} + V_0 e^{-j\mathit{kx}} + V_0 \Gamma_0 e^{j\mathit{kx}}}$$

$$V_b(x) = V_e \mathrm{e}^{-\mathrm{j}kx} + V_e \Gamma_e \mathrm{e}^{\mathrm{j}kx} - V_0 \mathrm{e}^{-\mathrm{j}kx} - V_0 \Gamma_0 \mathrm{e}^{\mathrm{j}kx}$$

where, as usual, $k = 2\pi/\lambda$. The reflection coefficients, Γ_e and Γ_0, are calculated in terms of the even and odd characteristic impedances, $Z_e = 2\ Z_{CM}$ and $Z_0 = Z_{DIFF}/2$, in the usual way, i.e., $\Gamma_{e,0} = (Z_0 - Z_{e,0})/(Z_0 + Z_{e,0})$ (see Chapter 10). Note that Z_0 is the *load* impedance for the even and odd waves.



Assume a unity amplitude wave incident at Port 1, i.e., $V_a(-\lambda/4) = 1$. The voltage at the isolated port must be zero, i.e., $V_b(0) = 0$. Use these two equations to find V_e and V_0. Then use V_e and V_0 to show that the coupled voltage, $V_3 = V_b(-\lambda/4)$ is given by $c = (Z_e - Z_o)/(Z_e + Z_o)$. Finally, impose the (match) condition that $I_1 = 1/Z_0$, i.e., $I_a(-\lambda/4)) = 1/Z_0$, to show that $Z_e Z_o = Z_0{}^2$.

CHAPTER

16 Waveguide circuits

In this chapter we examine rectangular metal waveguides and, in particular, their most common mode of operation, the fundamental "TE_{10}" mode. We will also see how the concepts developed for two-conductor transmission lines apply to waveguides and look at waveguide versions of some low-frequency components.

The ability of a hollow metal pipe to transmit electromagnetic waves can be demonstrated by holding it in front of your eye. You can see through it, so, at least, it passes electromagnetic waves of extremely short wavelengths. From a purely dimensional analysis, you would guess correctly that the longest wavelength a pipe could transmit must be of the order of the pipe's transverse dimensions. It turns out that, for propagation in a rectangular pipe, the free-space wavelength, c/f, must be less than twice the longer transverse dimension and, for a circular pipe, less than 1.706[1] times the diameter. Waveguides have less loss and more power handling capacity than coaxial lines of the same size and they need no center conductor nor insulating structures to support a center conductor. Metal waveguides are used most often in the range from 1000 MHz to 100 GHz, where they have practical dimensions. Waveguides for optical frequencies are coated glass fibers.

16.1 Simple picture of waveguide propagation

A common RF engineering argument for the plausibility of transmitting electromagnetic waves through a hollow metal pipe is shown in Figure 16.1, where a two-conductor transmission line evolves into a waveguide. Quarter-wave shorted stubs are added to the line. Since a shorted quarter-wave line presents an open circuit, these stubs do not short the line. More stubs are added to both sides until a rectangular pipe is formed.

This plausibility argument, while not rigorous, does illustrate some important properties of waveguide propagation in the fundamental mode (the

---

[1] The factor 1.706 is $\pi/1.841$, where 1.841 is the smallest root of the equation $\mathrm{d}/\mathrm{d}x\, J_1(x) = 0$ and $J_1(x)$ is the first-order Bessel function of the first kind, a function whose shape resembles $\sin(x)/(x+1)^{1/2}$.

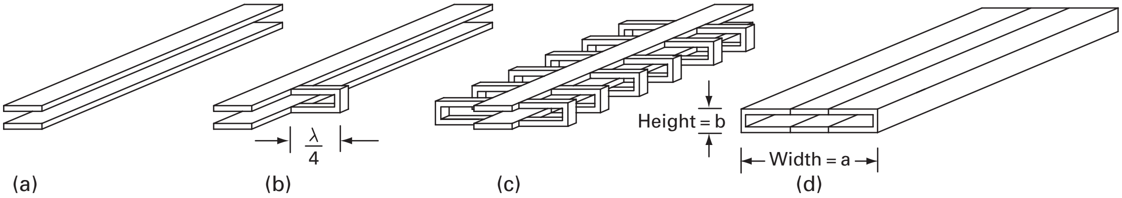

Figure 16.1. Transmission line-to-waveguide evolution. Shorted quarter-wave stubs do not short the transmission line.

simplest and lowest frequency mode): the electric field, which is essentially vertical between the conductors in Figure 16.1(a), becomes perfectly vertical in the waveguide, though its magnitude must fall to zero at the waveguide's sides, since the metallic walls short out any tangential electric field. And, just as the conductors of the transmission line of Figure 16.1(a) can have any separation and still support wave propagation, the waveguide of Figure 16.1(d) can have any height. The width, however, is critical. The total width of the guide must be at least $\lambda/2$ to accommodate a quarter-wave stub on each side and still have nonvanishing conductor strips, as shown in Figure 16.1(c). This means that there is a low-frequency cutoff; wave propagation is not possible if the wavelength is greater than $2a$ where a is the waveguide width (the longer dimension).

Standard waveguide designations indicate the shape and size of the guide. WR430, for example, denotes "Waveguide, Rectangular," 4.3 inches (10.9 cm) wide. The standard width-to-height ratio is two-to-one. (While the height of the guide can be made arbitrarily small, the waveguide will become increasingly lossy because, for a given power, the currents increase.) One of the largest standard waveguide sizes, WR2300, with a width of 23 inches (58.4 cm), has a low-frequency cutoff of 257 MHz. One of the smallest, WR3, with a width of 0.03 inches (0.076 cm), has a low-frequency cutoff of 197 GHz.

For a standard (width = 2 × height) waveguide, the fundamental mode, called the *TE_{10} mode*, is the only possible mode for frequencies above the low-frequency cutoff and below twice the low-frequency cutoff. Other modes exist above this one-octave range. At frequencies where higher modes are possible, these modes can be unintentionally excited at sharp bends, robbing power from the desired mode. This power does not couple properly to circuit elements designed for the fundamental mode and dissipates in the walls. Whenever possible, a microwave system designer therefore tries to use only the fundamental mode.

The essential details of this most important mode are derived and discussed below.

16.2 Exact solution: a plane wave interference pattern matches the waveguide boundary conditions

Exact solutions for the E and B fields within waveguides of arbitrary shape are normally deduced through a head-on assault using Maxwell's equations.

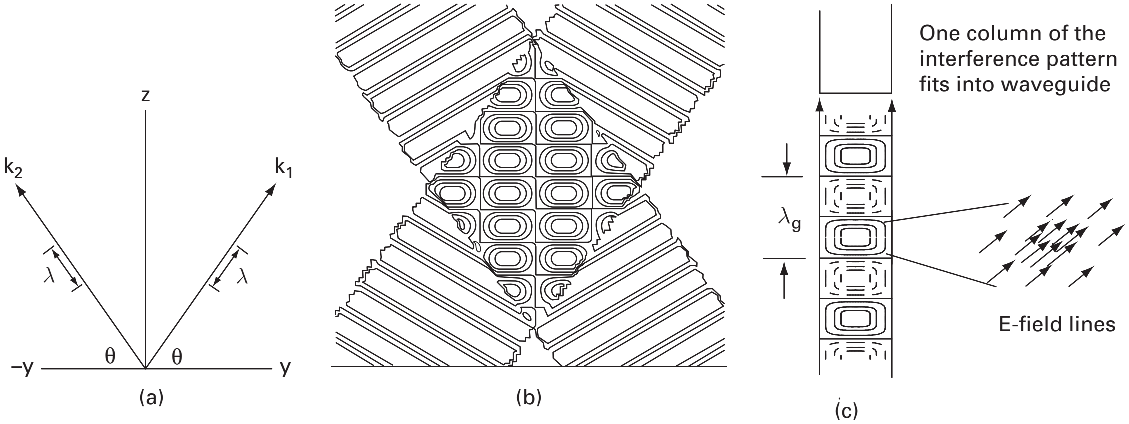

Figure 16.2. Superposition of two plane waves (a) produces an interference pattern (b) streaming in the *z*-direction. One (or more) columns of that pattern satisfies waveguide boundary conditions (c). *E* is in the *x*-direction (coming out of the page).

However, for rectangular waveguides, an exact solution can be obtained indirectly by setting up two plane waves in empty space.

A single plane wave satisfies Maxwell's equations inside a waveguide, but cannot satisfy the boundary conditions at the metal walls. However, the superposition of two properly chosen plane waves forms a traveling interference pattern which does satisfy the boundary conditions and is therefore a valid solution to the waveguide problem. This solution technique can be compared with the "image charge" method in electrostatics, often introduced as a technique to solve for the electric field when a point charge sits alone above an infinite metal sheet. An equal but opposite charge is placed at the mirror image point behind the sheet and the sheet is removed. The electric field lines connecting the charges pass perpendicularly through the x–y plane, satisfying the boundary condition that the E field must be perpendicular when intersecting a conducting surface. The superposition of the two fields, that of the actual charge and that of the image charge, is the solution to the original problem.

Here we construct a solution by superposing two plane waves, identical except for their propagation directions. Both plane waves will be polarized in the x-direction, i.e., their electric fields are in the x-direction. Since electromagnetic waves in free space are transverse waves, the propagation vectors, $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$,[2] corresponding to these waves must both lie in the y–z plane, as shown in Figure 16.2(a).

The first wave, with propagation vector $\boldsymbol{k}_1$, travels in the NNE direction, while the other, $\boldsymbol{k}_2$, travels NNW. In (b), the plane waves are drawn as streams with finite width. Contour lines of the electric field are perpendicular to the directions of propagation. Figure 16.2(b) shows that, in the area where the streams overlap, the sum of the individual electric fields produces an *interference pattern* consisting of columns of cells which stream northward in the z-direction. If we could watch two waves come together in the ocean, we would see them produce this interference pattern. As the streams leave the overlap region, they recover their original plane wave form. In the interference pattern, the contour lines of constant E resemble squared-off ovals. (Remember that $\boldsymbol{E}$ is always perpendicular to the page; the oval-like figures are contours of field strength; they are not field lines.)

---

[2] By definition, the propagation vector, $\boldsymbol{k}$, is in the direction of travel, i.e., perpendicular to the wavefront, and has magnitude $|\boldsymbol{k}| = 2\pi/\lambda$.

The pattern formed by a column of cells (Figure 16.2c) solves the waveguide problem if the width of the cells is equal to a, the width of the waveguide. Why is this a solution? First, the electric field at the side walls is zero at all times, satisfying the boundary condition that, at a conducting wall, there can no parallel electric field. Second, the electric field is always in the x-direction, so it is perpendicular where it intersects the top and bottom walls, satisfying the boundary on those walls as well. Third, each plane wave and therefore their sum, is a solution to Maxwell's equations in empty space, i.e., the interior of the waveguide. What about all the columns of cells outside the boundary of the waveguide? We can forget them, just as we ignore the electric field on the image charge side of the x–y plane in the electrostatic example.

Let us apply a little algebra to find the wave's propagation vector, cutoff frequency and phase velocity. Let k denote the magnitude of $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ so that $\boldsymbol{k}_1 = k\cos(\theta)\,\hat{\boldsymbol{y}} + k\sin(\theta)\,\hat{\boldsymbol{z}}$ and $\boldsymbol{k}_2 = -k\cos(\theta)\,\hat{\boldsymbol{y}} + k\sin(\theta)\,\hat{\boldsymbol{z}}$. The electric field is the sum of the fields of the two waves, i.e.,

$$E(r,t) = \frac{-E}{2\mathrm{j}}\mathrm{e}^{\mathrm{j}(\omega t - k_1\cdot r)} + \frac{E}{2\mathrm{j}}\mathrm{e}^{\mathrm{j}(\omega t - k_2\cdot r)}, \tag{16.1}$$

where the vector $\boldsymbol{r}$ denotes position in the y–z plane and E is a constant equal to the twice maximum electric field of each wave. The amplitudes, $-E/(2\mathrm{j})$ and $E/(2\mathrm{j})$, have been chosen so that $y=0$ will be a column boundary and also to phase the E field to be maximum at $z=0$ when $t=0$. Substituting the expressions for $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$, we have

$$\begin{aligned} E &= E\Big(-\mathrm{e}^{(\mathrm{j}\omega t - k(z\cos\theta + y\sin\theta))} + \mathrm{e}^{\mathrm{j}(\omega t - k(z\cos\theta - y\sin\theta))}\Big)/(2\mathrm{j}) \\ &= E\sin(ky\sin\theta)\mathrm{e}^{\mathrm{j}(\omega t - kz\cos\theta)}. \end{aligned} \tag{16.2}$$

As always, it is the real part of $\boldsymbol{E}$ that is the actual electric field. Note that all the y dependence is contained in the expression $\sin(k\sin(\theta)\,y)$. This is independent of t, so, in the y-direction, the diffraction pattern is a standing wave. The z and t dependence, however, are contained in the wave factor $\mathrm{e}^{\mathrm{j}(\omega t - kz\cos\theta)}$, so the entire diffraction pattern propagates in the $(+z)$-direction with an effective wavevector $k_{\text{guide}} = k\cos\theta$. For a wave of a given frequency, we can find the value of θ that satisfies the side-wall boundary condition. Suppose that the bottom wall of the waveguide extends from $y=0$ to $y=a$, i.e., the guide width is a. The boundary condition at $y=0$ is satisfied for any value of θ, since $\sin(0)=0$. But the boundary condition at $y=a$ demands that $\sin(k\sin(\theta)\ a)=0$. This will be satisfied if $k\sin(\theta)\ a = n\pi$, where n is an integer. Here we will let $n=1$, so that $\sin(\theta) = \pi/(ka)$ and $\cos(\theta) = (1-[\pi/(ka)]^2)^{1/2}$. Thus the E field in the waveguide is

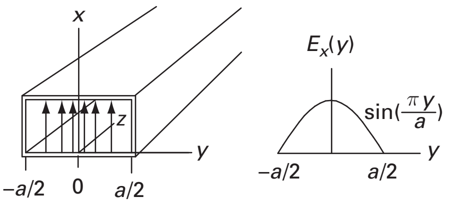

Figure 16.3. Electric field configuration in the TE_{10} mode.

given by (the real part of) $E = E\sin(\pi y/a)e^{j(\omega t-k_g z))}$ where = $k\cos(\theta)=k(1-[\pi/(ka)]^2)^{1/2}$. Figure 16.3 shows how the magnitude of the E field is a maximum at the center line of the waveguide and falls to zero at the side walls.

16.2.1 Guide wavelength

From the expression for k_g, we see that the spatial period along the waveguide will be $2\pi/k_g$. Solving for this length, known as the *guide wavelength*, we find

$$\lambda_{\text{guide}} = \frac{\lambda}{\sqrt{1-\left(\frac{\lambda}{2a}\right)^2}}. \tag{16.3}$$

16.2.2 Magnetic field

Just as the electric field in the guide is the superposition of the electric fields of two plane waves, the magnetic field is the superposition of their magnetic fields. For a plane wave, the magnetic field is perpendicular to both the electric field and the propagation vector,

$$\boldsymbol{B} = \hat{k} \times \mathbf{E}/c, \tag{16.4}$$

where c is the speed of light. The magnetic fields of our two plane waves have z-components as well as y-components, so the magnetic field in the waveguide is not purely transverse with respect to the direction of propagation. In this TE_{10} mode and all other TE modes, only the electric field is purely transverse. There are also TM modes, in which only the magnetic field is purely transverse. Waveguides, unlike coaxial cable, have no TEM modes, in which both E and H fields are transverse.

We can use Equation (16.4) to find the magnetic of field each plane wave and then sum them to get the field in the waveguide. The result is

$$\frac{B_y}{E} = \frac{k_g}{\omega}\sin\left(\frac{\pi y}{a}\right)e^{j(\omega t-k_g z)} \tag{16.5}$$

and

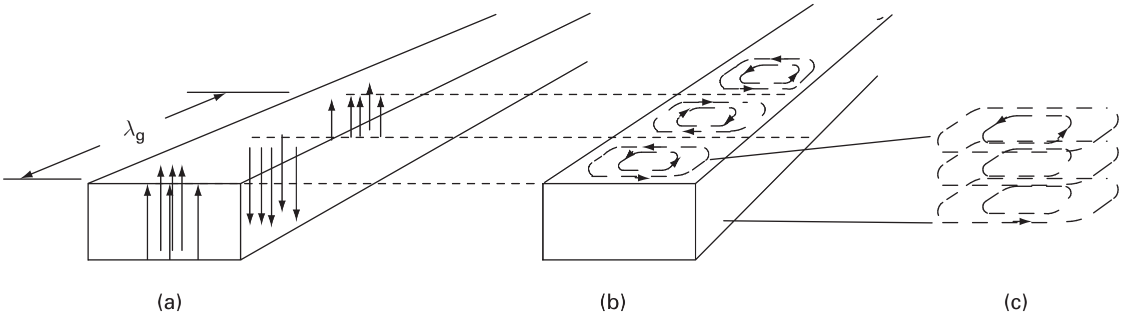

Figure 16.4. Electric field lines (a) and magnetic field Lines (b) The electric lines are bundles of vertical vectors while the magnetic lines are stacks of concentric loops (c.).

$$\frac{B_z}{E} = \frac{\pi}{\mathrm{j}a\omega}\cos\left(\frac{\pi y}{a}\right)\mathrm{e}^{\mathrm{j}(\omega t - k - gz)}. \tag{16.6}$$

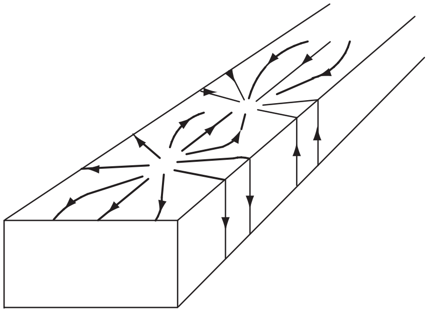
The form of this B field is shown in Figure 16.4(b).[3]

Note that the magnetic field lines are stacked concentric loops in the y-z plane with no component normal to the walls. You can use Equations (16.5) and (16.6) to find the exact shape of these loops (see Problem 16.4).

16.2.3 Wall currents

Wall currents, which flow on the inside surfaces of the waveguide, are determined by the tangential magnetic field. The currents are perpendicular to the B field and their magnitude (in amperes/meter) is given by B/μ_0 (the permeability of free space, μ_0, is equal to $4\pi{\cdot}10^{-7}$). The wall currents are indicated in Figure 16.5. These currents converge or diverge from areas on the broad wall

Figure 16.5. Wall currents (solid lines) in relation to the magnetic field (dashed lines).



---

[3] The reader familiar with Maxwell's equations can quickly derive Equations (16.5) and (16.6) from Equation (16.2) by applying the curl E equation, which here becomes $\mathrm{j}\omega B_y = -\partial E_x/\partial z$ and $\mathrm{j}\omega B_x = \partial E_x/\partial y$.

where positive charge is arriving or leaving. The E-field lines start and end at these charge patches. Note that the currents on the narrow walls are perfectly vertical because the tangential magnetic field has no x-component.

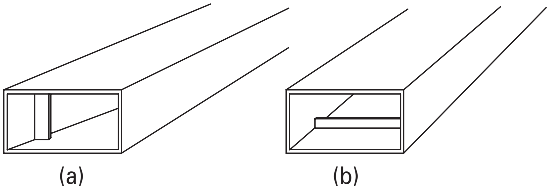
The fields and currents shown in Figures 16.2–16.5 are, of course, snapshots at an instant in time. As the wave propagates, these patterns move uniformly along the z-axis with a (phase) velocity given by $v_{\text{ph}} = \omega/\beta$.

16.3 Waveguide vs. coax for low-loss power transmission

Consider a situation requiring a low-loss transmission line. Let us compare a standard 2:1 aspect ratio waveguide to a cylindrical coaxial line. To minimize the loss we will make both as large as possible, but here we will impose the restriction that they are also small enough so that modes higher than the fundamental mode cannot propagate. Appendix 16.1 shows that the diameter of this lowest-loss coaxial line and the height of the lowest-loss waveguide are very close to $\lambda/2$ and that the coaxial line will have 2.4 times the loss of the waveguide and will carry only 23% as much power before breakdown.

16.4 Waveguide impedance

There are several ways to define an impedance for a waveguide. One way is to define the voltage to be the potential difference between the top and bottom walls at the middle of the guide and the current to be the integrated current across the top wall. The ratio of voltage to current gives an impedance. Another definition uses voltage and power flow. Still another method uses the ratio of electric field to magnetic field at the center of the guide. The various definitions give $Z_0 = 377$ ohms (impedance of free space) within a factor of 2. But regardless of how impedance is defined, there is no ambiguity in the concept of reflection coefficient. Recall that a shunt capacitance on an ordinary (TEM) transmission line produces a reflection coefficient on the negative j-axis of the Smith chart. The same kind of reflection is produced in a waveguide by a short vertical post or a horizontal iris. These obstructions are therefore called "capacitive posts" or "capacitive irises." An iris across the narrow dimension of the guide causes a reflection on the positive j-axis so is called an "inductive iris." Figure 16.6 shows examples of inductive and capacitive irises. (The equivalent circuit for a thin iris is just a single shunt susceptance.)



(a) (b)

Figure 16.6. Waveguide irises: (a) inductive iris; (b) capacitive iris.

The combination of an inductive and a capacitive iris (a thin wall with a hole) is equivalent to a parallel resonant circuit. You can see how these resonant irises could be spaced at quarter-wave intervals in a waveguide to make a coupled-resonator filter.

16.5 Matching in waveguide circuits

Impedance matching in waveguide circuits can be done with the same techniques used for ordinary transmission lines. Suppose we are using a waveguide to supply power to some device, maybe a horn antenna, and that we have an instrument – a reflectometer or network analyzer – that can measure the reflection coefficient looking into the waveguide. We can locate the reflection coefficient on the complex reflection plane (Smith chart) as shown in Figure 16.7.

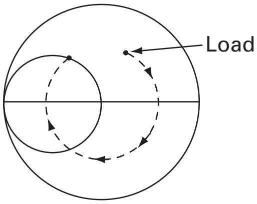


Figure 16.7. A load's reflection coefficient located on the Smith chart.

As we move down the guide, away from the load, the reflection coefficient circles the center of the chart and eventually arrives at the unity conductance circle. We locate this position on the guide and install the appropriate inductive or capacitive iris. In practice the tuning process is sometimes very simple: we find the point at which we need to add shunt capacitance. If the reflected wave is small (not a severe mismatch) we do not have to add much capacitance so we get out the ball-peen hammer and dent the broad side of the guide. An expert learns just how hard to swing the hammer.

A note on matching: suppose we join two dissimilar waveguides (perhaps of different sizes) at a junction, which could be some kind of elbow, coupling, butt joint, etc. Assume that the system is nominally lossless, i.e., all metal. We want to match the junction so that a wave coming from either direction will suffer no reflection. We carry out the above procedure on one side of the junction. Do we have to then match the other side? No, the job has been done. Time-reversal produces an equally good solution to Maxwell's equations in which all the power flows in the opposite direction. Of course this applies just as well to ordinary (TEM) transmission lines as it does to waveguides. This simple argument fails for lossy junctions because the time-reversed solution requires the absorptive material to *produce* power, but a stronger argument, based on the reciprocity theorem leads to the same conclusion.

16.6 Three-port waveguide junctions

Two kinds of waveguide T-junctions (three-port junctions) are shown in Figure 16.8.

The *series-T* gets its name from the fact that the voltage of the input guide divides between the two output guides. This works out well because the half-height output guides have half the impedance of the input guide and the junction is inherently matched. (The half-height guides could be increased to full-width in a gradual taper that would not cause much reflection.) The *shunt-T* applies the full input voltage across each of the output arms – not such a natural as the series-T.

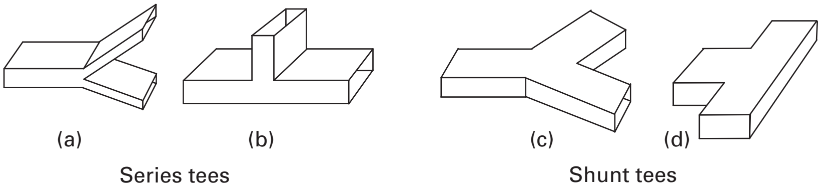

Figure 16.8. Waveguide T-junctions.

16.7 Four-port waveguide junctions

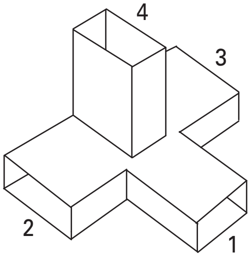

Figure 16.9. Waveguide Magic T.

The *Magic T* hybrid can be built using a procedure that itself seems like magic. We start with the bare waveguide junction (nothing hidden inside) as shown in Figure 16.9.

First we match Port 1, i.e., eliminate reflections from Port 2 when the other ports are feeding matched, i.e., reflectionless, loads. To do this we start by putting matched loads on Ports 2 and 3. (We do not have to put a load on Port 4 since, by symmetry, it is isolated from Port 1.[4]) With the loads in place we measure the reflection at Port 1 and install the necessary iris (or dent) somewhere down line 1. Then we do the same process on Port 4. That's it. The two matches and the isolation by virtue of symmetry are sufficient. We now have a perfectly matched Magic T hybrid.

Simple narrowband transitions from coax to waveguide have mostly been built with empirical methods. With the aid of three-dimensional finite element simulation programs, wideband transitions have been designed. In general, the designer first looks at the fields on both sides and finds a mechanical structure that causes the main features of the fields to line up. The remaining reflection should be small and can be tuned out with a small iris or other structure whose complexity depends on the desired bandwidth.

Rectangular waveguides, like TEM lines, can carry only one signal in each direction. But square or round guides can have two independent waves; they are both fundamental mode waves but they have different polarizations. To launch or recover these two waves independently requires an *orthomode coupler*, which has no TEM counterpart. The simplest orthomode couplers use coaxial or waveguide connections mounted at right angles on the sides of the square or round guide. Some couplers produce circular rather than rectangular polarizations. Wideband orthomode transitions are always needed for radio astronomy and their development is an active field.

---

[4] The *E* field is vertical as a wave enters Port 1. Would it point left or right as it emerged from Port 4? Since the geometry is symmetric, there is no reason to favor right or left. Hence, no wave emerges from Port 4.

Appendix 16.1 Lowest loss waveguide vs. lowest loss coaxial line

For lowest loss we will make the waveguide and the coaxial line as large as possible, but, as explained above, with the restriction that each be capable of supporting only its fundamental mode. Our lowest loss $TE_{1,0}$ waveguide will be made with its width equal to the wavelength. (If it is any wider, the second mode, $TE_{2,0}$, becomes possible.) We will make the height equal to half the width, i.e., the usual aspect ratio. For air-filled coaxial line at the frequency where non-TEM modes become possible, the inner and outer radii, r_i and r_o, satisfy the inequality $(r_o + r_i)\,\pi \geqq 1.03\lambda$.[5] The equal sign applies when $r_i / r_o = 1/3.6$. This ratio also provides the lowest loss air-filled coaxial line for a given outer diameter (see Appendix 16.2). Note that the characteristic impedance, $Z_0 = 60 \ln (r_o / r_i)$, will be 77 ohms for this lowest-loss coaxial cable. Using this ratio of diameters, the maximum outer diameter is given by $r_o = 1.03\lambda\pi^{-1}/(1+1/3.6) = 0.26\lambda$. These relative waveguide and coax cross-sections are shown in Figure 16.10.

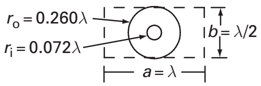

Figure 16.10. Relative cross-sections of lowest-loss waveguide and coaxial cable.

Let us compare the losses. The amplitude of a wave propagating in the $(+x)$-direction on any lossy line is proportional to $\exp(-\alpha x)$ where α, the loss factor, has units of inverse meters. The power is therefore proportional to $\exp(-2\alpha x)$ and the fractional power loss per meter is 2α. Note that $20 \log(e)\alpha = 8.686\alpha$ dB/meter. Because of the skin effect, the loss of a line is proportional to its surface resistance which is given by

$$R_S = \sqrt{\frac{\omega\mu}{2\sigma}} \quad \text{ohms per square} \tag{16.7}$$

where σ is the bulk dc conductivity and ω is the (angular) frequency. (For copper, $R_s = 2.61 \times 10^{-7}$ ohms/$\sqrt{\text{Hz}}$; for aluminum, $R_s = 3.26 \times 10^{-7}$ ohms/$\sqrt{\text{Hz}}$). The loss factor for air-filled coax line is given by

$$\alpha_{\text{coax}} = \frac{R_s}{2Z_0}\left(\frac{1}{2\pi r_o} + \frac{1}{2\pi r_i}\right). \tag{16.8}$$

Our lowest loss coax line has $Z_o = 77$, $r_o = 0.26\lambda$ and $r_i = 0.072\lambda$ so its loss becomes

$$(\alpha_{\text{coax}})_{\min} = 0.0183\frac{R_s}{\lambda}. \tag{16.9}$$

For air-filled rectangular waveguide in the fundamental mode the loss factor is given by

$$\alpha_{WG} = \frac{R_s}{377}\frac{\left(1 + \dfrac{2b}{a}\left(\dfrac{\lambda}{2a}\right)^2\right)}{b\sqrt{1 - \left(\dfrac{\lambda}{2a}\right)^2}} \tag{16.10}$$

---

[5] Reference [2], p. 42.

where 377 ohms is $\sqrt{\mu_0/\epsilon_0}$, the "impedance of free space." In our case $a = 2b = \lambda$ so

$$(\alpha_{\mathrm{WG}})_{\min} = \frac{R_{\mathrm{s}}}{\lambda}\frac{5}{337\sqrt{3}} = 0.0076\frac{R_{\mathrm{s}}}{\lambda}. \tag{16.11}$$

The loss of the coax is therefore higher than that of the waveguide by a factor of 0.0183/0.0076 or about 2.4. What about power handling capacity? The breakdown of either the waveguide or the coax depends on the maximum E field, $E_{\max}$. (For air at sea-level pressure, $E_{\max}$ is about 30 000 volts/cm.) For rectangular waveguide in the fundamental mode the power is related to the maximum E field by

$$\frac{\mathrm{Pwr}}{{E_{\max}}^2} = \frac{1}{4\cdot 377}ab\frac{\lambda_0}{\lambda_g} = 6.63 \times 10^{-4}ab\frac{\lambda_0}{\lambda_g} \tag{16.12}$$

where Pwr is in watts, $E_{\max}$ is in volts/cm, a and b are in cm, λ_0 is the free-space wavelength, and λ_g, the guide wavelength, is given by

$$\lambda_g = \frac{\lambda_0}{\sqrt{\left(1-\left(\frac{\lambda_0}{\lambda_{\mathrm{cutoff}}}\right)^2\right)}}. \tag{16.13}$$

For our waveguide $\lambda_0/\lambda_{\mathrm{cutoff}} = 1/2$ so $\lambda_g = 2\lambda_0/\sqrt{3}$ and

$$\frac{\mathrm{Pwr}}{{E_{\max}}^2} = 5.74 \times 10^{-4}ab = 5.74 \times 10^{-4}\lambda\,\lambda/2 = 2.37 \times 10^{-4}\lambda^2. \tag{16.14}$$

Turning to the coax, the ln(r) dependence of voltage and the characteristic impedance, $Z_0 = (377/2\pi)\ln(r_{\mathrm{o}}/r_{\mathrm{i}}) = 60\ln(r_{\mathrm{o}}/r_{\mathrm{i}})$ allow us to find the power in terms of the maximum E field:

$$\frac{\mathrm{Pwr}}{{E_{\max}}^2} = \frac{Z_0 r_{\mathrm{i}}^2}{2\cdot 60^2}. \tag{16.15}$$

In our case $Z_0 = 77$ and $r_{\mathrm{i}} = 0.072\lambda$ so

$$\frac{\mathrm{Pwr}}{{E_{\max}}^2} = \frac{77}{2\cdot 60^2}(0.072\lambda)^2 = 0.55 \times 10^{-4}\,\lambda^2. \tag{16.16}$$

We see that the waveguide can handle 2.37/0.55 = 4.3 times the power of the minimum loss coaxial line. The waveguide is clearly better both for loss and power handling capacity. In high-power applications the waveguide has the additional advantage that there are no interior surfaces needing cooling and no mechanical spacers to center an inner conductor. (Insulating spacers in high-power coaxial lines must fit tightly; high voltage develops across any gap. This problem generally reduces the power-handling capacity of the coaxial line by something like an order of magnitude.)

Appendix 16.2 Coax dimensions for lowest loss, highest power, and highest voltage

Lowest loss

For a given outer diameter, the characteristic impedance of a coaxial line is increased by making the inner diameter smaller. For a given power, the current is decreased. But the smaller inner conductor has more resistance. The I^2R product, i.e., the dissipation, has a minimum when the ratio of diameters is 3.6. This follows from Equation (16.8) which can be rewritten as

$$\alpha_{\text{coax}} = \frac{R_{\text{s}}}{2 \cdot 60 \cdot 2\pi r_{\text{o}}} \frac{1}{\ln(x)} (1 + x) \tag{16.17}$$

where $x = r_o/r_i$. The minimum of $(1+x)/\ln(x)$ occurs at $x = 3.6$ so the characteristic impedance of lowest-loss air-filled coaxial line is $Z_0 = 60 \ln(3.6) = 77$ ohms.

Highest power

From Equation (16.15) we see that to maximize the power-handling capability of the coaxial line we must maximize the expression $Z_0 \, r_i^2$, i.e., we must maximize $\ln(x)/x^2$. The maximum occurs when $\ln(x) = 1/2$ so the characteristic impedance of the maximum power line is $Z_0 = 60/2 = 30$ ohms.

Maximum voltage

If the line is to withstand maximum voltage the optimum value of $\ln(x)$ is 1 and the characteristic impedance is 60 ohms. This also follows from Equation (16.15): if we express power as $V_{\max}{}^2/(2Z_0)$ then $V_{\max}$ is proportional to $Z_0 \, r_i$ or $\ln(x)/x$, which reaches a maximum at $x = e$.

Relative performance of 50-ohm coaxial line

The 50-ohm line commonly used in RF work ($x = r_o/r_i = 2.3$) strikes a compromise between lowest loss, highest power and highest voltage. For loss, we compare $(1+x)/\ln(x)$ for $x = 2.3$ and $x = 3.6$ to see that the 50-ohm line will have only 10% more loss than a 77-ohm line with the same outer diameter. For power handling, we compare $\ln(x)/x^2$ and find that the 50-ohm line can carry 62% as much power as a 30-ohm line with the same outer diameter. Finally, for voltage we compare $\ln(x)/x$ and find that the 50-ohm line can handle 98% as much voltage as a 60-ohm cable with the same outer diameter.

Problems

Problem 16.1. Suppose a car enters a long tunnel which is essentially a rectangular metal tube 10 meters wide by 5 meters high. The car radio becomes silent inside the tunnel. Was the radio more likely tuned to an AM station or an FM station?

Problem 16.2. Examine the waveguide current distribution shown in Figure 16.5 (for the fundamental mode) and draw a sketch showing the position(s) in which a narrow slot could be cut through the waveguide wall without affecting its operation.

Problem 16.3. Describe an experimental setup that could be used to demonstrate the waveguide E-field and B-field distributions shown in Figure 16.4.

Problem 16.4. In the discussion just above Equation (16.2), let $n = 2$ instead of 1. For this choice of n (the TE_{20} mode), find the cutoff wavelength and the guide wavelength. Sketch the electric and magnetic field lines.

Problem 16.5. Use Equations (16.5) and (16.6) to find the mathematical shape of the magnetic field loops. Hint: the slope of a field line, $\mathrm{d}z/\mathrm{d}y$, is given by B_z/B_y. Set up the equation $\mathrm{d}z/B_z = \mathrm{d}y/B_y$ and note that the left side contains only z while the right side contains only y. They can therefore be integrated separately. Remember to add a constant of integration.

CHAPTER

17

Small-signal RF amplifiers

In this chapter we discuss the amplifiers used commonly in the front-end and IF stages of receivers and in antenna-mounted preamplifiers. The maximum output power of these amplifiers is typically from 0.01 W to 0.1 W (10–20 dBm). The power amplifiers discussed in Chapter 3 use the full range of the transistor conductance to “push” or “pull” the output voltage to any value from zero to the dc supply voltage(s). Small-signal amplifiers, on the other hand, are class-A amplifiers in which the signal voltages are small, compared with the dc bias voltages. The small ac signals add to dc bias voltages, so the output signal, δV_{out}, produced by an input signal δV_{in} is given by $\delta V_{out} = [dV_{out}/dV_{in}]\ \delta V_{in} + 1/2\ [d^2 V_{out}/dV_{in}^2]\ (\delta V_{in})^2 + \cdots$ The ac voltage gain is, therefore, $dV_{ou}t/dV_{in}$, evaluated at the quiescent bias point. When operated over only a small range of δV_{in}, the higher derivatives of V_{out} versus V_{in} make only small contributions, and the amplifier is essentially linear. Key characteristics of these amplifiers are gain, bandwidth, input and output impedances, linearity (those higher derivatives), and internally generated noise.

17.1 Linear two-port networks

Small-signal amplifiers are linear amplifiers; the output signal should be a faithful reproduction of the input signal.[1] A general definition of small-signal amplifiers could be that they are amplifiers built entirely of nominally linear elements (which include resistors, capacitors, inductors, transmission lines, and transistors operated over a small differential range), from which it follows that the overall circuit will also be nominally linear. An amplifier, being an example of a two-port network (or simply a “two-port”), has an input terminal, an output terminal, and a common terminal (ground). The operation of any linear two-port can be described by four variables: the input and output voltages and currents. Any two of these variables can be considered independent variables ("input" or "cause"). The remaining two variables are then dependent variables ("output" or "effect"). If, for example, V_1 and V_2 are chosen as the dependent variables, the two-port is described by the equations:

---

[1] While small-signal amplifiers are linear almost by definition, an important exception is the limiting amplifier or *limiter*. In these amplifiers, the gain decreases for increasing signal levels. A cascade of limiters can have an output level almost independent of input level. A limiter is used ahead of an FM detector if the particular FM detector is sensitive to amplitude variations as well as frequency variations.

$$V_1 = Z_{11}I_1 + Z_{12}I_2 \tag{17.1}$$

$$V_2 = Z_{21}I_1 + Z_{22}I_2. \tag{17.2}$$

For this choice of dependent variables, the four coefficients are known as the Z *parameters*. We are implicitly dealing with ac circuit analysis, so these four parameters generally are complex and are functions of frequency. The important point to note is that, for a given frequency, *any* two-port network (amplifier, filter, transmission line, etc.) can be completely described by just four complex numbers. By convention, the current at either terminal is positive when it flows *into* the terminal. Note that the output variables are linear functions of the input variables, since the input variables appear raised only to the first power.[2] By inspection of Equation (17.1) we see that Z_{11} is the network's input impedance when the output current is zero, i.e., when the output is open circuited. The *forward transfer impedance*, Z_{21}, is the open-circuit output voltage divided by the input current – a "transimpedance." If we are given the load impedance, we can use Equations (17.1) and (17.2) to calculate the power gain of an amplifier (Problem 17.1). The *reverse transfer impedance*, Z_{12}, is a measure of reverse feedthrough. If the RF amplifier preceding an unbalanced mixer in a superheterodyne receiver has reverse feedthrough, some power from the local oscillator will get to the antenna and be radiated. But what is more important, reverse feedthrough can cause an amplifier to oscillate for certain combinations of input and output terminations. This two-port formalism provides more than just a top-level description of an amplifier. It is the basis for amplifier circuit analysis and design, since the active devices (transistors) inside the amplifier can themselves be represented as two-port networks, whose parameters are furnished by the manufacturer on data sheets. Another equivalent set of parameters is the Y-parameters, defined by

$$I_1 = Y_{11}V_1 + Y_{12}V_2 \tag{17.3}$$

$$I_2 = Y_{21}V_1 + Y_{22}V_2. \tag{17.4}$$

Conversion formulas between parameter sets are easily derived. For example,

---

[2] The dependence of the output variables on only the first power of the input variables follows from a general definition of linearity: If an input *a* causes an output *A* and an input *b* causes an output *B*, then an input C_1a+C_2b, where C_1+C_2 are constants, will result in an output C_1A+C_2B.

$$Y_{11} = \left.\frac{I_1}{V_1}\right|_{V_2=0.} = \left[Z_{11} - \frac{Z_{21}Z_{12}}{Z_{22}} \right]^{-1}. \tag{17.5}$$

The widely used *S-parameters*, which are the subject of Chapter 28, form another equivalent four-parameter set, for which the variables are linear combinations of the voltages and currents, and correspond to input and output waves at each port. Two of the parameters, S_{11} and S_{22}, are reflection coefficients, while the other two are transmission coefficients. A characteristic impedance, Z_0, usually 50 ohms, is implicit. Again, conversion formulas are readily derived, for example,

$$S_{11} = \frac{Y_{22} + Z_0^{-1} - Z_0(Y_{11}Y_{22} + Y_{11}Z_0^{-1} - Y_{12}Y_{21})}{Y_{22} + Z_0^{-1} + Z_0(Y_{11}Y_{22} + Y_{11}Z_0^{-1} - Y_{12}Y_{21}}. \tag{17.6}$$

In this introductory chapter, we discuss amplifiers in terms of voltages and currents, in the interest of presenting the basic concepts in terms totally familiar to the reader.

17.2 Amplifier specifications – gain, bandwidth, and impedances

The small-signal gain (forward and reverse), bandwidth, input impedance and output impedances could be called “linear specifications” because they can all be calculated from the amplifier’s Z-parameters or from any of the other equivalent sets of parameters. The gain and bandwidth of an amplifier are ultimately limited by the characteristics of the transistor(s). Transistors have unavoidable built-in reactances: there are at least two capacitors in even the simplest transistor circuit models (approximate equivalent circuits). Elaborate models for microwave transistors can contain a dozen capacitors and inductors. Amplifiers designed for narrowband use (fractional bandwidths of 20% or less) use input and output matching networks to absorb or “cancel” these reactances. At higher frequencies, the shunt capacitive reactances become lower. The matching networks must then necessarily have higher loaded Qs which means that bandwidth decreases. This limitation is fundamental; no matter how complicated the matching network, gain must be traded for bandwidth. Negative feedback around a transistor will lessen the effect of its reactances. But feedback decreases the gain so again there is a tradeoff between gain and bandwidth. In some applications the input and output impedances of an amplifier are critical. For example, if a narrowband filter is placed between two amplifiers, the amplifiers must present the proper impedances to the filter if the intended passband shape is to be realized. The frequency dependences of the input and output impedances of an amplifier are, of course, related to the bandwidth, since the frequency response is normally determined by mismatch (i.e., reflection).

17.2.1 Amplifier stability

An amplifier is required to be stable (not oscillate) in its working environment. A 100-MHz amplifier, for example, will not be satisfactory if it oscillates, even at a very different frequency, say 1 GHz. Oscillation invariably takes the circuit into large-amplitude excursions and the combination of amplification and oscillation is highly nonlinear. An amplifier that remains stable when presented with *any* combination of (passive) source and load impedances (but no external feedback paths) is said to be *unconditionally stable*. Unconditional stability is not always necessary. An IF amplifier in a receiver needs only to be stable in its never-changing working environment. The input RF amplifier in a short-wave radio, however, might be connected to any random arbitrary antenna so it should be unconditionally stable, at least with respect to input impedance. General-purpose commercial modular amplifiers are usually designed to be unconditionally stable. Using these, a system designer can realize a needed transfer function by cascading amplifiers, filters, etc., and know that the combination will be stable. Stability, like gain and input and output impedances, is predictable from the two-port parameters. To find whether an amplifier will be unconditionally stable, it is necessary and sufficient to show that the real parts of the input and output impedances for any frequency are positive for any passive load and source impedances. Suppose that an analysis shows that for some combinations of load impedance and frequency, the real part of the input impedance is negative, but never more negative than −5 ohms. Then adding a series resistor of more than 5 ohms to the input of the amplifier would make it unconditionally stable. Such resistive remedies, however, always decrease gain and increase internally generated noise. The reverse transfer parameter (Z_{12}, Y_{12}, S_{12}, …) plays a key role in stability. For example, a sufficient (but not necessary) condition for unconditional stability is that its reverse transfer parameter be equal to zero. It is important to note, however, "unconditional stability" simply means that the two-port cannot be provoked into oscillation by varying its termination impedances. A multistage amplifier circuit could contain an oscillating internal stage and still have input and output impedances with positive real parts for all frequencies and arbitrary terminations. (Of course a multistage amplifier will be unconditionally stable if every stage is unconditionally stable.)

17.2.2 Overload characteristics

Any amplifier will become nonlinear at high enough signal levels, if only because the output runs up against the "rail" of the dc power supply. But before this occurs, transistor nonlinearity comes into play. A straightforward specification of an amplifier's upper power limit is the *1-dB compression point*. This is the value of the output power at which the gain has dropped by 1 dB, i.e., the point at which the output power is 79.4% of what would be predicted on the basis of low-power gain measurements.

Intermodulation

Small departures from linearity, even when the amplifier is far below compression, become a concern in a receiver when the passband of an RF amplifier contains two or more signals at frequencies f_a, f_b, f_c, … that are much stronger than the desired signal (the signal that will be isolated downstream by a narrow bandpass filter). Nonlinearity can produce mixing products at frequencies of $n_a f_a + n_b f_b + n_c f_c + \cdots$ where $n_i = 0, \pm1, \pm2, \ldots$ In receivers, the most troublesome of these products are the third-order products $2f_a - f_b$ and $2f_b - f_a$. (Third-order products will be inevitably produced if the output voltage of an amplifier contains even a small term proportional to the cube of the input voltage.) The special problem with these particular products is that they can fall within the IF passband. To see this, suppose f_2 and f_3 are the frequencies of signals close enough to a desired frequency, f_1, that they will pass through the broadband front-end of a receiver. The local oscillator is tuned to convert f_1 to the center of the IF passband. But the third-order products $2f_3 - f_2$ and/or $2f_2 - f_3$, being very close to f_1, can also fall within the narrow IF passband and interfere with the desired signal. Second-order intermodulation is not so troublesome since the products have frequencies far outside the IF passband.

A standard measurement of intermodulation is the *two-tone test*, which uses two closely spaced signals of equal amplitude, A. On a log-log plot of output power versus input power each of these fundamental signals will fall on a 45° line, with slope = 1. The third-order products, however, will fall on a line with slope = 3 because the power in the third-order products is proportional to the cube of the power in each of the input signals. The *third-order intercept* is the point at which the third-order product would have as much power as each of the fundamental signals. Usually the number given for the intercept point is the *output* signal strength. The second-order intercept is defined the same way. Figure 17.1 shows a third-order intercept point of about +37 dBm. Generally an

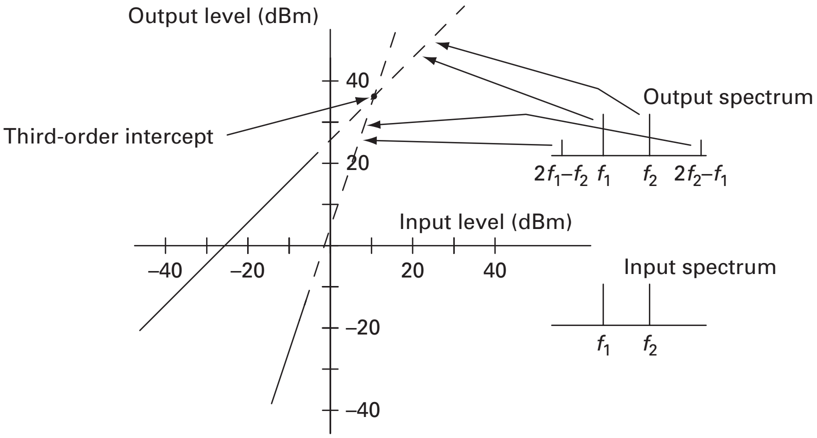

Figure 17.1. Two-tone test to specify amplifier linearity.

amplifier cannot be driven all the way to the intercept points; they are extrapolations from measurements made at much lower input levels. (The output strengths of the fundamental and the second- or third-order product need only be measured at one input level. Lines with slopes of one, two, or three are then drawn through them to locate the intercepts.)

Dynamic range

Every amplifier adds some noise to the signal. (Later we will discuss amplifier noise in some detail.) Very weak signals will be buried in this noise and lost. The *dynamic range* of an amplifier is therefore determined at the low end by the added noise and at the high end by nonlinearity. In order to handle strong signals, a receiver should keep mixing products small by having as little amplification as possible prior to the narrowest bandpass filter. We will see, on the other hand, that if a receiver begins with a mixer or with a narrowband filter, the loss in these elements adds noise and will render the receiver less sensitive than if the first element after the antenna had been a low-noise amplifier. A trade-off must often be made between sensitivity and dynamic range. Power dissipation is obviously important for battery-operated equipment where milliwatts may count. But to achieve high dynamic range, a small-signal amplifier may have a fairly high-power quiescent point and have to dissipate as much as several watts of power.

17.3 Narrowband amplifier circuits

Amplifiers for frequencies below about 30 MHz look very much like resistance-coupled audio amplifiers. The load resistors are replaced by shunt inductors which cancel the transistor capacitances, which would otherwise tend to be short circuits at RF. These resonant circuits make a narrowband amplifier. Often an even narrower bandpass is desired; the inductors are given smaller values and are shunted with external capacitors (effectively increasing the transistor capacitances). Focusing on one stage of an amplifier (or an amplifier of one stage), the fundamental design decisions are transistor selection and circuit configuration, i.e., common-emitter, common-base, or common-collector. (Here, and usually elsewhere, *emitter, base*, and *collector* can also mean *source, gate, and drain*.) The choice of a transistor will be based on the ability to provide gain at the desired frequency, noise, and perhaps linearity. The orientation of the transistor might be common-emitter when maximum gain is required, common-base when the device is being pushed near its upper frequency limit or when the isolation between input and output is critical, or common-collector when very low output impedance is needed. As far as noise goes, it turns out that the three orientations are equivalent when used in a high-gain multistage amplifier.

17.4 Wideband amplifier circuits

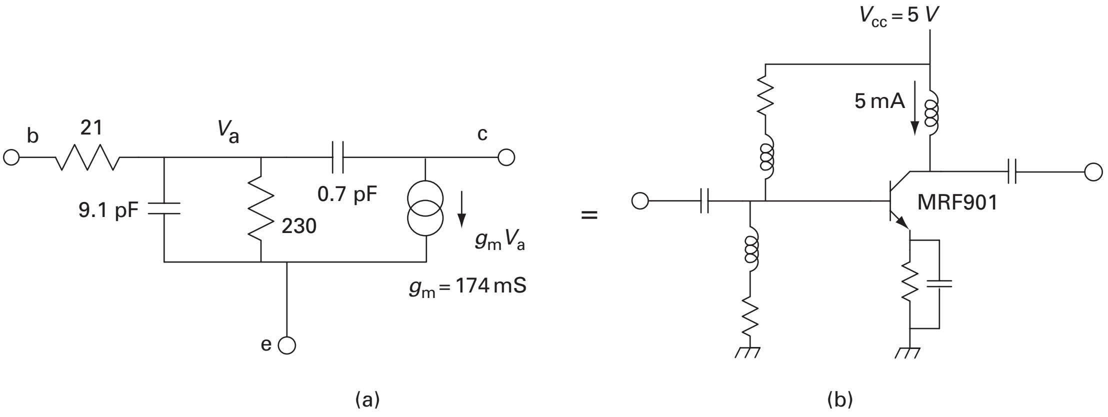
Most wideband amplifiers use feedback. An unbypassed emitter impedance provides series feedback. An impedance between collector and base provides shunt feedback. Commercial modular general-purpose amplifiers use resistive series and shunt feedback. These amplifiers are quite flat up to one or two GHz and have input and output impedances close to 50 ohms over the whole range. Resistive feedback is simple but degrades the noise performance of an amplifier. Wideband low-noise amplifiers often use feedback networks made only of lossless elements, i.e., reactors. The Miller[3] effect multiplies the effective input capacitance in a common-emitter amplifier. This capacitance can be neutralized, at least in a narrowband amplifier. Wideband amplifiers often use the *cascode* circuit in which a common-emitter input stage drives a (low impedance) common base stage. Another good high-frequency circuit, the differential pair, uses an emitter follower stage (high input impedance and low output impedance) to drive a common-base stage.

17.5 Transistor equivalent circuits

An amplifier designer needs a precise electrical description of the transistor(s). For analysis, it is sufficient to have tables of the small-signal parameters of the transistor(s). These tables are usually given in data sheets from the manufacturer; they can be produced using a vector network analyzer. A table of numbers, however, is an awkward representation for design (synthesis) and a common tactic is to represent the transistor by an (approximately) equivalent model circuit of resistors, capacitors, inductors, voltage-controlled voltage generators, voltage-controlled current generators, etc. An exact equivalent circuit for a single frequency can be constructed directly from the small-signal parameters corresponding to that frequency (Problem 17.4). This might be an adequate model for the design of a narrowband amplifier but remember that even an amplifier intended for only a narrow frequency range must be stable at *all* frequencies. For this reason, and also to aid in the design of wideband amplifiers, models are constructed to represent the transistor over a wide frequency range. Normally the topology of an equivalent circuit is based on the construction and physics of the transistor. The element values are determined by least-square fitting programs that make the small-signal parameters of the model agree as closely as possible with the measured small-signal

---

[3] The collector signal in a common-emitter amplifier has a larger magnitude (due to amplification) than the base signal. It also has the opposite sign. The voltage across the transistor's inherent base-to-collector capacitance is therefore larger than the base voltage. As a result, more current flows in this capacitance than if the collector were grounded. The value of the capacitance is, in effect (Miller effect), multiplied.



(a) (b)

Figure 17.2. Simple equivalent circuit model for the MRF901 bipolar transistor (100 MHz-2 GHz).

parameters of the actual transistor over the desired frequency range. Agreement can always be improved by adding more elements to the model, but an overly-complicated model will block the intuition of the designer. Equivalent circuits have from one to perhaps twenty parameters. Figure 17.2(b) shows a simple "hybrid-π" equivalent circuit model for a common high-frequency transistor. The component values in the model circuit were determined by least-square fitting to the data sheet values over the range from 100 to 2000 MHz. Since the equivalent circuit models a *biased* transistor, it is actually equivalent to the circuit like that of Figure 17.2(a), which includes a power supply and dc biasing components. The biasing components include three resistors to set the dc collector current. A bypass capacitor grounds the emitter at RF frequencies. Blocking capacitors keep the dc bias voltages from interacting with circuitry outside the transistor and vice versa. An RF choke (inductor) provides enough reactance that practically no signal current can flow from the collector to V_{cc} (RF ground). Two more two chokes prevent RF currents from flowing in the base bias resistors. (Usually these resistors have high enough values that these chokes are unnecessary.)

17.6 Amplifier design examples

Designing a small-signal amplifier for microwave frequencies can be difficult, especially when the design must meet specifications for frequency response, gain, stability, input and output impedances, and noise. Computer-aided design is often used. But, to provide an example, let us design a simple amplifier using the transistor model of Figure 17.2. The amplifier is to be driven from a 50-ohm source and is to drive a 50-ohm load. The only other specifications imposed are that the power gain be at least 10 dB at 430 MHz, and that the amplifier not oscillate while connected to the specified source and load. Let us try a very simple common-emitter circuit consisting of the transistor with a matching inductor in series with the collector (rather than going with a two-element

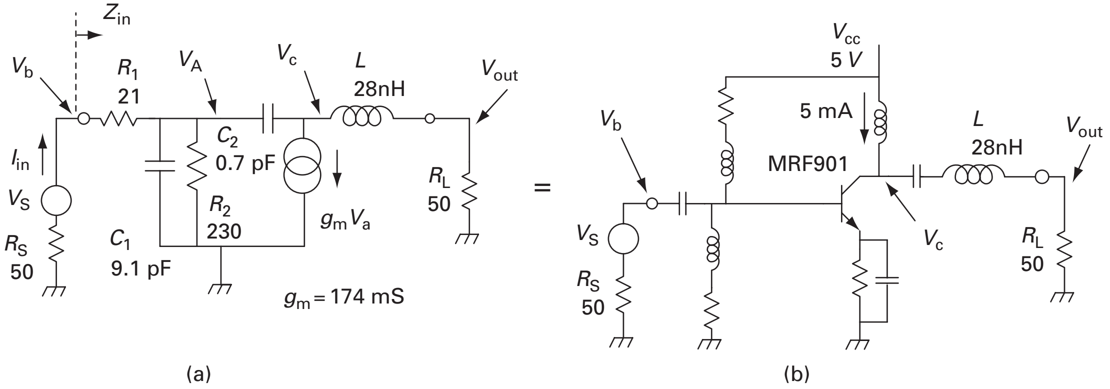


Figure 17.3. Common-emitter amplifier design example: (a) small signal equivalent circuit; (b) full circuit.

matching circuit on each side). The small-signal equivalent circuit of the amplifier is shown in Figure 17.3(a), while the complete amplifier, including bias circuitry, is shown in Figure 17.3(b).

The circuit of Figure 17.3(a) can be analyzed to find V_c in terms of V_b. The output voltage, V_{out}, is then simply $V_c R_L/(R_L + j\omega L)$. Note first that the currents to ground must sum to zero or

$$\frac{V_A - V_b}{R_1} + \frac{V_A}{R_2} + V_A j\omega C_1 + V_A g_m + \frac{V_c}{j\omega L + R_L} = 0. \tag{17.7}$$

Next, consider the current flowing to the left through C_2. This gives us the equation

$$(V_c - V_A)j\omega C_2 = \frac{V_A - V_b}{R_1} + \frac{V_A}{R_2} + V_A j\omega C_1. \tag{17.8}$$

Solving these two equations for V_c as a function of V_b, we find

$$V_c = \frac{-V_b(g_m - j\omega C_2)/R_1}{j\omega C_2(1/R_1 + 1/R_2 + j\omega C_1 + g_m) + (1/R_1 + 1/R_2 + j\omega(C_1 + C_2))/(R_L + j\omega L)}. \tag{17.9}$$

From inspection of Figure 17.3, we see that $V_{out} = V_c R_L/(R_L + j\omega L)$ and that the input current, I_b, is given by $I_b = (V_b - V_A)/R_1$. Since we have already found V_c as a function of V_b, Equation (17.7) (or 17.8) gives us V_A, which lets us calculate I_b and also the input impedance, $Z_{in} = V_b/I_b$. The input power (drive power delivered to the amplifier) is given by $|I_b|^2$ Re(Z_{in}). The power gain of the amplifier is then calculated from

$$\text{Power Gain} = \frac{\text{power out}}{\text{power in}} = \frac{|V_{out}|^2/R_L}{|I_b|^2 \mathrm{Re}(Z_{in})}. \tag{17.10}$$

These expressions are easy to evaluate using a program such as Mathcad or MATLAB. Using Equation (17.9), we find that the power gain at 430 MHz reaches a maximum of 17.25 dB for $L = 28$ nH. This is within 0.25 dB of the

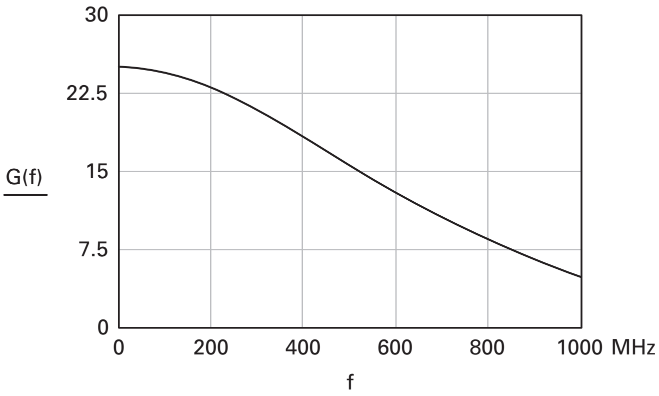

Figure 17.4. Power gain vs. frequency for common-emitter amplifier design example.

maximum power gain available from this transistor (which could be obtained by using a two-element output matching network rather than just a series inductor). Figure 17.4 shows the power gain versus frequency. The input impedance is 13.3–17.0j, from which you can calculate that the output power can be increased by 2.18 dB by the addition of an input matching network to transform the 50-ohm source impedance to 13.3+17.0j.

Analysis of even this simple amplifier requires a fair amount of algebraic effort. Problem 17.5 shows you how to add the hybrid-π transistor model to the circuit analysis program of Problem 1.3. This addition will let you plot the frequency response and find input and output impedances of this amplifier or any arbitrary cascade of transistors and other two-port devices.

We can check the stability of this amplifier when connected to the specified 50-ohm source and load impedances by verifying that any arbitrary set of initial conditions (two capacitor voltages and one inductor current, at $t=0$) results in transient currents that decay exponentially rather than grow exponentially. Because the circuit is linear, we know that there will be transient solutions in which the time dependence goes as $e^{j\omega t}$, where ω is a *characteristic frequency.* If ω has a positive imaginary part, the solution decays exponentially. To find the characteristic frequencies, we set the source voltage, V_s, equal to zero, and assume that V_A and V_B in Equations (17.7) and (17.8) are proportional to $e^{j\omega t}$. Solving these equations results in a third-order polynomial in ω which must be equal to zero. The three roots of the polynomial turn out to be $\omega_1 = j\,2.64E9$, $\omega_2 = j2.16E9$, and $\omega_3 = j18.1E9$. This shows that all three of these transient solutions will decay exponentially, since their imaginary parts of the three frequencies are all positive.[4] For example, $e^{j\omega_1 t} = e^{-2.64E9\ t}$, which is an exponential decay with a time constant of 0.38 nsec. A superposition of these three particular solutions that satisfies an arbitrary initial set of initial conditions will, therefore, produce a decaying transient and this circuit will be stable with the 50-ohm source and load impedances.

---

[4] Here, the three roots are purely imaginary. In general, they also have real parts, corresponding to decaying *oscillations*. For example, if the load resistance is changed from 50 to 500 ohms, the three roots become j2.44e8 and ±6.89e9 + j1.94e10.

Let us check stability if we add an input matching network consisting of a series inductor with 17 ohms of reactance to cancel the −j17.0 input reactance and a transformer to step the 50-ohm source down to 13.3-ohm input resistance. With the addition of a fourth reactive element, the circuit will now have four characteristic frequencies. Straightforward algebraic manipulations produce a fourth-order polynomial in ω whose four roots are ±4.18E9 +j7.83E8, j2.28E10, and j2.48E10. Since the imaginary parts are positive, the amplifier remains stable with this input matching network and the amplifier's *available gain* (power available from the amplifier divided by power available from the source) becomes equal to the power gain. Chapter 28 discusses how stability is usually evaluated in the context of *S* parameters.

Figure 17.5(a) shows an amplifier using the same transistor model arranged in a common-base configuration; the base is grounded and the input signal is applied to the emitter. The equivalent small-signal circuit is shown in (b).

You can analyze this circuit with the methods used above for the common-emitter configuration. Write one equation that sets to zero the sum of all the currents away from node "A." Do the same for node "c" (the collector terminal) and solve the two equations simultaneously for V_c as a function of V_e (the emitter voltage).

Figure 17.6 shows a model for a microwave GaAS FET, which can be used in place of the BJT model for the same kind of amplifier analysis. Manufacturers'

Figure 17.5. A common-base RF amplifier.

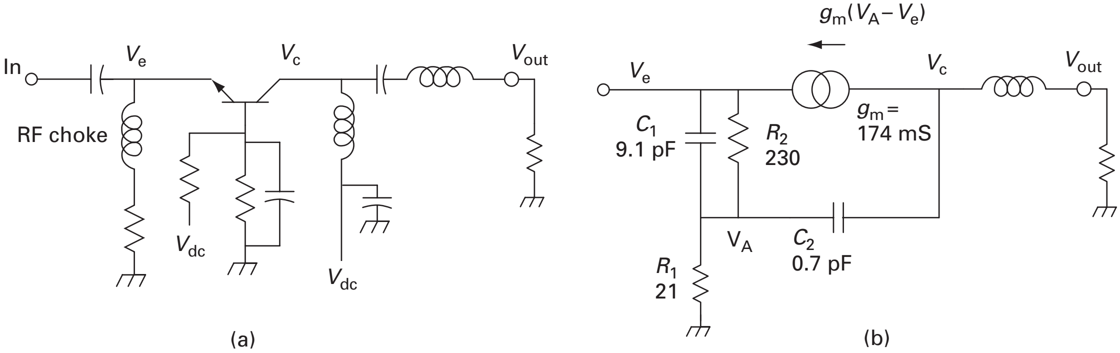

Figure 17.6. High-frequency GaAs FET model.

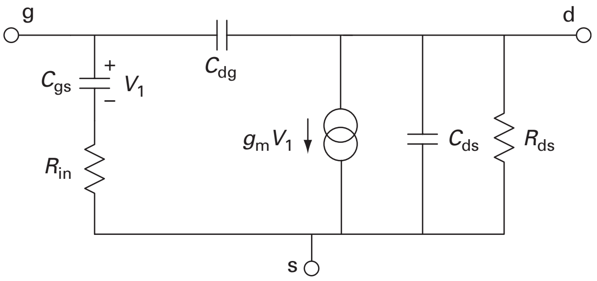


data sheets often include model circuits along with two-port data. There are many excellent textbooks devoted entirely to the amplifier design.

17.7 Amplifier noise

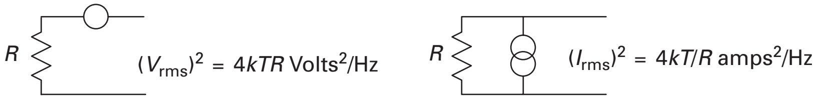
The output signal from any amplifier will always include some random noise generated within the amplifier itself. Most of the hiss from a radio receiver is due to noise generated by atmospheric electricity. But if the antenna is disconnected, the noise does not entirely disappear. The remainder is being generated within the receiver. Physical mechanisms that cause this noise include thermal noise (discussed below) and shot noise, which is noise due to the randomness in the flow of discrete charges – electrons and holes in transistors. The first stage in most receivers is an RF amplifier, and its noise usually dominates any other receiver-generated noise. This is easy to see; since this stage usually has considerable gain, its output power will be much greater than the noise power contributed by the second stage, so the second stage will hardly change the signal-to-noise ratio. In the same way, noise contributed by the third stage is even less important, and so forth.

Thermal noise

Thermal noise is such a universal phenomenon that it provides the very vocabulary for the definition of terms such as *receiver noise temperature* and *antenna noise temperature*. Let us examine the fundamentals of thermal noise. Any object, being hotter than absolute zero, converts thermal energy (molecular vibrational energy) into electromagnetic radiation: at infrared radiation for ordinary temperatures, but also visible radiation, if the object is red hot. Likewise, a resistor can convert thermal energy into electrical power. If two resistors are connected in parallel, each one delivers a tiny amount of electrical power (in the form of a random voltage waveform) to the other. If they are at equal temperatures, the power flow is equal in both directions.

How much power can a resistor generate by virtue of being hot? Answer: Any resistor can deliver kT watts per hertz, that is, kT is the spectral density of the power that a resistor of R ohms will deliver to a matched load (a load of impedance R+j0). Here k is Boltzmann's constant (1.38×10^{-23} joule/kelvin $= 1.38 \times 10^{-23}$ watt seconds/kelvin) and T is the absolute temperature. It is useful to remember that for $T_0 = 290$ K, which is universally taken as a standard reference temperature, the power available from a resistor, referred to 1 mW, is $= -114$ dBm/MHz, since $10 \log (1.38 \times 10^{-23} \times 10^3 \times 290 \times 10^6) = -114$.

To demonstrate that a resistor should produce this power, kT watts/Hz, an argument appropriate to radio engineering considers an antenna surrounded by a blackbody, i.e., an antenna within a cavity whose walls are at temperature T_1. We will be concerned with the spectral density at a particular spot frequency so



R
$(V_{rms})^2 = 4kTR$ Volts^2/Hz
R
$(I_{rms})^2 = 4kT/R$ amps^2/Hz

Figure 17.7. Equivalent circuits for a resistor as a noise source.

we can specify that the antenna be resonant, i.e., that it have a purely resistive impedance, R+j 0, at that frequency. Let a transmission line connect the antenna to a resistor R which is outside the blackbody but also at temperature T_1. We know the antenna will intercept blackbody radiation and that power will be transmitted through the line to the external resistor. We also know from thermodynamics that, in this isolated system, it is impossible for the resistor to get hotter than T_1; heat cannot flow from a colder to a hotter object. The only way to resolve this is for the resistor to produce an equal amount of power, which travels back to the antenna and is radiated back into the cavity. We can use some antenna theory to calculate the power. All antennas are directive; when used to receive, they have more effective area to intercept power from some directions than from other directions. But for any antenna, the average area turns out to be $\lambda^2/4\pi$ where λ is the wavelength. Blackbody radiation flux at long wavelengths is given by the Rayleigh–Jeans law, brightness = $2kT/\lambda^2$ watts/m^2/Hz/steradian. This includes power in two polarizations. Since any antenna can respond to only one polarization, we use half the Rayleigh–Jeans brightness to calculate the power the antenna puts on the transmission line:

$$P = \int \frac{B(\theta,\phi)}{2} A(\theta,\phi)\mathrm{d}\Omega = \frac{kT}{\lambda^2}\frac{\lambda^2}{4\pi}4\pi = kT. \qquad (17.11)$$

This value, kT, is then also the power a resistor of R ohms will deliver to another resistor of R ohms. It follows that the open-circuit noise voltage from a resistor is therefore $\langle V_n^2 \rangle = 4kTR$ volt^2/Hz. Figure 17.7 shows the Thévenin and Norton equivalent circuits of a resistor as a noise generator.

17.8 Noise figure

At any given frequency, a figure of merit for a receiver, an amplifier, a mixer, etc., is its *noise figure*, whose definition is as follows:

> Noise figure is the ratio of the total output noise power density to the portion of that power density engendered by the resistive part of the source impedance, with the condition that the temperature of the input termination be 290 K.

Noise figure is a function of frequency and of source impedance but (as we will see later) is independent of output termination. Consider Figure 17.8.

The voltage source V_n represents the thermal noise voltage from R_s, the resistive part of the source impedance. The source, V_s, is the actual signal voltage, if any. The internal noise of the amplifier can be considered to result

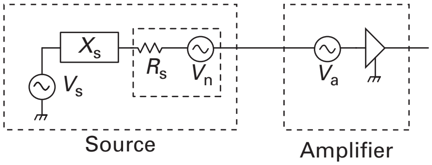


Figure 17.8. Equivalent circuit of an amplifier and signal source.

from another equivalent input noise source, V_a, at the input of the amplifier. With this model, the noise figure, as defined above, can be written in terms of V_n and V_a: $F = (V_n{}^2 + V_a{}^2)/V_n{}^2$. Note that, because the amplifier noise is represented by an equivalent generator at the input side, this expression does not contain G, the gain. Since $V_n{}^2$ is proportional to the source temperature, T_0, it is natural to assign the amplifier an equivalent noise temperature by writing the noise figure as $F = (T_0 + T_a)/T_0$. This amplifier noise temperature is just $T_a = (F-1)T_0 = (F-1) \times 290$ K. Conversely, the noise figure is given by $F = (290 + T_a)/290$. An amplifier can have a noise temperature less than its physical temperature. The dish-mounted amplifiers used for home satellite reception have typical noise temperatures of 30 K. (Refrigeration, however, can help; FET amplifiers for radio astronomy are often physically cooled to about 10 K and produce noise temperatures of only a few kelvins.)

So far we have not mentioned the signal voltage, V_s. Equation (17.12) shows that the noise figure also specifies the ratio of the input signal-to-noise ratio to the output signal-to-noise ratio:

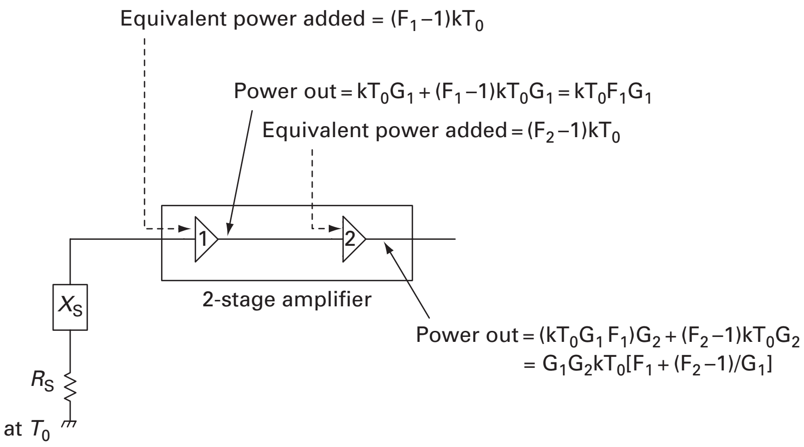
$$\frac{\text{Input SNR}}{\text{Output SNR}} = \frac{V_s^2/V_n^2}{V_s^2/(V_n^2 + V_a^2)} = (V_n^2 + V_a^2)/V_n^2 = \mathrm{F}. \tag{17.12}$$

Cascaded amplifiers

The noise from an amplifier of only modest gain will not totally dominate the noise added downstream, so it is useful to know how noise figures add. Suppose amplifier 1, with noise figure F_1 and gain G_1, is followed by amplifier 2 with F_2 and gain G_2. Suppose further that they are matched at their interface so that $G = G_1G_2$ and that the output impedance of amplifier 1 is equal to the source impedance corresponding to the specified F_2. Figure 17.9 shows how to compute the overall noise figure.

The noise figure of the cascade is $F_{12} = F_1 + (F_2 - 1)/G_1$. It is interesting to calculate the noise figure of an infinite cascade of identical amplifiers as it is a lower limit to the noise we would get from any shorter cascade. You can verify that T_{infinity}, the equivalent noise temperature of the infinite chain, is given by $T_a/(1 - 1/G)$ where T_a and G refer to the individual identical amplifiers.

Finally, let us look at the overall noise figure of an amplifier preceded by an attenuator, as shown in Figure 17.10. Suppose the gain of the attenuator is G_{attn}. (The gain of an attenuator is less than unity; the gain of a 6-db attenuator, for example, is 1/4.) Referred to the amplifier input, the noise power engendered by



Equivalent power added = $(F_1-1)kT_0$
Power out = $kT_0G_1+(F_1-1)kT_0G_1=kT_0F_1G_1$
Equivalent power added = $(F_2-1)kT_0$
1

R_S
at T_0

Figure 17.9. Overall noise figure of cascaded amplifiers.

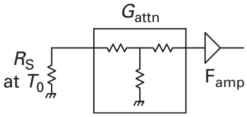

Figure 17.10. An amplifier preceded by an attenuator.

the source resistance is T_0G_{attn}. Since the amplifier still sees its standard source impedance, its total noise, referred to the input, is still $(F_{amp})T_0$.

The overall noise figure is therefore

$$F_{tot}=\frac{F_{amp}T_0}{G_{attn}T_0}=\frac{F_{amp}}{G_{attn}} \tag{17.13}$$

so, if an amplifier is preceded by an M-dB attenuator ($G_{attn}=10^{-M/10}$), the noise figure of the combination is M dB higher than the noise figure of the amplifier alone. We could just as well have derived this result by using the relation for cascaded devices. The noise figure of the attenuator, from the definition of noise figure, is $F_{attn}=kT_0/(G_{attn}kT_0)=1/G_{attn}$. The noise figure of the cascade becomes $F_{tot}=1/G_{attn}+(F-1)/G_{attn}=F/G_{attn}$ as before.

17.9 Other noise parameters

In what we have considered so far, the noise produced by a device, a transistor, amplifier, etc. is specified by a single parameter, its noise figure. But the noise figure depends on the source impedance from which the device is fed, which makes this parameter something less than a complete noise description of the device. We will see in Chapter 24 that a total of *four* noise parameters are sufficient to describe a device. The noise figure for any given source impedance can then be calculated from these four parameters which are R_{opt}, X_{opt}, F_{min}, and R_n. The (complex) impedance $Z_{opt}=R_{opt}+X_{opt}$ is the source impedance that yields the minimum noise figure, F_{min}. The "noise resistance," R_n, is a parameter that determines how fast the noise figure increases as the source impedance departs from Z_{opt}. We will see in Chapter 24 that the noise figure for an arbitrary source impedance is given by

$$F=F_{min}+(R_n/G_s)|Y_{source}-Y_{opt}|^2. \tag{17.14}$$

(Here Y_{opt} is just $1/Z_{\mathrm{opt}}$ and G_s is the real part of the source admittance.) We will also see that noise figure is somewhat deficient as a figure of merit. A piece of wire has $F = 1$ but is not a valuable amplifier since it has no gain. With a given transistor, circuit A might produce a lower noise figure than circuit B, but circuit A may have less gain. We will see that T_{infinity}, defined above, is the proper figure of merit.

17.10 Noise figure measurement

A straightforward determination of an amplifier's noise figure is possible if one knows its gain and has a spectrum analyzer suitable for measuring noise power density. Consider the common situation where we have an amplifier to be used in a 50-ohm environment. We connect a 50-ohm load to its input and use the spectrum analyzer to measure the output power density, S_{out}(watts/Hz), at the frequency of interest. We know that the portion of this power density engendered by the input load is kTG, where G is the amplifier gain. The noise figure is therefore given by $F = S_{\mathrm{out}}/(kTG)$. This assumes we have done the measurement at $T = 290\,\mathrm{K}$. If T was not 290, you can verify that $F = [S_{\mathrm{out}} - Gk(\mathrm{T} - 290)]/(290Gk)$. For low-noise amplifiers, a comparison method is used. This method requires a cold load and a hot load, i.e., two input loads at different temperatures, T_{hot} and T_{cold}. The amplifier is connected to a bandpass filter (whose shape is not critical) and then to a power meter (which needs to have only relative, not absolute accuracy). The ratio of power meter readings, hot to cold, is called the Y-factor. The noise temperature of the amplifier is then given by:

$$T_a = (T_{\mathrm{hot}} - YT_{\mathrm{cold}})/(Y - 1). \qquad (17.15)$$

Problems

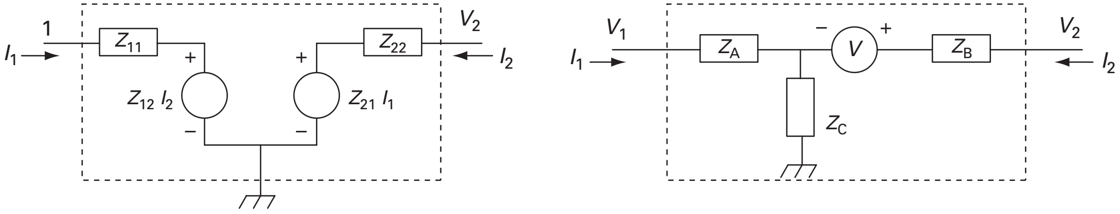
Problem 17.1. Derive an expression for the power gain (output power/input power) for the two-port network described by Equations (17.1) and (17.2) when the load impedance is Z_L.

Problem 17.2. For a general two-port network, derive expressions for the Y parameters in terms of the Z parameters.

Problem 17.3. (a) A certain amplifier with 20 dB of gain has a third-order intercept of 30 dBm (one watt at the output). If the input consists of 0 dBm (0.001watt) signal at 100 MHz and another 0 dBm signal at 101 MHz, what will be the output power of the third-order products at 102 MHz and 99 MHz?

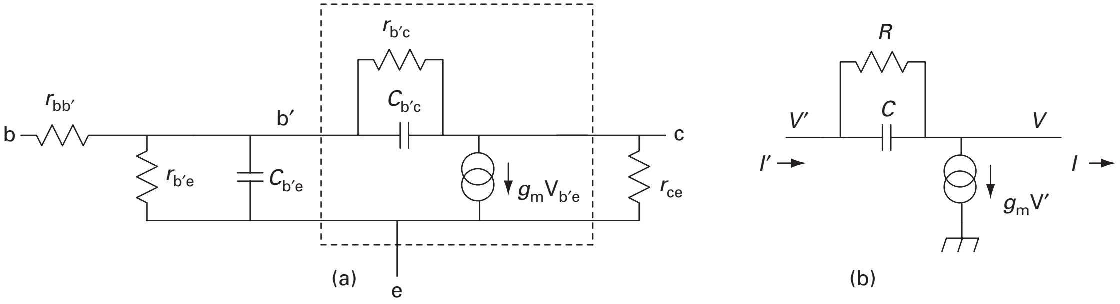
(b) Same as (a) except that the input signal at 100 MHz increases in power to 10 dBm (0.1 watt) while the input signal at 101 MHz remains at 0 dBm.

Problem 17.4. The Z-parameter description of a two-port corresponds in a one-to-one fashion to the equivalent circuit shown below in (a). Another circuit is shown in (b). Find expressions for Z_A, Z_B , Z_C and V in terms of the Z parameters to make the two circuits equivalent.



(a) (b)

Problem 17.5. The figure below at (a) shows a small-signal hybrid-π model for a common-emitter BJT transistor. (This model contains one more component than the model of Figure 17.2.)



(a) (b)

The components form a simple ladder network, except for the portion inside the dashed line box. Show, for this box, the circuit in (b), that the relations between the input voltage and current and the output voltage and current are given by

$$V' = \frac{V}{1 - g_m Z} + \frac{IZ}{1 - g_m Z}$$

and

$$I' = \frac{V g_m}{1 - g_m Z} + \frac{I}{1 - g_m Z}.$$

Use these equations to make this box a new circuit element in the analysis program of Problem 1.3. The program will then be able to analyze BJT common-emitter amplifiers. (Note that the other two resistors and the other capacitor in this hybrid-π model can be included in a circuit as if they were external components.)

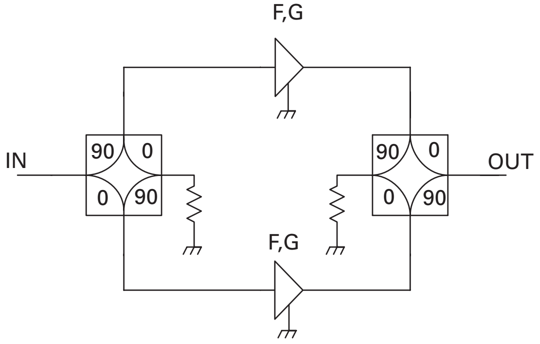
Example answer: For the MATLAB example given in Problem 1.3, add the element, “HY_PI” by inserting the following sequence of statements in the “elseif chain”:

```
elseif strcmp(component,HY_PI)==1
ckt_index=ckt_index+1; gm=ckt{ckt_index}; %gm
ckt_index=ckt_index+1; R=ckt{ckt_index};%R
ckt_index=ckt_index+1; C=ckt{ckt_index}; %C
Z=R/(1+1j*w*R*C);
Iold=I; I=(I+gm*V)/(1-gm*Z);V=(V+Iold*Z)/(1-gm*Z);
```

Problem 17.6. Show that the noise figure of an infinite cascade of identical amplifiers is given by $F_\infty = (F - 1/G)/(1 - 1/G)$. Assume that the amplifiers have a standard input and output impedance such as 50 ohms, that G is the gain corresponding to this impedance, that F is the noise figure corresponding to a source of this impedance, and that F_∞ is also to be with respect to this standard impedance. Hint: use the formula for a cascade of two amplifiers and the standard "infinite-chain-of-anything" technique – adding another link does not change the answer.

(This problem is not just academic. With only a few amplifiers the gain will be high enough to make the noise figure very close to F_∞ which is the best possible combination of the given amplifiers.)

Problem 17.7. Consider the balanced amplifier circuit shown below. The 3-dB, 90° hybrids are ideal. The amplifiers are identical and all impedances are matched. The individual amplifiers have power gain G and noise figure F_0. The hybrids are perfect, i.e., they have no internal loss and are perfectly matched.



a. Show that the overall noise figure of this circuit is equal to the noise figure of the individual amplifiers.
b. If one amplifier dies, i.e., provides zero output, what is the overall noise figure?

Problem 17.8. We derived the overall noise figure, $F_{\text{tot}} = F\,(G_{\text{attn}})^{-1}$, for an amplifier preceded by an attenuator when the physical temperature of the attenuator is T_0, the standard 290 K reference temperature. Assuming now that the attenuator is at some different physical temperature, T_1, show that the overall noise figure is given by $(G_{\text{attn}})^{-1}$ $[G_{\text{attn}} + (T_1/T_0)(1 - G_{\text{attn}}) + \mathrm{F} - 1]$.

CHAPTER

18 Demodulators and detectors

In communications equipment, "detection" is synonymous with demodulation, the process of recovering information from the received signal. The term detector is also used for circuits designed to measure power, such as square-law microwave power detectors. In this chapter we discuss various AM, FM, and power detector circuits. The demodulator is the last module in the cascade of circuits that form a receiver and at this stage the frequencies (IF or baseband) are relatively low. For this reason the detector (and, sometimes, the final IF bandpass filter) was the first receiver section to evolve from analog to digital processing, notably in broadcast television receivers. Receivers for ordinary AM and FM have, for the most part, continued to use traditional analog detectors, but receivers for the newer digital radio formats can also use their digital signal processors to demodulate traditional AM and FM broadcasts. Demodulators for OFDM and CDMA digital modulation formats are discussed in Chapter 22.

18.1 AM detectors

There are two basic types of AM detector. An envelope detector uses rectification to produce a voltage proportional to the amplitude of the IF voltage. A "product" detector multiplies the IF signal by a reconstituted version of the carrier. This detector is a mixer (see Chapter 5), producing sum and difference frequencies. The sum component is filtered away. The difference frequency component, at $f = 0$ (baseband), is proportional to the amplitude of the IF voltage.

18.1.1 AM diode detector

The classic diode envelope detector circuit for AM is shown in Figure 18.1. The input signal voltage, $V_{\text{sig}}\cos(\omega t)$, is usually provided by a tuned transformer at the output of the IF amplifier. This tuned circuit forms part of the IF bandpass filter.

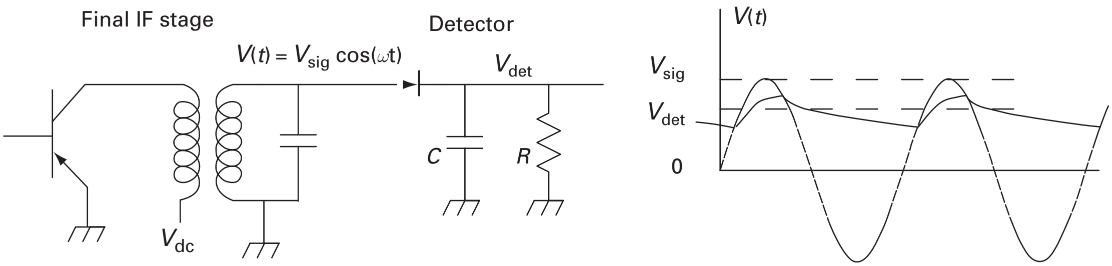

Figure 18.1. Diode envelope detector.

The diode and the parallel *RC* form a fading-memory peak detector. Except for the resistor, *R*, the output capacitor would remain charged to the maximum peak voltage of the input sine wave. The resistor provides a discharge path so that the detector output, V_{det}, can follow a changing peak voltage (AM). Since the input sine wave, an RF signal, has a much higher frequency than the amplitude modulation frequencies, the *RC* time constant can be made large enough so that the droop between charge pulses is much less than indicated in Figure 18.1. (Of course the time constant must also be small enough that output voltage can accurately follow a rapidly changing modulation envelope.) This detector, or any other envelope detector, is known as a *linear detector* since its output voltage is linearly proportional to the amplitude of the input sine wave.

Analysis assuming an ideal rectifier

Note that the detector of Figure 18.1 is identical to a simple half-wave rectifier capacitor-input power supply. As with the power supply, this circuit has poor regulation with respect to a changing load. But here we have a constant load resistance *R* (which we will assume includes the parallel input resistance of the subsequent audio amplifier). The equivalent circuit is shown in Figure 18.2. If the diode is modeled as a perfect rectifier (zero forward resistance and infinite reverse resistance) the analysis of this circuit is straightforward. The value of the diode's forward resistance, R_{d}, can be increased to account for source resistance. But here the high-*Q* resonant circuit at the detector input forces the waveform to remain sinusoidal. If we assume that *C* is large enough to make the output ripple negligible compared to the output voltage, the output voltage, V_{det}, can be calculated by noting that V_{det}/R must equal the average current through the diode, which is the average of $(V-V_{\mathrm{det}})/R_{\mathrm{d}}$ during the part of the input cycle

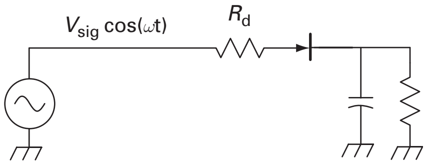

Figure 18.2. Diode envelope detector equivalent circuit.

when this expression is positive. The result is that V_{det} is proportional to the source voltage. (Curves showing output voltage vs. ωCR for various values of R_{d}/R are found in the power supply chapters of many handbooks.) The ratio of V_{det} to the peak source voltage is known as the detector efficiency. For a typical AM detector, $R \geq 10R_{\mathrm{d}}$ and $\omega CR \geq 100$. This gives a detector efficiency greater than 65% and an rms ripple less than about 1% of the dc output. With the assumed ideal rectifier, however, R could be any value. The analysis in the following section shows the limitations imposed on R by a real diode.

Analysis with a real diode

Here we will discard the perfect rectifier in favor of the standard diode for which $I_{\mathrm{diode}} = I_{\mathrm{s}} \exp(V_{\mathrm{diode}}/V_{\mathrm{T}} - 1)$, where I_{s} is the reverse saturation current and V_{T} is the so-called thermal voltage, 0.026 volts.[1] In the equivalent circuit of Figure 18.2, we will now let R_{d} be zero, i.e., we will assume that any voltage drop across the diode's bulk resistance is negligible compared to the drop across the junction. As before, the analysis to find V_{det} consists in equating V_{det}/R to the average current through the diode:

$$\frac{V_{\mathrm{det}}}{R} = \langle I_{\mathrm{diode}} \rangle = \frac{1}{2\pi} \int_0^{2\pi} I(\theta)\mathrm{d}\theta \tag{18.1}$$

where

$$I(\theta) = I_s\{\exp[(V\cos\theta - V_{\mathrm{dc}})/V_T] - 1\}. \tag{18.2}$$

This pair of equations is equivalent to

$$\frac{V_{\mathrm{det}}}{0.026} = \ln\left(\frac{V_s I(V)}{2\pi(V_{\mathrm{det}} + V_{\mathrm{s}})}\right), \tag{18.3}$$

where V_{s}, a "saturation voltage," is defined by $V_{\mathrm{s}} = I_{\mathrm{s}} R$ and

$$I(V) = \int_0^{2\pi} \exp(V\cos\theta/0.026)\mathrm{d}\theta. \tag{18.4}$$

Using a desk-top computer math utility to solve Equation (18.3) results in a set of curves (Figure 18.3) showing V_{det} vs. V for various values of V_{s}. Note that the detector output is very nonlinear for low-amplitude input signals when V_{s} is less than about 0.01 V. Suppose, then, that we pick $V_{\mathrm{sat}} = 0.01$ V. A germanium diode or zero-bias Schottky diode might have a saturation current of 10^{-6} A, which would

---

[1] The thermal voltage is given by kT/e, where e is the charge of an electron, k is Boltzmann's constant, and T is an assumed temperature, 300 K.

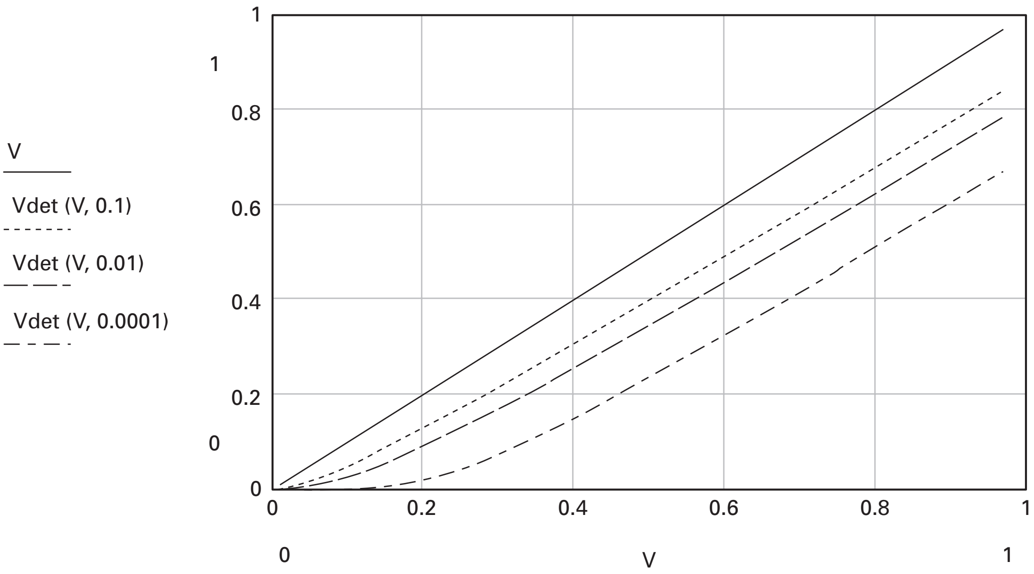

Figure 18.3. Detector output vs. input voltage for several values of $V_s = I_s R$.

then require that $R = 0.01/10^{-6} = 10$ k ohms, a convenient value. The low I_s of an ordinary silicon diode might require that R be more than 10^7 ohms, which would require the audio amplifier to have an inconveniently high input impedance. The power dissipated in the detector is V_{det}^2/R. This detector would typically produce, say, 2 V (to operate up in the linear range), which corresponds to a power dissipation of $2^2/10^4 = 0.4$ mW. For a given signal strength at the receiver input, the RF stages must have enough gain to produce 0.4 mW.

AC-coupled diode detector

Sometimes circuit considerations require that the detector input be ac coupled. In this case a dc return must be furnished for the detector diode. Such a circuit is shown in Figure 18.4 where an RF choke (a large value inductor) provides this

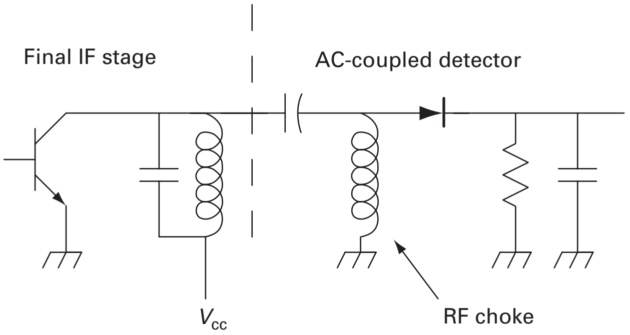

Figure 18.4. AC-coupled diode detector.

dc return path, forcing the average voltage at the left side of the diode to be zero, as in the circuits of Figures 18.1 and 18.2.

18.1.2 Product detectors

Demodulation of SSB and Morse code (cw) signals is usually done by a *product detector* which mixes (multiplies) the IF signal with a locally generated carrier. The resulting difference frequency components become the demodulated signal, while the sum frequency components are discarded. This is shown in Figure 18.5. The free-running oscillator is historically known as a *beat frequency oscillator* (BFO).

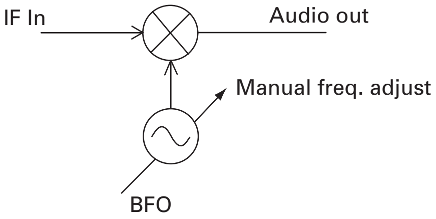

Figure 18.5. Product detector for SSB and CW.

For SSB reception of voice signals, the frequency of the BFO is manually adjusted until the audio sounds approximately natural. For Morse code reception, the BFO is deliberately offset to produce an audible tone, the "beat note." This was first done by the radio pioneer, Reginald Fessenden. In his heterodyne detector, the predecessor to the Edwin Armstrong's superheterodyne, the incoming signal voltage was combined with the voltage from a local oscillator,[2] which was a small arc source, an early negative resistance oscillator.

A product detector can also be used for AM demodulation. Again the signal is *multiplied* by a locally generated carrier. Here the local carrier must have the frequency and phase of the received carrier. Any error in frequency creates a strong audio beat note with the carrier of the received signal and an error in phase reduces the amplitude. Nevertheless, the product detector overcomes the limitations of diode envelope detectors; the input signal levels do not have to be as high and there is no low-signal threshold below which the detector is useless. When the AM signal is consistently strong (usually the case for most broadcast listeners) the local carrier can be a hard-limited version of the input signal. This works because, in double sideband AM, the modulated signal has the same zero crossings as the unmodulated carrier. The product detector shown in Figure 18.6 uses this method. This detector is commonly used for the video detector in analog television receivers.

[2] In his heterodyne patent of 1902, Fessenden proposed that the transmitting station send *two* signals, closely spaced in frequency. At the receiver, the nonlinear detector would produce an audible beat note. One of these signals could be continuous (not keyed). Instead, it became practical to produce the continuous signal at the receiver site using a *local* oscillator.

Figure 18.6. Product AM detector.

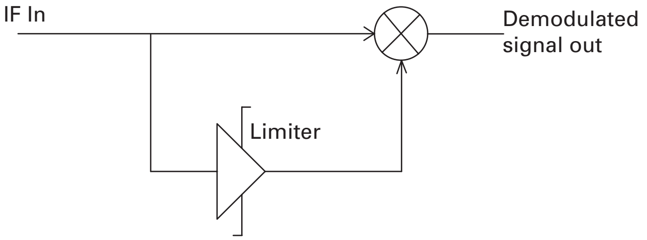

Figure 18.7. Synchronous AM detector.

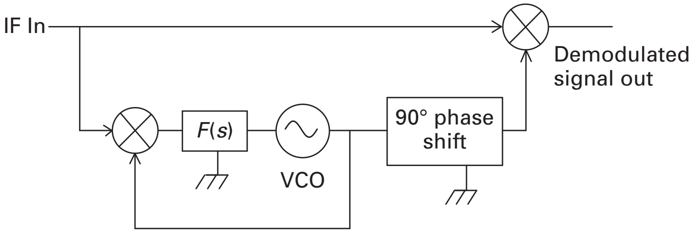


The *synchronous detector*, shown in Figure 18.7, is an improved product detector circuit in which a phase lock loop is used to generate the local carrier. The carrier of the input signal provides the reference signal for the loop. In a practical circuit, a limiting amplifier can be used at the reference input to make the loop dynamics independent of the signal level.

The PLL gives the synchronous detector a flywheel effect: the narrowband loop maintains the regenerated carrier during abrupt selective fades (common in short-wave listening). This prevents distortion, common in short-wave receivers, caused by momentary dropouts of the carrier. The PLL provides, in effect, a bandpass filter so narrow that its output cannot change quickly. Note the 90° phase shift network; if the phase detector is the standard multiplier (mixer), the VCO output phase differs from the reference phase by 90°. Without the network to bring the phase back to 0°, the output of the detector would be zero.

18.1.3 Digital demodulation of AM

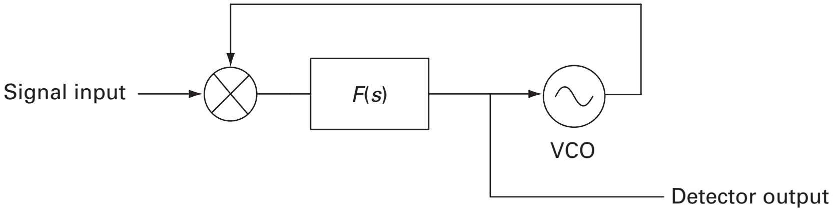
The analog AM demodulators discussed above can be implemented as well in digital circuitry. Envelope detection via full-wave rectification of the IF signal can be done by simply taking the absolute value of the numbers produced by the A-to-D converter. For digital processing, the IF signal is often converted to two baseband signals, I and Q, which result from mixing the IF signal with $\cos(\omega_{\mathrm{IF}}t)$ and $\sin(\omega_{\mathrm{IF}}t)$. In this case, the amplitude of the signal is given by $(I^2 + Q^2)^{1/2}$, which can also be computed digitally, though not as easily as $|V|$. Synchronous detection can be done.

18.2 FM demodulators

A variety of circuits, often called *discriminators*, have been used to demodulate FM. Most of these circuits are sensitive to amplitude variations as well as frequency variations, so the signal is usually amplitude limited before it arrives at the FM detector. This reduces the noise output, since amplitude noise is eliminated (leaving only phase noise). In addition, it ensures that the audio volume is independent of signal strength.

18.2.1 Phase lock loop FM demodulator

We have already pointed out that a phase lock loop may be used as an FM discriminator. As the loop operates, the instantaneous voltage it applies to the voltage-controlled-oscillator (VCO) is determined by the reference frequency, which here is the signal frequency. The linearity of the VCO determines the linearity of this detector, shown in Figure 18.8.

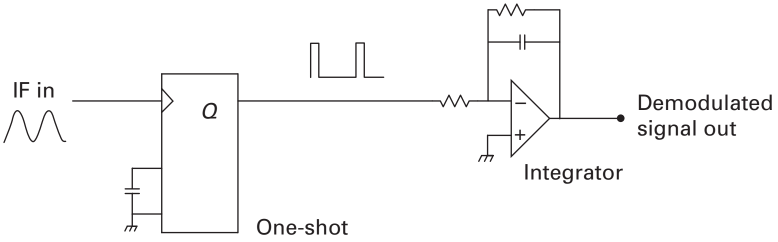


18.8. Phase lock loop FM detector.

18.2.2 Tachometer FM detector

A tachometer FM detector or "pulse counting detector", shown in Figure 18.9, is just a one-shot multivibrator that fires on the zero crossings of the signal. Each positive zero crossing produces a constant-width output pulse. The duty cycle of the one-shot output therefore varies linearly with input frequency so, by integrating the output of the one-shot, we get an output voltage that varies linearly with frequency.

Figure 18.9. Tachometer FM detector.



18.2.3 Delay line FM detector

The *delay line discriminator* is often used in C-band satellite television receivers to demodulate the FM-modulated video and sound. The IF frequency in these receivers is typically 70 MHz. Figures 18.10 shows a quarter-wave delay line (which could be a piece of ordinary transmission line) which delays the signal at one input of the multiplier. If the input signal is $\cos((\omega_0+\delta\omega)t)$, then the signal at the output of the delay line is $\cos((\omega_0+\delta\omega)(t-\tau)) = \sin((\omega_0+\delta\omega)t-\tau\delta\omega)$ and the baseband component at the output of the multiplier is $-\sin(\tau\delta\omega)$. For small $\tau\delta\omega$ this is just $-\tau\delta\omega$. The output voltage is thus proportional to the frequency offset, $\delta\omega$. If the delay line is lengthened by an integral number of half-wave lengths, the sensitivity of the detector is increased, i.e., a given shift from center frequency produces a greater output voltage.

FM quadrature demodulator

The *quadrature FM demodulator*, shown in Figure 18.11, is the same as the delay line discriminator except that an *LC* network is used to provide the delay, i.e., a phase shift that varies linearly with frequency. These circuits are commonly used in integrated circuits for FM radios and television sound; the *LC* networks or an equivalent resonator is normally an off-chip component.

18.2.4 Slope FM detector

Slope detection, in which FM modulation is converted to AM modulation, is the original method to demodulate FM. The amplitude response of the IF bandpass filter is made to have a constant slope at the nominal signal frequency. An input signal of constant amplitude will then produce an output signal whose amplitude depends linearly on frequency. A simple envelope detector can detect this amplitude variation. An AM receiver can slope-detect an FM signal if detuned slightly to put the FM signal on the upper or lower sloping skirt of the IF passband filter. A refined balanced slope detector (Figure 18.12) uses two filters with equal but opposite slopes. The filter outputs are individually envelope-detected and the detector voltages are subtracted. This makes the output voltage zero when the input signal is on center frequency, f_0, and also linearizes the detector by cancelling even-order curvature, such as an $(f - f_0)^2$ term, in the filter shape.

The Foster–Seeley "discriminator," a classic FM detector, is an example of a balanced slope detector, though this is hardly obvious from the circuit, shown in Figure 18.13.

Note that the transformer has a capacitor across both its primary and its secondary. If the transformer had unity coupling, a single capacitor on one side or the other would suffice. The fact that there are two capacitors tells us the

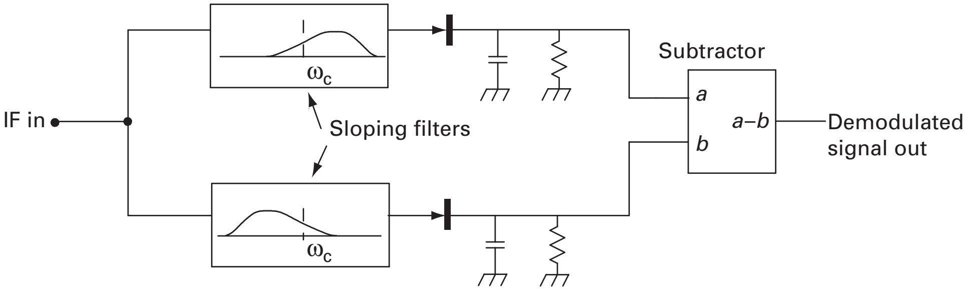

Figure 18.12. Balanced slope FM detector.

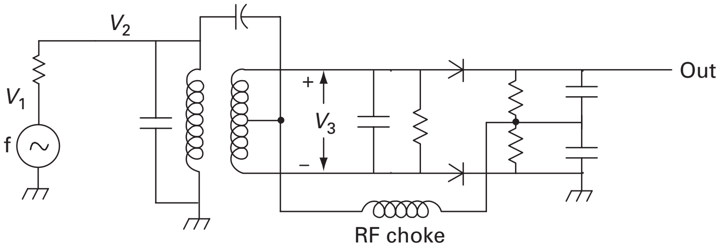

Figure 18.13. Foster–Seeley FM detector.

coupling is not unity; leakage inductance is an element in this circuit. In fact, the leakage inductance, and the magnetizing inductance, are used in a phase shift network, shown in Figure 18.14(a), used to produce the FM-to-AM conversion.

In this circuit, L_1 and L_2 are, respectively, the leakage and magnetizing inductances of the transformer. At the center frequency, f_c, V_2 lags V_3 by 90°. As the frequency increases from f_c, this lag increases. Mostly because of the change in relative phase over the operating region, the magnitude of the vector sum $V_2 + 0.5V_3$ decreases with frequency, while the magnitude of the vector sum $V_2 - 0.5V_3$ increases with frequency. These two combinations correspond to the outputs of the sloping filters in Figure 18.12.

Figure 18.15 is an equivalent circuit of the Foster–Seeley detector using an equivalent circuit for a transformer made up of the leakage inductance, the magnetizing inductance, and an ideal transformer. We will assume for convenience that the primary and secondary inductances and the coupling coefficient have values that give the ideal transformer a 1:1 ratio (see Problem 14.9).

Comparing Figures 18.15 and 18.13, you can see how the top and bottom halves of the transformer secondary are used to add $0.5V_3$ and $-0.5V_3$ to V_2. The

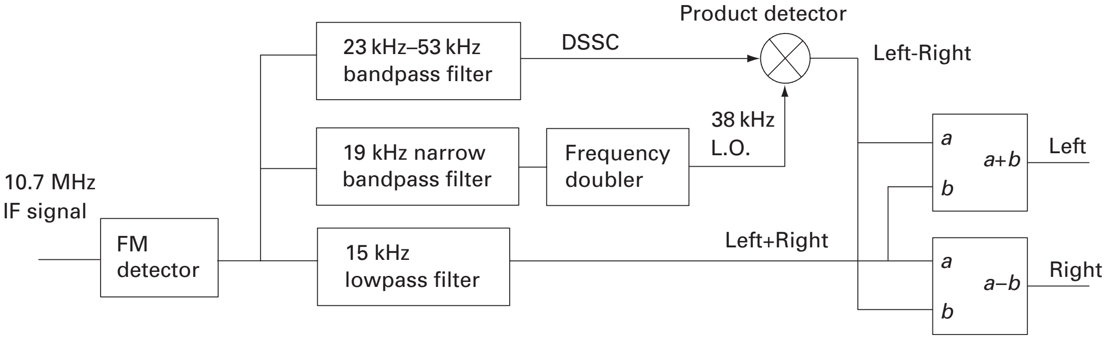
diode detectors produce voltages equal to the magnitudes of $V_2+0.5V_3$ and $V_2-0.5V_3$ and these magnitude voltages are subtracted, as in Figure 18.12, to produce the output. The RF choke provides a dc return for the diodes. Note that the subtractor can be eliminated by moving the grounding point in the secondary circuit to the bottom of the transformer's secondary winding. The dc blocking capacitor that bridges the transformer is only needed if there is a dc voltage on the primary winding, as when the signal source is the collector of a transistor biased through the primary winding. Finally, note that the capacitor and resistor in parallel with the magnetizing inductance L_2 in the equivalent circuit are actually located on the secondary side of the transformer which is equivalent to being on the left-hand side of the 1:1 ideal transformer.

18.2.5 FM stereo demodulator

Stereo FM, a compatible add-on dating to the 1960s, transmits an L+R (left plus right) audio signal in the normal fashion, and this signal is used by monaural receivers (or stereo receivers switched to "mono"). At the transmitter, The L−R audio is multiplied by a 38 kHz sine wave to produce a DSBSC (double sideband suppressed carrier) signal. This signal, well above the audio range, is added to the L+R audio signal, together with a weak 19 kHz sine wave "pilot" signal. The sum of these three signals, an example of *frequency division multiplexing* (FDM), drives the VCO (or equivalent) to produce the FM signal. At the receiver, the sum signal is demodulated by any ordinary FM demodulator. After demodulation, the L−R signal is brought back down to baseband by a product detector, i.e., a multiplier with a 38 kHz L.O. This L.O., which must have the correct phase (and therefore also the correct frequency), is derived by putting the pilot signal through a frequency doubler. This is shown in the block diagram of Figure 18.16.

Figure 18.16. FM stereo broadcast receiver broadcasting block diagram.



Note that the L−R signal has been doubly demodulated: first by the FM detector and then by the AM product detector. In this stereo system, the L−R signal is more susceptible to noise than the L+R signal. For “full quieting” stereo reception, about 20 dB more signal strength is required than for equivalent monaural reception. For this reason, FM stereo receivers are provided with manual or automatic switches to select monaural (L+R only) operation.

18.2.6 Digital demodulation of FM

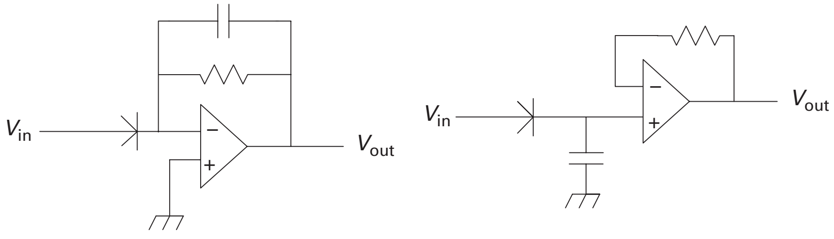
When the IF signal has been converted into baseband I and Q signals, the phase of the IF sample is given by $\tan(\theta(t)) = Q(t)/I(t)$. Since frequency is the time derivative of phase, we take the differential of this expression: $(1+\tan^2 \theta)\delta\theta = \delta Q/I - Q\delta I/I^2$. Substituting Q/I for $\tan \theta$ yields

$$\delta\theta = \frac{I\delta Q - Q\delta I}{I^2 + Q^2}. \tag{18.5}$$

For each sampled I, Q pair, $\delta\theta$ is calculated from this pair and the previous pair. The resulting values of $\delta\theta$ are proportional to $\mathrm{d}\theta/\mathrm{d}t = \omega$. (Note that this could also be done with analog circuitry. Only two analog multipliers would be needed if the IF signal has passed through a limiter, making $(I^2 + Q^2)$ a constant.)

18.3 Power detectors

Square-law detectors are not used as demodulators but are used in laboratory instruments that measure power (wattmeters and rms voltmeters). If we are measuring a sine wave we know that the rms voltage is equal to the peak voltage divided by $\sqrt{2}$. When we know the shape of the waveform, a true square-law meter is not necessary. Even noise power can sometimes be estimated with other than a square-law device. The power of a Gaussian random noise source can be measured by averaging the output of a V^{2n} law device or a $|V|^n$ law device where $n = 1,2, \ldots$ The square-law device, however, is always the optimum detector in that it provides the most accurate power estimate for a fixed averaging time. When we need the optimum power measuring strategy or if we need to measure the rms voltage of an unknown waveform, we must average the output from a true square-law device. “True rms voltmeters” built for this purpose use a variety of techniques to form the square of the input voltage. Some instruments use a network of diodes and resistors to form a piecewise approximation of a square-law transfer function. Other instruments use a thermal method where the unknown voltage heats a resistor. The temperature of the resistor is monitored by a thermistor while a servo circuit removes or adds dc (or sine wave ac) current to the resistor to keep it at a constant temperature. The diode network



(a) (b)

Figure 18.17. (a) Simple diode power detector; (b) preferred detector.

requires large signals and the thermal method has a very slow response. Gilbert cell analog multipliers can be used to square the input voltage, but they are limited to relatively low-frequency signals. Generally, when the power is very low and/or the frequency is very high, and/or a very wide dynamic range is needed, the square-law detector uses a semiconductor diode. A simple (but not particularly recommended) circuit is shown in Figure 18.17. In this circuit the average current through the diode is converted to a voltage by the op-amp. The virtual ground at the op-amp input ensures that V_{in} is applied in full to the diode.

It is important to remember that the I vs. V curve for a diode does not follow a square law, even in a limited region. Rather, the law of the diode junction is exponential: $I = I_s[\exp(V/V_T) - 1]$ where V_T, the thermal voltage, is 26 mV. The diode is used at voltages much smaller than V_T so it is permissible to write $I = I_s[\,V/V_T + 1/2(V/V_T)^2 + 1/6(V/V_T)^3 + 1/24(V/V_T)^4]$. Obviously we can restrict the input voltage enough to neglect the last term. But what about the first term, the linear term? This dominant term will provide a current component that has the same frequency spectrum as the input signal; if that spectrum extends down to zero the output of the detector will be corrupted with extra noise. The third-order term will also have a baseband component. But if the input signal is a bandpass signal, the first-order and third-order terms are high-frequency signals that will be eliminated by whatever lowpass filter is applied to do the averaging (the capacitor in the above circuit). The simple square-law diode detector, then, is appropriate for measuring signals whose frequency components do not extend down into the baseband output spectrum of the detector circuit. (You can think of various two-diode balanced circuits to cancel the linear component but remember that the two diodes must be matched very closely to start with and then maintained at the same temperature.) The diode and op-amp circuit shown above serves to explain why diode detectors are used for bandpass signals but not for baseband signals. A better circuit – the preferred circuit – is shown in Figure 18.17(b). Here the sensitivity is not dependent on I_s and the circuit has a much better temperature coefficient. In this circuit no dc current can flow in the diode. The capacitor, however, ensures that the full ac signal voltage is applied to the diode. Expanding the exponential relation for the diode current and taking only the dc components we have

$$0 = \frac{-V_{\mathrm{dc}}}{V_{\mathrm{T}}} + \frac{\frac{1}{2}\langle {V_{\mathrm{in}}}^2 \rangle}{{V_{\mathrm{T}}}^2} \tag{18.6}$$

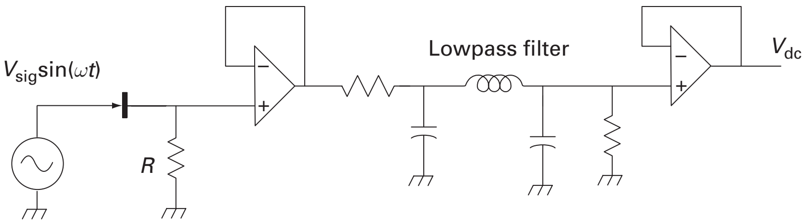
and

$$V_{\mathrm{dc}} = \frac{\frac{1}{2}\langle {V_{\mathrm{in}}}^2 \rangle}{V_{\mathrm{T}}} \tag{18.7}$$

which shows that the dc output voltage is indeed proportional to the average square of the input voltage.

Problems

Problem 18.1. Assume that in the envelope detector circuit shown below, the diode is a perfect rectifier (zero forward resistance and infinite reverse resistance) and that the op-amps are ideal.



(**a**) Calculate the efficiency, V_{dc}/V.

(**b**) Calculate the effective load presented to the generator (the value of a resistor that would draw the same average power from the source).

Problem 18.2. Draw a vector diagram to show why an envelope detector will produce an audio tone when it is fed with the sum of an IF signal and a (much stronger) BFO signal.

Problem 18.3. Show that the voltage divider network in Figure 18.11(b) can produce an output voltage shifted 90° from the input voltage when the input voltage is at a specified center frequency, ω_0. Determine the position of the output phase when the input signal is slightly higher or slightly lower than ω_0.

Problem 18.4. When an interfering AM station is close in frequency to a desired AM station, an audio tone "beat note" is produced, no matter whether the receiver uses an envelope detector or a product detector. (In the case of an envelope detector, the beat note is produced because the amplitude of the vector sum of the two carriers is effectively modulated by an audio envelope. In the case of the product detector, the carrier of the undesired station acts as a modulation sideband and beats with the BFO.) Will the same thing happen with FM? Suppose two carriers (i.e., cw signals), separated by say, 1 kHz, appear in the IF passband of an FM receiver. Let their amplitudes be in the ratio of, say, 1:10. Draw a phasor diagram of the sum of these two signals. Does the vector sum have phase modulation? Will the receiver produce an audio tone? What happens in the case when the amplitudes of the two signals are equal?

Problem 18.5. Try the following experiment with two FM receivers. Tune one receiver to a moderately strong station near the low-frequency end of the band. Use the other receiver (the local oscillator) as a signal generator. (This receiver must have continuous rather than digital tuning.) Turn its volume down and hold it close to the first receiver so there will be local oscillator pickup. Carefully tune the second receiver 10.7 MHz higher in frequency until an effect is produced in the sound from the first receiver. What is the effect? Can you use this experiment to confirm your answer to Problem 18.4?

CHAPTER

19

Television systems

Television system dissect the image and transmit the pixel information serially. The image is divided into a stack of horizontal stripes (“lines”) which are scanned left to right, producing a sequence of pixel (picture element) brightness values. The lines are scanned in order, one after the other, from top to bottom. Brightness values for each pixel are transmitted to the receiver(s). The image is reconstructed by a display device, whose pixels are illuminated according to the received brightness values. This chapter presents television technology in historical order: (1) the electromechanical system that Nipkov patented in 1884 but which was not demonstrated until 1923; (2) all-electronic television, made possible by the development of cathode ray picture tubes and camera tubes; and (3) digital television, which uses data storage and processing in the receiver, allowing the station to update the changing parts of the image, rather than retransmit the entire image for every frame. With the lowered data rate, the bandwidth needed previously to transmit one analog television program can now hold multiple programs.

19.1 The Nipkov system

Electronic image dissection and reconstruction were first proposed in the Nipkov disk system, patented in 1884, which used a pair of rotating disks, as shown in Figure 19.1. The camera disk dissected the image while the receiver disk reconstructed it. The receiver screen, a rectangular aperture mask, was covered by an opaque curtain containing a pin hole, illuminated from behind by an intensity-modulated gas discharge lamp. The position of the pin hole was analogous to the position of the illuminated spot on a CRT. This scanning pinhole was actually a set of N pinholes, arranged in a spiral on an opaque disk that rotated behind the aperture mask. Only one hole at a time was uncovered by the aperture. As the active hole rotated off the right-hand side of the aperture, the next hole arrived at the left-hand side, displaced downward by one scanning line. Identical holes in the transmitter disk

allowed light from the original image to hit a photocell. Of course the rotating disks had to be synchronized, but when the disks were driven by synchronous motors on the same ac power grid, it was only necessary to find the correct phase.

This primitive low-resolution system was finally demonstrated in 1923 after the invention of the photoelectric cell, vacuum tube amplifier, and neon glow lamp. While the eye views only a single illuminated spot, the persistence of human vision retains an image on the retina of the eye long enough to make the image appear complete if the entire screen is scanned at a rate more than about 20 times per second.[1] Some early experimental broadcasts were made with this very low resolution system in the U.S. on 100-kHz wide channels in the 2–3 MHz range.

19.2 The NTSC system

All-electronic television broadcasts were first made in Germany in 1935 and in England in 1936. The system used in the United States was proposed by the National Television Standards Committee (NTSC) of the Radio Manufacturers Association (RMA). Commercial broadcasting using the NTSC began on July 1, 1941. NBC and CBS both started television service that day in New York City. These stations and four others (Philadelphia, Schenectady, Los Angeles, Chicago) maintained broadcasts throughout World War II to some 10–20 thousand installed receivers. Compatible color broadcasting was added to the NTSC standard in the early 1950s. An engineering tour de force, this system effectively transmits simultaneous red, green, and blue images through the original 6-MHz channels in such a way that monochrome receivers are unaffected.

The NTSC standard specifies a horizontal-to-vertical aspect ratio of four-to-three for the raster (German for screen) with 525 horizontal lines, each scanned in 62.5 microseconds. About 40 of these lines occur during the vertical retrace interval, so there are some 525−40 or 485 lines in the picture. If the horizontal resolution were equal to the vertical resolution, the number of horizontal picture elements would be 4/3 × 485 = 646. The NTSC standard specifies somewhat less horizontal resolution: 440 picture elements. The horizontal retrace of a CRT requires about ten microseconds, so the active portion of each line is 62.5−10 = 52.5 microseconds. The maximum video frequency is therefore given by ½ × 440/52.5 = 4.2 MHz. (A video sine wave at 4.2 MHz would produce 220 white stripes and 220 black stripes.)

---

[1] The florescent “phosphorous” material on a television CRT faceplate provides addition persistence.

19.2.1 Interlace

The NTSC frame rate is 30 Hz, i.e., the entire image is scanned 30 times each second. The line rate is therefore 525 × 30 = 15 750 Hz. Interlaced scanning is specified. This is shown in Figure 19.2. Lines 1–262 and the first half of line 263 make up the first field. The second half of line 263 plus lines 264–525 make up the second field. The lines in the second field fit between the lines of the first field. Each field takes 1/60 sec, fast enough that the viewer perceives no flicker. If all 525 lines were scanned in 1/60 sec, the signal would require twice the bandwidth and the CRT beam deflection circuitry would require more power. Interlacing provides full resolution for fixed scenes but creates artifacts on moving objects (see Problem 19.5).

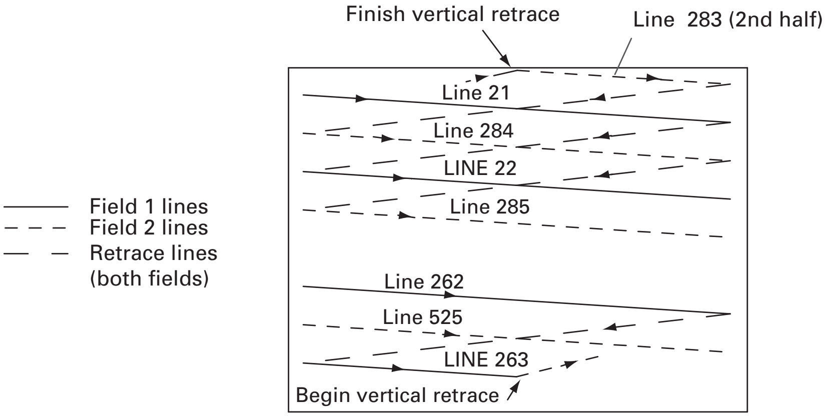

Figure 19.2. Interlaced scanning.

19.2.2 The video signal

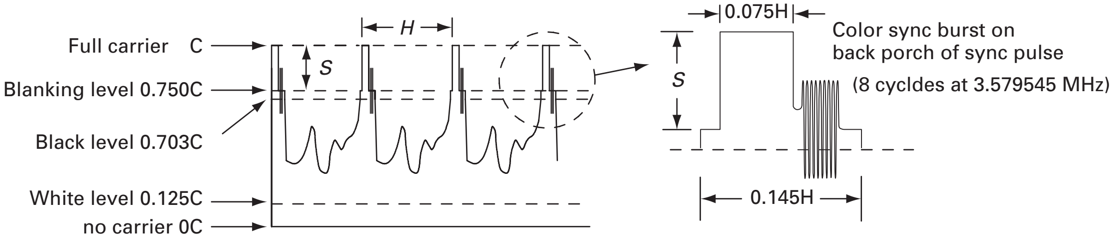
The video signal amplitude-modulates the video transmitter. Synchronization pulses are inserted between every line of picture information. The NTSC system uses negative video modulation so that less amplitude denotes more brightness. The principal reason for using this polarity is that impulse interference creates black dots rather than more visible white dots on the screen of the receiver.

19.2.3 Synchronization

A horizontal sync pulse is inserted in the retrace interval between each scanning line and is distinguished by having a higher amplitude than the highest amplitude picture information, i.e., the sync pulse is “blacker” than the black level already blanking the beam during the retrace. The composite video, picture information plus synchronizing pulses, is shown in Figure 19.3. This waveform, which would be observed at the output of the video detector after lowpass filtering to remove the 4.5 MHz sound, shows three successive scan lines.

Television receivers have a threshold detector in the synchronization circuitry in order to look only at the tips of the sync pulses, i.e., the portion that is above the black level, and therefore totally independent of the video information. The burst of eight sinusoidal cycles at 3.579 545 MHz on the “back porch” of each synch pulse provides a reference for the color demodulator, described later. A vertical sync reference is provided by a series of wider sync pulses that occur near the beginning of the vertical blanking period, i.e., every 1/60 second at the end of every field.

Figure 19.3. NTSC video waveforms.



19.2.4 Modulation

Radio transmission of video information (television) requires that we modulate a carrier wave with the composite video signal. The NTSC system uses full-carrier AM modulation for the video. Since the NTSC video signal extends to 4.2 MHz, ordinary double-sideband AM would require a bandwidth of 8.4 MHz. To save bandwidth, the lower part of the lower sideband is removed at the transmitter by filtering, allowing a 6-MHz channel spacing. The resulting *vestigial sideband* signal consists of the entire upper sideband, the carrier, and a vestige of the lower sideband, as shown in Figure 19.4.

At the receiver, a low-frequency video component, because it is present in both sidebands, would produce twice the voltage that would be produced by a high-frequency video signal, present only in the upper sideband. This problem is corrected by using an IF bandpass shape that slopes off at the lower end such as shown in Figure 19.5. At the video carrier frequency the amplitude response is ½. (This response is as good as and simpler to obtain than the dotted curve where all of the double sideband region is reduced to ½.)

0.75 MHz
4.2 MHz
4.5 MHz
6 MHz

Figure 19.4. NTSC 6-MHz channel allocation.

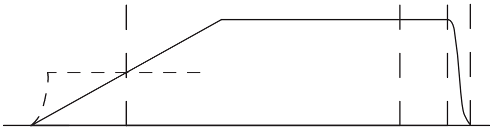

Figure 19.5. IF response to equalize the vestigial sideband.

For this IF equalization to work correctly, this IF filter should also have linear phase response. When surface acoustic wave (SAW) filters became available to determine the IF bandpass shape, this requirement was easily satisfied.

19.2.5 Sound

The audio or "aural" signal is transmitted on a separate carrier, 4.5 MHz higher in frequency than the video carrier. The NTSC system uses FM modulation for the audio component. The maximum deviation is 25 kHz, i.e., the maximum audio amplitude shifts the audio carrier 25 kHz. Normally the audio transmitter is separate from the visual transmitter and their signals are combined with a diplexer to feed a common antenna.

19.2.6 NTSC color

The NTSC standard for compatible color television was adopted in 1953. Like color photography, color television is based on a tricolor system. When two or more colors land at the same spot on the retina, their relative intensities determine the perceived hue. When three complete images in three suitably chosen primary colors are superimposed, the eye perceives a full-color image. The particular red, green, and blue standards specified in the NTSC standard were based on practical phosphors used for the dots on the faceplate of the CRT. Since color television requires the simultaneous transmission of three images, it is interesting to see how the color system can shoehorn three images into the 6-MHz channel originally allocated for a single monochrome image and do it in a way that made color broadcasts compatible with existing monochrome receivers. The solution to the bandwidth problem takes advantage of the fact that the monochrome video signal leaves empty gaps across the 6-MHz band. There is considerable redundancy in a typical picture. In particular, any given line is usually very much like the line preceding it (producing strong correlation at 62.5 microseconds) so the video signal is similar to a repetitive waveform with a frequency of 15 750 Hz, the horizontal scan frequency. If the lines were truly identical, the spectrum would be a comb of delta functions at 15 750 Hz and its harmonics. Since one line differs somewhat from the next, these delta functions are broadened, but the spectral energy is still clumped around the harmonics of the horizontal scanning frequency, leaving relatively empty windows which can be used to transmit color information. (Note that if the entire picture is stationary then the spectrum is a comb of delta functions spaced every 30 Hz and essentially all the bandwidth is unused.)

Instead of transmitting the red, blue, and green (RGB) signals on an equal basis, three linear combinations are used. One of these, the *luminance* signal, Y, is chosen to be the brightness signal that would have been produced by a monochrome camera: $Y = 0.299R + 0.587G + 0.114B$. The other two linear combinations are $I = 0.74(R-Y) - 0.27(B-Y)$ and $Q = 0.48(R-Y) + 0.41(B-Y)$.

The luminance signal directly modulates the carrier, just as in monochrome television, and monochrome receivers respond to it in the standard fashion. Each of the other two signals, I and Q, modulates a subcarrier (just as the Right-minus-Left audio signal modulates a 38-kHz subcarrier in FM stereo). The color subcarriers have the same frequency, 3.579 545 MHz, but they differ in phase by 90°. Figure 19.6 shows how two independent signals are transmitted and recovered using this quadrature AM modulation (QAM).

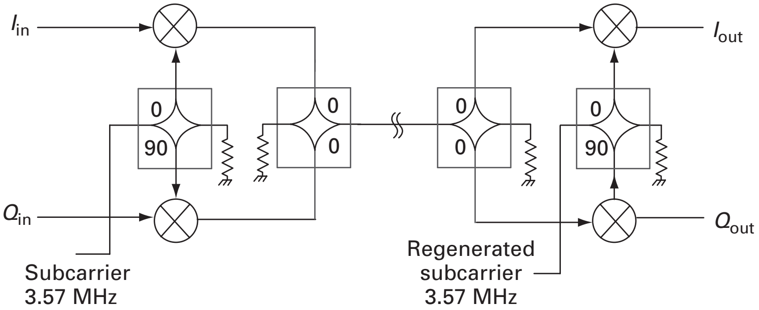

Figure 19.6. Quadrature AM modulator/demodulator lets the two color signals occupy one band.

The reference signal necessary to regenerate these local carriers is sent as a burst of about eight sinusoidal cycles at 3.579 545 MHz on the back porch of each horizontal sync pulse as shown in a previous figure. This "color burst" is used in the receiver as the reference for a phase lock loop. The color information, like the luminance information, is similar from line to line so its power spectrum is also a comb whose components have a spacing equal to the horizontal scanning frequency. The subcarrier frequency is chosen at the middle of one of the spectral slots left by the luminance signal so the comb of color sidebands interleaves with the comb of luminance sidebands – a frequency multiplexing technique known as spectral interlacing.

Compatibility is achieved because the spectral interlacing greatly reduces visible cross-talk between chrominance and luminance information. To see this, consider a very simple signal, a uniform color field such as an all-yellow screen. Since this field has a color, i.e., it is not black, white, or gray, there will be nonzero I and Q signals. In this example, since the color information is constant, the I and Q signals together are just a sine wave at the color subcarrier frequency. Their relative amplitudes determine the hue while their absolute amplitudes determine the saturation. One would expect this 3.58-MHz video component to produce vertical stripes. And the beam, as it sweeps across the screen, does indeed get brighter and dimmer at a 3.58-MHz rate, trying to make some 186 stripes in the 52.5 microsecond scan. But, on the next line, these stripes are displaced by exactly one half-cycle. The result is that the entire screen, rather than having 186 vertical stripes, has a fine-gridded checkerboard or "low visibility" pattern. Colored objects viewed on a monochrome receiver can be seen to have this low visibility checkerboard pattern. Note that there are some unusual situations where spectral interleaving does not work. If the image itself is like a checkerboard with just the right grid spacing the luminance signal will fall into the spectral slots allocated for the chrominance signal and vice versa. A herringbone suit for example, will often have a gaudy sparkling appearance when viewed on a color receiver. NTSC receivers eventually were equipped with comb filters to separate the chrominance and luminance signals, but at the expense of some vertical resolution.

The low-visibility principle is applied not only to avoid luminance–chrominance cross-talk but also to reduce the effect of the beat between the 4.5-MHz sound carrier and the color subcarrier. To take advantage of the low-visibility principle, television standards were modified slightly when color television was introduced. The sound carrier remained the same at 4.5 MHz above the video carrier. The relation between the horizontal scanning frequency, f_h, and the color subcarrier frequency, f_{SC}, was picked to be $f_{SC} = 227.5\, f_h$. Then the sound subcarrier-minus-color subcarrier beat was likewise made an odd number of half-multiples of the horizontal scanning frequency: $4.5\,\text{MHz} - f_{SC} = 58.5 f_h$. Putting these two relations together determines the horizontal frequency, 15 734.264 Hz, and the color subcarrier frequency, 3.579 545 MHz. The number of scanning lines remained at 525 so the vertical frequency changed from 60 Hz to $262.5f_{\mathrm{h}} = 59.940$ Hz. With these choices, the sound carrier is at 286 times the horizontal frequency. This would produce a high visibility pattern but the sound carrier is above the nominal video band and can be filtered out easily.

Color television receiver

The block diagram of Figures 19.7 shows the overall organization of an NTSC color television receiver. The first block is simply an AM radio receiver for VHF, UHF, and cable frequencies (about 52–400 MHz).

The carrier of the selected channel is translated to an IF frequency of 45.75 MHz and the IF bandwidth is about 6 MHz. The shape of the IF passband must be quite accurately set to equalize the vestigial sideband, to provide full video bandwidth, and to reject adjacent channels. This originally required careful factory adjustment of many *LC* tuned circuits but was later determined by the geometry in a single SAW filter. The IF signal contains the composite video (luminance and sync) plus the sound and color information. The sound and color signals, which are essentially narrowband signals around 4.5 MHz and 3.57 MHz, ride on top of the luminance signal. A 4.5-MHz bandpass filter isolates the sound signal in the block labeled "4.5-MHz FM Receiver." FM stereo sound uses the demodulator described in Chapter 18. The sound subcarrier is at 31.5 kHz so that the oscillator in the demodulator can be synchronized to the horizontal sweep trigger at 15.75 kHz. A 4-MHz lowpass filter eliminates the sound signal from the video. The resulting video signal, the "*Y*" signal, contains the brightness information and would produce the correct picture if sent to a monochrome picture tube.

Chrominance processor

The 3.57-MHz color burst on the back porch of the horizontal sync pulses provides a reference for the phase locked L.O. in this QAM demodulator. Not shown on the diagram is an electronic switch, the burst gate, which is controlled by the synchronization circuitry to apply the reference signal only during the burst period in order to improve the signal-to-noise ratio of the loop. The local carrier is fed to a product detector (multiplier) to demodulate the *I* signal. A 90° phase shift network proves a second local carrier, shifted in phase for a second product detector to demodulate the *Q* signal.

Sync processor

A comparator, with its threshold set at the black level, strips away the video signal, producing a clean train of sync pulses. As explained above, a simple RC differentiator then provides horizontal reference pulses and an RC integrator provides vertical reference pulses. A VCO, phase-locked to the horizontal reference pulses, provides a flywheel stabilized horizontal time base. The VCO operates at twice the horizontal frequency and is divided by 2 to provide 15 734 Hz for the PLL phase detector and to drive the horizontal deflection

circuitry. The VCO is also divided by 525 to provide an equally stable vertical time base. This divider must operate with the right phase for the picture to have the correct vertical alignment so the divide-by-525 counter has a reset input which will be triggered when the counter output has failed to coincide with several consecutive vertical reference pulses.

19.3 Digital television

The first digital television broadcasting in the U.S. began in 1998, following the 1996 adoption by the Federal Communications Commission (FCC) of the system developed by the Advanced Television Standards Committee (ATSC). Television stations were assigned new channels for digital broadcasting but have also continued their NTSC analog broadcasts during the digital phase-in period which, at this writing, is scheduled to end in 2009.

The ATSC standard incorporates MPEG-2 program compression (itself a standard, ISO/IEC 13818), which is based on the temporal and spatial redundancy of the video program material.[2] MPEG-2 is also used for digital television in Europe (DVB) and Japan (ISDB), for direct television broadcasts from satellites, and for DVDs. Digital processing and storage make it possible to exploit the redundancies of the program material to compress up to six standard-definition (480-line) programs or at least two high-definition (720 or 1080-line) programs into the same 6-MHz wide channel needed for a single NTSC program. (The same redundancies are exploited to a much smaller degree in the NTSC system with its temporally-interlaced fields and its frequency-interleaved luminance and chrominance signals.) The net data rate for the ATSC system is 19.3 Mbits/sec through a 6-MHz channel, after overhead for error correction. Let us estimate how much compression is involved when four standard-definition programs with typical frame-to-frame motion are compressed down to a total bit rate of 19.3 Mbits/sec. We will assume these programs are in the "480i" format, where 480×704 pixels are transmitted at a 30-Hz rate. Let us further assume there are three 8-bit numbers, a luminance value and two chrominance values, for each pixel. The overall data rate would be four channels $\times 480 \times 704 \times 8$ bits $\times$ 3(colors) $\times$ 30 Hz = 973 Mbits/sec. Dividing by 19.3 Mbits/sec, the compression factor is 50.4. When audio is included in the calculation, the factor increases slightly.

Digital television uses a three-step process. First, the video and audio program material, in raw digital bit streams, is compressed to packet streams having much lower bit rates. The video and audio packets, together with packets of ancillary data and null packets (padding) are merged together to form a stream of *transport packets*, each one containing 187 data bytes. The packets have headers to identify the program (since a stream may contain several independent programs) and the type of packet: video, audio, or, ancillary information, or null. Second, the stream of packets is run through a two-stage forward error correction (FEC) encoder which adds redundant bits to each packet so that the receiver can detect and correct transmission errors caused by noise and interference. Third, the bits in the stream of expanded packets produce the RF signal for transmission. This signal is single-sideband suppressed-carrier AM (SSBSC) except that a vestige of the lower sideband remains (as in the NTSC standard) and the carrier is not completely suppressed; a pilot carrier is inserted as a reference for synchronous detection in the receiver. At the receiver, the three steps occur in the opposite order. The bit stream is demodulated from the RF signal. The FEC-encoded packets are then decoded, correcting transmission errors and producing the original packets of compressed data. These packets are then separated, according to program, and each program is decompressed into the original audio and video bit streams.

---

[2] The ATSC system does not use the audio part of MPEG-2 for audio, but instead uses AC-3 (Dolby digital) compression, which provides each program with up to five full audio channels plus a low-frequency subwoofer channel for "surround sound."

19.3.1 MPEG encoding

The picture is encoded (compressed) at the lowest level in blocks of eight pixels by eight pixels. (Note that "compression" and "decompression" of the program data are usually called coding and encoding, the same terms used for the processes used to anticipate and correct transmission errors.) Video usually has a high degree of spatial correlation, i.e., adjacent pixels tend to have similar brightness and color. When an $(n \times n)$-pixel picture is encoded using a two-dimensional discrete Fourier transform (DCT), the resulting coefficient matrix can be inverse-tranformed to exactly reconstruct the picture. But if the coefficients are coarsely quantized, i.e., rounded to use fewer bits before the inverse transformation, the reconstructed picture is found to retain most of its original quality.[3] Moreover, because of spatial correlation, these coefficients tend to concentrate in one corner of the coefficient matrix. Away from this corner, the coefficients have low values. Thus, a great many of the coefficients can be represented as zeros and the rest by numbers of only a few bits, so DCT encoding providing a significant amount of compression.

Except for scene changes, the differences from one frame to the next are mostly due to motion of elements within the picture (subject motion) or motion of the picture as a whole (camera motion). From frame to frame, a given block will therefore mostly just shift its position somewhat. In the ATSC system, for each 16 × 16 block (*macroblock*) in a new frame, the MPEG encoder determines the displaced macroblock in the previous frame that provides the best match by minimizing the sum of the absolute values of the differences of the pixel brightness values. The position of the displaced macroblock is specified by a *motion vector*, e.g., 1,1 would indicate that the best match macroblock is shifted one pixel up and one pixel to the right. These motion vectors are part of the video update information. The rest of the information consists of DCT-tranformed *differences* between the pixel values in these displaced "prediction" macroblocks and the new pixel values in the block being updated. At the encoder, the macroblock is subdivided into four 8 × 8 blocks, and the 64 pixel differences for each block which, again, have considerable spatial correlation, are transformed using an 8 × 8 DCT.[4] (It is computationally more efficient to transform small blocks, and the 8 × 8 size was found adequate to provide the desired compression.) When most of the coefficients in a transformed block are negligible, the resulting stream of digital numbers consists mostly of zeros, and run-length encoding (specification of the number of consecutive zeros) is used to increase the degree of compression. The number of consecutive zeros is increased by using a certain zigzag readout ordering of the coefficient differences. In addition, variable length coding is used for the nonzero transform differences; the viewer can tolerate coarser quantization for the high spatial frequencies.

---

[3] The same principle is used for audio compression. Blocks of audio voltage samples are transfomed and the resulting coefficients are compressed and transmitted.

Note that not all the frames can be predicted from previous frames; channel surfers need the picture to change promptly and, of course, a change of scene requires all-new data. Occasional *refresh frames* (tagged as such) are therefore inserted into the stream of prediction/correction frames. In a refresh frame, every block is transmitted. Between refresh frames, only changing macroblocks need to be transmitted. As in the NTSC system, the two color signals can have lower spatial resolution than the luminance signal, just as a black and white photograph can be "colorized" using a relatively broad brush. In the ATSC system, each of the two color elements has half the resolution (1/4 the number of pixels) as the luminance element, further compressing the video signal. The output from the MPEG encoder, together with the audio material, is a string of 188-byte packets: 187 data bytes plus one sync byte. Note that the packets are asynchronous; their lengths and mix is program dependent. Video and audio are both time-stamped so that they can be aligned by the decoder. After leaving the MPEG encoder, the bits in the 187 data bytes are "pseudo-randomized" by multiplication with the bits from a pseudo-random shift register sequence. This step, which is undone in the receiver, just ahead of its MPEG decoder, ensures that the spectrum is flat, even if the output of the encoder is interrupted, and makes it easier for the receiver to find the transmission packet sync byte which is added during the forward error correction encoding.

19.3.2 Forward error correction

The ATSC system applies two levels of forward error correction. "Forward" means that bits added in the encoding process make it possible to correct errors rather than simply detect them. Of course, this works only up to a limit; when the signal-to-noise ratio drops below a threshold, uncorrectable errors begin to produce visible artifacts and beyond this, the signal soon suffers total

---

[4] The DCT can be done by multiplying the (8 × 8) pixel or pixel difference matrix by an (8 × 8) transform matrix. The inverse of this matrix provides the inverse transformation. However, there are faster methods, analogous to the FFT algorithm for calculating the DFT.

degradation – the well known "threshold effect" in digital communication links. The bit-randomized MPEG packets are first processed by a Reed–Solomon encoder which adds 20 parity bytes to the 187 data bytes increasing each packet to 207 bytes. This Reed–Solomon encoding makes it possible to correct up to 10 defective bytes per packet, no matter how many bit errors these bytes contain. The next stage is an interleaving (shuffling) of bytes within blocks of 52 of the 207-byte packets. This interleaving makes it less likely that a wide noise burst will leave more than 10 bad bytes in any packet after de-interleaving has been done at the receiver. The second level of FEC encoding is a convolutional or trellis encoding, which is effective against white noise. The trellis encoder produces three output bits for every two input bits, bringing each packet up to $207 \times 3/2 \times 8 = 2484$ bits, or $2484/3 = 828$ three-bit (eight-level 8-VSB) symbols. The trellis encoding is a flow process; each bit triplet leaving the trellis encoder is calculated from only the last four pairs of input bits. Finally, a four-symbol sync sequence is added for a grand total of 832 8-VSB symbols per transmitted packet, as shown in Figure 19.8.

With the concatenated Reed–Solomon and Trellis error correction coding, the threshold of visibility for the ATSC system occurs at a S/N ratio of 14.9 dB. At this threshold, the data segment (832-symbol transmission packet) error rate is about 1.93×10^{-4} or 2.5 segment errors per second.[5] The FCC requires that over the area of service, a broadcaster's ATSC signal must exceed the threshold by 7 dB. Compared to NTSC, ATSC broadcasting requires less than 1/10 as much transmitter power. (Nearly all the ATSC transmitted power bears information, while much of the NTSC power goes into the carrier and horizontal sync pulses.)

---

[5] These numbers are taken from ATSC Document A/54A, "Recommended Practice Guide to the Use of the ATSC Digital Television Standard."

19.3.3 RF modulation

The three-bit symbols are converted by an A-to-D converter into an eight-level analog signal which amplitude modulates the carrier wave. The carrier is suppressed except for a low-amplitude pilot. Figure 19.9 shows a modulator circuit whose input is the stream of transmission packets, each containing 832 three-bit symbols, including the four-symbol segment sync. A filter eliminates all but a vestige of the lower sideband.

19.3.4 HDTV receiver

The ATSC standard provides 18 different video formats, ranging from high-definition 1920 × 1080 pixels, interlaced with 60 fields/second or noninterlaced with 30 or 24 frames/second, down to 640 × 480 pixels, interlaced with 60 fields/second or noninterlaced with 60, 30, or 24 frames/second. The receiver identifies the video format being used and decodes the video. It then scales and interpolates the decoded image to produce a picture that fits the native resolution of the display screen, unless the program happens to match the native resolution. When the screen does not have the same aspect ratio (16:9 or 4:3) as the program, the receiver will produce a "letter box" display, with the picture between black horizontal strips, or a "keyhole" display, with the picture between black vertical strips, or the view may be able to opt for a distorted picture that fills the screen. Figure 19.11 is a simplified block diagram for an ATSC television receiver.

Figure 19.11. An ATSC television receiver block diagram.

The conventional RF sections are all in the first row of blocks. The signal is first mixed down to a first-IF frequency, often around 44MHz. Just as in an NTSC receiver, the L.O. for the first mixer selects the channel. The amplified IF signal is synchronously detected by multiplying it by a sine wave at the carrier frequency. This sine wave is produced by a VCO referenced to the pilot carrier in a phase lock loop. Without the 90° phase shifter in the loop, the VCO output would be 90° out of phase with the pilot carrier and there would be no output from the synchronous detector. (If the consortium that developed the ATSC standard had opted for quadrature AM (QAM), there would have been two final mixers producing I and Q signals, rather than just a single mixer producing the I signal.) The detected signal, which is a zero-frequency IF "baseband" signal, is fed to an A-to-D converter. While the amplitude of the signal has nominally only eight levels (three bits), at this point it is still dithered by multipath echos and noise, so the A-to-D converter may have eight or ten bits. The clock rate of this converter may be a multiple of the symbol rate in order to recover the symbol clock with high precision. The clock recovery block finds the four-symbol segment sync sequence and phase locks the recovered symbol clock to it.

The equalizer is an adaptive filter which serves two purposes. It corrects the overall frequency response (transfer function) to minimize intersymbol interference (see Chapter 22) and it cancels echos – multipath interference. Both of these functions are essential in order to reproduce the transmitted signal well enough to distinguish one of eight possible amplitude values for each symbol. The usual form of the equalizer is a transversal FIR filter with programmable tap weights (amplitude and phase). The weighted outputs from the taps are summed to form the filter output. Every 313th transmission packet contains a "training" sequence, which is a reference waveform used by the receiver to determine the proper weights for the equalizer filter taps. Once the equalizer and the overall gain are correctly set, the signal can be sampled at the symbol rate × 1 to reproduce the data stream shown in Figure 19.8. Subsequent processing steps then undo the various stages of encoding. A trellis decoder (Viterbi decoder) is followed by a block that de-interleaves the bytes. Then the Reed–Solomon encoding is decoded. Finally, the pseudorandom coding is undone and the data can proceed to the MPEG decoder, which outputs synchronized video and audio.

Problems

Problem 19.1. Suppose the NTSC signal from a television receiving antenna consists of the direct signal (via the line-of-sight path to the transmitting station) and a weak secondary signal (via reflection from a metal tower off the line-of-sight). If the path taken by the secondary signal is 1 km longer than the path of the direct signal, what will be the position of the "ghost" image on the screen of the receiver?

Problem 19.2. Motion pictures from film shot at 24 frames/second are transmitted as 60 field/second television images using a technique called *3:2 pull down*. A film frame is held in place while two television fields are transmitted. The subsequent film frame is then pulled down and held in place while three television fields are transmitted. Show that this scheme results in an average film rate of 24 frames/second.

Problem 19.3. Consider a high-definition television monochrome signal with 1920×1080 pixels and progressive scan (no interlace) at 60 frames/sec. If the brightness of each pixel is specified by an 8-bit number, and if no compression is used, what is the data rate? Answer: 995 Mbps. What compression ratio is needed if this signal is to be transmitted over a standard width television channel at a rate of 19.3 Mbits/second?

Problem 19.4. Suppose an NTSC test pattern consists of five vertical bars of equal width but different colors. Let the bars all have the same luminance (brightness) and be only lightly colored (unsaturated). Sketch the waveform for one line of video.

Problem 19.5. Interlaced scanning provides more resolution for fixed scenes but can produce artifacts with moving objects. Think of a situation where interlaced scanning could make a moving object vanish.

Problem 19.6. Shannon's channel capacity theorem states that data, if suitably encoded for error correction, can be sent with an arbitrarily low error rate if the net data rate (bits/sec.) does not exceed the channel capacity, given by $C = B\log_2(1+S/N)$. Compare the ATSC bit rate, 19.3 Mbits/second with the theoretical capacity of the 6-MHz channel at the threshold S/N ratio of 14.9 dB.

CHAPTER

20

Antennas and radio wave propagation

While discussing transmitter and receiver circuitry we did not have to know much about antennas or propagation. It sufficed to know only that a voltage applied to the terminals of a transmitting antenna causes a proportional voltage to appear very shortly thereafter at the terminals of a receiving antenna. To be more exact, it was sufficient to know that everything between the terminals of the two antennas is equivalent to a linear two-port network. Here we will consider the transmission through this propagation link.

When an ac source (transmitter) is connected to an antenna (practically any metal structure) the resulting current has a component that is in phase with the applied voltage. The impedance of the antenna therefore has a real part, a resistance, and draws power from the source. If the antenna is efficient, most of the power flows away from the antenna in the form of (energy-bearing) electromagnetic waves and only a small fraction of the power will be dissipated by ohmic heating of the antenna itself. The impedance will also generally have a nonzero imaginary part, a reactance. If the reactance is zero at the operating frequency the antenna is said to be resonant, just as an *RLC* circuit is purely resistive at its resonant frequency. An external tuning network (an *antenna tuner*) can be used to cancel the reactance and also transform the resistance to a value that matches a receiver's input impedance or to a value that draws a desired amount of power from a transmitter.

20.1 Electromagnetic waves

As an electromagnetic wave propagates away from the transmitting antenna, it takes on a spherical wavefront. By the time it reaches a distant receiving antenna, the wavefront has a very large radius of curvature and is essentially a plane wave. The ***E*** and ***H*** vectors (electric and magnetic fields, measured respectively in volts/m and amperes/m) both lie in the plane of the wavefront, i.e., they are transverse to the direction of propagation as shown in Figure 20.1. The fields are in phase with each other; they rise and fall together in space and time.

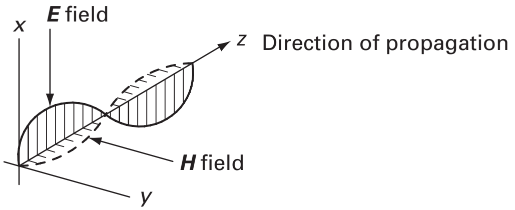

Figure 20.1. An electromagnetic wave – the ***E*** and ***H*** fields are transverse to the direction of propagation.

The ratio of the electric field strength to the magnetic field strength in free space is given by $E/H = (\mu_0/\varepsilon_0)^{1/2} = 120\pi = 377$ ohms. This ratio is known as the "impedance of free space." These fields are perpendicular to each other and their vector cross-product, $\boldsymbol{E} \times \boldsymbol{H}$, points in the direction of propagation. A continuous monochromatic wave has sinusoidal spatial components, $E_0 e^{-jkz}$ and $H_0 e^{-jkz}$, as shown in the figure. The wavenumber, k, is defined as $2\pi/\lambda$ radians per meter. The phase velocity, ω/k, is given by $c = (\mu_0\varepsilon_0)^{-1/2} = 3 \times 10^8$ m/s (the speed of light).

20.1.1 Propagation in a vacuum

Static electric and magnetic fields are always associated with sources, i.e., electric field lines terminate on electric charges and magnetic field lines encircle current filaments. But when an antenna launches an electromagnetic wave, the field lines break away from the sources, reconnecting into closed loops, and the wave becomes autonomous. For a vacuum, Maxwell's curl equations are

$$\nabla \times \boldsymbol{E} = -\mu_0 j\omega \boldsymbol{H}, \tag{20.1a}$$

$$\nabla \times \boldsymbol{H} = \varepsilon_0 j\omega \boldsymbol{E}. \tag{20.1b}$$

The right-hand sides of these equations are like sources; the E-field is produced by the changing H-field and the H-field is produced by the changing E-field. You can verify the statements made above about plane waves by writing the E-field shown in Figure 20.1 as $\boldsymbol{E} = \hat{x}E_0 e^{j(\omega t - kz)}$ and substituting it into Equation (20.1a) to get $\boldsymbol{H}$. You can then verify that $\boldsymbol{H}$ satisfies Equation (20.1b).

Electromagnetic waves are produced by electric charges undergoing acceleration. Time-varying currents contain accelerating charges. A sinusoidally time-varying current distribution on an antenna launches sinusoidal electromagnetic waves. The time-averaged power density or "energy flux" of the waves is given by $S = ½(E \times H) = ½E^2/377$ watts/m^2, where E and H are the (peak) field amplitudes and the factor ½ is the time average of $\cos^2(\omega t)$. At a receiving antenna, the fields from an incident wave produce currents that result in a voltage at the antenna terminals.

20.2 Radiation from a current element

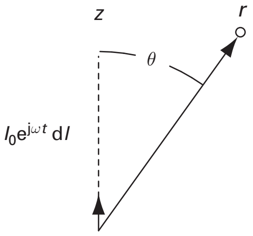

Figure 20.2. An elemental sinusoidal ac current element.

Just as Maxwell's equations can be manipulated to yield back Coulomb's law (which gives the E-field from an elementary point charge) and Ampere's law (which gives the H-field from a constant current element), they can also be stirred together to yield the E and H fields produced by a *time-varying* current element. The E and H fields produced by an antenna are superpositions of the E and H fields from every elemental ac current element on the antenna. Consider an ac current element in the z-direction, as shown in Figure 20.2.

This element has length δl and carries a current $I_0 \cos(\omega t)$ which, as usual, we express as $I_0 e^{j\omega t}$. At the observation point, $\boldsymbol{r}$, the magnetic field is given by

$$\delta H = \frac{I_0 \delta l}{4\pi}\left(\frac{jk\sin(\theta)e^{j(\omega t - kr)}}{r} + \frac{\sin(\theta)e^{j(\omega t - kr)}}{r^2}\right), \tag{20.2}$$

where $k = \omega/c$ and θ is the angle between the current element $\boldsymbol{\delta l}$ and the vector $\boldsymbol{r}$. Equation (20.2) is Ampere's law, generalized for an elemental current with a sinusoidal time variation. The direction of $\boldsymbol{\delta H}$ is given by $\boldsymbol{\delta l} \times \boldsymbol{r}$ (into the page). The first term in the bracket falls off slowly as $1/r$ and is the radiation term. The second term falls off quickly as $1/r^2$ and corresponds to near-field stored energy; j is just a phase factor since $j = e^{j\pi/2}$. The normally implicit $e^{j\omega t}$ term is included here to highlight the wave term, $e^{j\omega t - kr}$. If we let the frequency approach zero, the radiation term vanishes (since k goes to zero), the second term becomes $\sin(\theta)/r^2$ and Equation (20.2) reduces to Ampere's law (also known as the Biot – Savart law) for calculating the magnetic field produced by a dc current element.

Figure 20.3 shows the radiation pattern (*antenna pattern*) obtained from the radiation term in Equation (20.2) (the first term in the bracket). This is a surface plot where the distance from the origin to any point on the surface is proportional to the power radiated in that direction, i.e., proportional to $|\boldsymbol{H}|^2$ at a large constant value of r. We do not have to work out the E-field separately, since we already know that, in the far field, $\boldsymbol{E}$ is perpendicular to both $\boldsymbol{H}$ and $\boldsymbol{k}$ and that its magnitude (in volts/m) is 377 times the magnitude of $\boldsymbol{H}$ (in amps/m).[1]

In this chapter we are interested in radiation far from the antenna, so we can ignore the near-field (second) term in Equation (20.2). At any observation point, the H-field is the integral of the contributions from every current element in any given antenna. For a wire antenna, we would evaluate a line integral. For a reflector antenna, we would have a surface integral, summing up the contributions from the current flowing on each element of the surface.

---

[1] If we do need to know E in the $1/r^2$(near field) region, we can calculate the curl of H from Equation (20.3) and plug that into Equation (20.2) to get E.

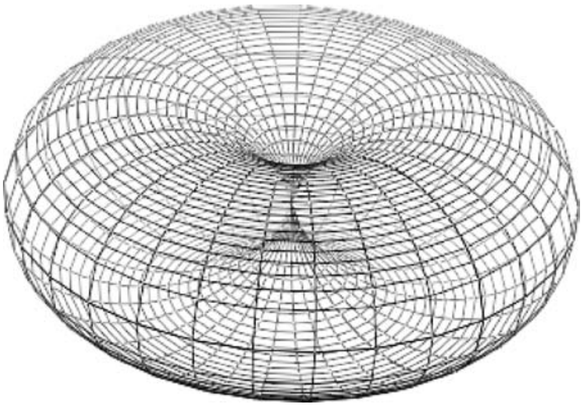

Figure 20.3. Elementary dipole radiation pattern (surface of constant field strength).

20.3 Dipole antenna

A short dipole antenna (shorter than, say, $\lambda/20$) will have the same radiation pattern as the elemental dipole since we can consider it to be a string of elemental dipoles, short enough that the phase paths from every one to the observation point are essentially the same. Thus, the string is equivalent to a single elemental dipole of strength $I\delta\, l = \sum I_i \delta l_i$. We can calculate the power radiated by a single elemental dipole by integrating the average energy flux density, ½EH, over the surface of a bounding sphere to include the power radiated in every direction. Using the radiation term in Equation (20.2) for H, we have

$$\delta H = \frac{I_0 \delta l}{4\pi}\left(\frac{jk\sin(\theta)\mathrm{e}^{\mathrm{j}(\omega t - kr)}}{r}\right), \tag{20.3}$$

$$\begin{aligned}
\text{Total Pwr} &= \int (1/2) EH \mathrm{d}S = \int (1/2)(\mu_0/\epsilon_0)^{1/2} H^2 r^2 \mathrm{d}\boldsymbol{\Omega} \\
&= (1/2)(\mu_0/\epsilon_0)^{1/2}(I_0 k\delta l/(4\pi))^2 \int \frac{\sin^2(\theta)}{r^2} r^2 \mathrm{d}\boldsymbol{\Omega} \\
&= (1/2)(\mu_0/\epsilon_0)^{1/2}(I_0 k\delta l/(4\pi))^2 \int_0^{\pi} 2\pi \sin^3(\theta)\mathrm{d}\theta \qquad (20.4) \\
&= (1/2)120\pi(I_0(2\pi/\lambda)\delta l/(4\pi))^2 8\pi/3 \\
&= 40\pi^2 (I_0 \delta l/\lambda)^2.
\end{aligned}$$

It turns out that the current distribution for a short dipole is a triangle function (actually the almost linear ramp portion of a sine function near zero), as shown in Figure 20.4.

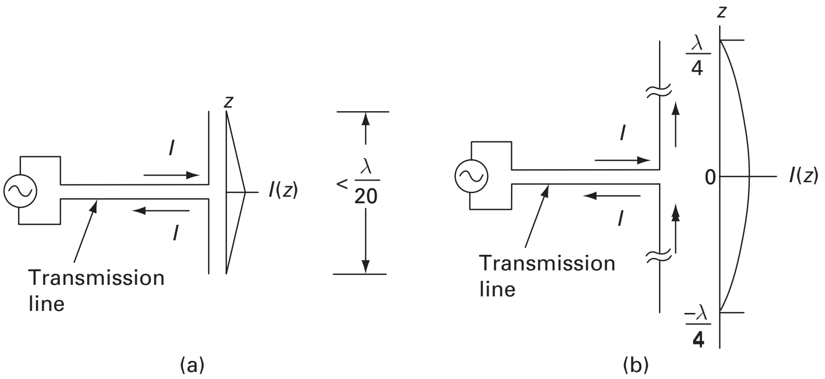

Figure 20.4. (a) A short dipole has a triangular current distribution. (b) A half-wave dipole has a sinusoidal current distribution.

The average current for a short dipole is therefore half the input current, so the power radiated is

$$P_{\text{short dipole}} = 40\pi^2 \left(\frac{I_{\text{in}}}{2} l/\lambda\right)^2, \tag{20.5}$$

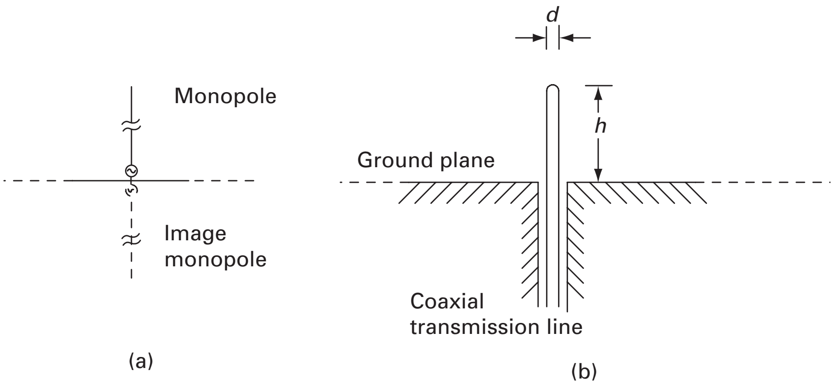
where I_{in} is the peak input current and l is the length of the dipole. The input power must be equal to ½ $I_{\text{in}}{}^2 R$, where R is the real part of the antenna's input impedance, known as the *radiation resistance*. For the short dipole, we can therefore write

$$R_{\text{short dipole}} = 2P_{\text{short dipole}}/I_{\text{in}}{}^2 = 20\pi^2(l/\lambda)^2. \tag{20.6}$$

For a short dipole with $l = 0.05\lambda$, $R = 0.49$ ohms. The imaginary part of the input impedance is negative and large, corresponding to a series capacitance with a low value. An antenna tuning network that increases the low value of R and tunes out the high value of capacitive reactance will need at least one high-value inductor. However, the limited Q of practical inductors will introduce losses that result in very low efficiency. A counterpart to the elemental dipole is the elemental current loop or *elemental magnetic dipole* (as opposed to *elemental electric dipole*). The loop is assumed to have constant current and its radiation pattern is the same as the pattern of the elemental dipole. A very small loop antenna has an extremely low radiation resistance and a high positive (inductive) reactance. It is an inefficient antenna in that its ohmic resistance is usually higher than its radiation resistance.

In practice, most dipoles have an overall length of $\lambda/2$. At this resonant length, the impedance of a thin wire dipole seen at the center gap is 73.1 + j0 ohms, an entirely practical value. Resonant loops, with a circumference of the order of a wavelength, are also practical antennas. While transmission line arguments can

Figure 20.5. Fat monopole geometry.



be used to show that the current distribution on a wire dipole is nearly sinusoidal, going to zero at the open ends, rigorous calculations of current distributions on arbitrary antennas require elaborate self-consistent treatments of the currents and fields. A benchmark problem is the fat dipole antenna shown in Figure 20.5(b). This "monopole" is really a dipole, since the ground plane induces an image monopole as shown in Figure 20.5(a).

This geometry is appealingly simple; the radiating element, as it enters the hole in the ground plane, becomes the center conductor of a coaxial line. You can find theoretical and experimental plots of input impedance of this antenna in most standard antenna textbooks. You can also model this dipole if you have access to a program for three-dimensional electromagnetic field simulation, such as Ansoft's HFSS.

20.4 Antenna directivity and gain

The radiation from any antenna is always stronger in some directions than in others; no antenna can be an isotropic radiator.[2] Let the energy flux (W/m^2) produced in a given direction be denoted as $S(\theta,\phi,r)$, where we are using standard polar coordinates. As before, the integral of S over an enclosing sphere will be the total radiated power transmitted, P_{RAD}:

$$\int S(\theta,\varphi,r)r^2\,\mathrm{d}\boldsymbol{\Omega} = P_{\mathrm{RAD}}. \tag{20.7}$$

---

[2] It is topologically impossible to have a constant tangential vector field on the surface of a sphere, a theorem sometimes expressed as "You cannot comb the hair smooth on a billiard ball." Thus, in the far field of an antenna (at a distance greater than the square of the largest physical dimension of the antenna divided by the wavelength), where the E and B fields are transverse (tangent to the surface of a sphere surrounding the antenna), the fields cannot be everywhere constant. The radiation pattern of an antenna, therefore, cannot be isotropic.

For any given direction, the ratio of the flux to the average flux is defined as the *directivity* of the antenna

$$D(\theta, \Phi, r) = \frac{S(\theta, \Phi, r)}{P_{\mathrm{RAD}}/(4\pi r^2)}. \tag{20.8}$$

An equivalent statement is that the directivity is the factor by which the flux in the strongest direction exceeds the flux from a hypothetical isotropic antenna radiating the same total power. We know that the radiation flux eventually falls off as r^{-2}. For large r, then, the far-field directivity, D, is a function only of the polar coordinates θ and ϕ. Combining Equations (20.7) and (20.8), we see that the average directivity of an antenna is unity:

$$\frac{1}{4\pi}\int D(\theta, \Phi)\mathrm{d}\boldsymbol{\Omega} = 1. \tag{20.9}$$

Directive gain, $G(\theta,\phi,\mathrm{r})$, has the same definition as the directivity except that the radiated power is replaced by P_{inc}, the power incident on the antenna terminals:

$$G(\theta, \Phi, r) = \frac{S(\theta, \Phi, r)}{P_{\mathrm{inc}}/(4\pi r^2)}. \tag{20.10}$$

If an antenna has no ohmic losses and its feedpoint impedance matches the transmission line impedance (so that no power is reflected), all the incident power will be radiated and the directive gain will be equal to the directivity. In most antennas used for transmitting, the losses are no more than a few percent and the distinction between directivity and gain is unimportant.[3] The maximum value of an antenna's directive gain is simply called the gain. A transmitter connected to an antenna having a gain of 20 dB will produce a directed signal 100 times more powerful than if it were connected to a hypothetical lossless isotropic radiator.

Since we have already calculated the total power radiated by an elemental dipole (Equation 20.4), we can easily calculate its directivity. The maximum flux density, calculated from Equation (20.3), is $S_{\max} = (60/\pi)[\,I_0 k\,\delta\,l\,/(4\pi r)]^2$, where we have substituted 120π for $(\mu_0/\varepsilon_0)^{1/2}$. Dividing $\mathrm{S}_{\max}$ by the average flux density, S_{avg} = total power/$(4\pi r^2)$, yields a directivity of 1.5. As explained above, this will also be the directivity of a short dipole. The directivity of a half-wave dipole is 1.64 and its radiation pattern differs little from that of the elemental dipole.

---

[3] Small inefficient antennas are adequate for low-frequency receivers. Even though antenna losses add noise at the receiver input, signal strengths in the AM broadcast band and short-wave bands must already be considerably higher than this added noise in order to exceed the noise power from static (atmospheric electricity). Even with an inefficient antenna, the total power delivered to the receiver is much greater than the thermal noise added by the antenna and by the receiver itself.

20.5 Effective capture area of an antenna

The distance between transmitting and receiving antennas is generally so large that a plane wave can be assumed incident on the receiving antenna. The energy extracted from the incident wave is, of course, proportional to the average energy flux density, $\frac{1}{2}E \times H$ W/m^2. The proportionality constant is called the *effective area* (capture area) of the receiving antenna. It turns out, as shown below, that the effective area is proportional to gain:

$$A_{\text{eff.}} = G\lambda^2/4\pi. \tag{20.11}$$

Since gain and effective area are proportional, there is really no distinction between transmitting antennas and receiving antennas; the best transmitting antenna (most gain) is also the best receiving antenna (most capture area). A standard derivation of Equation (20.11) begins by applying the reciprocity theorem[4] to a system of two arbitrary antennas. The two antennas, as shown in Figure 20.6, need not be identical. We can suppose they are both matched to the same impedance value and that we have both a generator and a receiver that match this impedance. First we connect the generator to Antenna 1 and measure the power from Antenna 2.

If we now interchange the generator and load, the reciprocity theorem states that the power delivered to the load will be unchanged. Expressing this in terms of gain and effective area, we have $G_1A_{\text{eff }2} = G_2A_{\text{eff }1}$ or $G_1/A_{\text{eff }1} = G_2/A_{\text{eff }2}$, from which we see that the ratio of gain to effective area has the same constant value for any and all antennas. We can pick any conveniently simple antenna

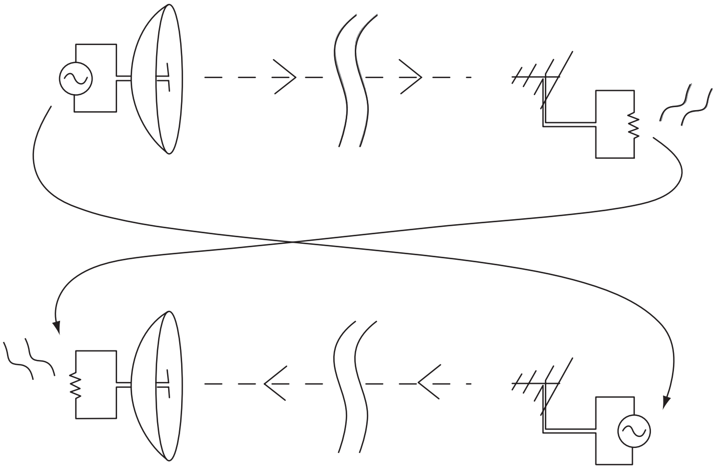


Figure 20.6. Reciprocity: received power is unchanged when source and load are interchanged.

---

[4] The remarkable reciprocity theorem finds application in mechanics, optics, and acoustics as well as electrical engineering.

and use electromagnetic theory to calculate its gain and effective area. When this is done, it is found that the ratio of gain to effective area is $4\pi/\lambda^2$. A half-wave dipole antenna has a maximum gain of 1.64. Its effective area is therefore $1.64\,\lambda^2/4\pi$. If the dipole is made of thin wire, it has no real physical area, only a length, yet it has a nonzero effective area and can extract energy from an incident electromagnetic wave. Note that even a very short dipole has nearly the same effective area as a half-wave dipole. The effective area of a microwave dish antenna can approach its physical area, as we will see below, but normally it is from 50 to 80 percent of the physical area. This fraction, known as *aperture efficiency*, is usually set not by ohmic losses but rather by the illumination pattern of the primary feed antenna. A perfectly uniform illumination pattern (and no ohmic loss) produces an aperture efficiency of unity. The Arecibo radio telescope dish uses an aperture 700 ft in diameter (area = 35 800 m^2). Its aperture efficiency is about 70% at $\lambda = 12$ cm (the wavelength used there for radar astronomy) so its gain, using Equation (20.11), is $G = 4\pi(0.70 \times 35\,800)/(0.12)^2 = 22 \times 10^6$ or 73 dB.

20.6 Reflector and horn antennas

Radar antennas and satellite TV dishes are familiar examples of reflector antennas. From a transmitting standpoint, a primary or "feed" antenna illuminates the reflector. Currents induced in the metallic surface of the reflector become secondary radiators and their radiation forms the beam of the antenna. The larger the dish, the more directive the antenna, as we will see. These antennas are examples of "aperture antennas;" one can readily identify the aperture (usually circular) from which the radiation emanates, as if from a searchlight.

Let us use Equation (20.3) to calculate the radiation from a large flat rectangular metal plate on which there is a surface current density, J_S, which has the same amplitude and phase at every point.[5] For surface current, $J_S\mathrm{d}x\mathrm{d}y$ replaces $I_0\mathrm{d}l$ in Equation (20.3). To find the antenna pattern we integrate over the plate, summing up the contributions from each element of area. These are phasor contributions and the far field is actually an interference pattern. Once we have calculated the antenna pattern, we will integrate the power over a bounding sphere, as we did for the elemental dipole, to determine the total power radiated. With this, we can then calculate the gain.

Figure 20.7 shows the geometry for this antenna. The size of the plate is $2a$ by $2b$. Radiation will be strongest in the z-direction, perpendicular to the plate. We

---

[5] Such a current distribution could be established by illuminating the plate with radiation from a dipole far out in front of the plate, though this would not be an efficient feed antenna, since the plate would intercept only a small fraction of the dipole's radiation.

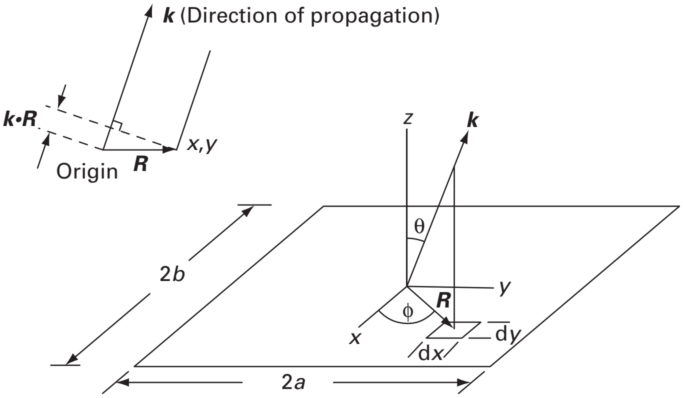

Figure 20.7. Rectangular aperture antenna geometry.

will assume that both a and b are much greater than λ, anticipating that this will form a very concentrated beam.[6]

The vector from the center of the plate to a distant observation point is denoted by $\boldsymbol{r}$, and the vector from the center of the aperture to an arbitrary point x,y on the aperture is denoted by $\boldsymbol{R}$. Again using the first term (the radiation term) of Equation (20.3), we see that the contribution to the distant H field from an element of area at the center of the plate is given by $\delta H = J_S\,\mathrm{d}x\mathrm{d}y\ \mathrm{j}k(4\pi r)^{-1}\cos(\theta)\mathrm{e}^{\mathrm{j}(\omega t-kr)}$ where, as always, $k = 2\pi/\lambda$ and $\boldsymbol{k}$ is directed from the plate to the point $\boldsymbol{r}$. Note that the $\sin(\theta)$ factor in Equation (20.3) is here $\cos(\theta)$ because the current is perpendicular, not parallel, to the z-axis. We will replace this $\cos(\theta)$ by unity, anticipating that, when both a and b are much greater than λ, the pattern will be highly concentrated around the $\theta = 0$ direction. Away from the origin, radiation to the point $\boldsymbol{r}$ from any other point on the plate will be shifted in phase by $\boldsymbol{k}\cdot\boldsymbol{R}$ radians, as shown by the inset in Figure 20.7. Using standard polar coordinates, this phase shift is given by

$$\boldsymbol{k}\cdot\boldsymbol{R} = xk_2 + yk_y = k\ \sin(\theta)[x\cos(\phi) + y\sin(\phi)]. \tag{20.12}$$

If we assume a uniform field over the aperture, the field at r, θ, ϕ can now be written as

$$\begin{aligned} H(r,\theta,\phi) &= \frac{jkJ_S\mathrm{e}^{\mathrm{j}\omega(t-kr)}}{4\pi r}\int_{-b}^{b}\int_{-a}^{a}\mathrm{e}^{\,\mathrm{j}k\cdot R}\mathrm{d}x\mathrm{d}y \\ &= \frac{jkJ_S\mathrm{e}^{j\omega(t-kr)}}{4\pi r}\int_{-b}^{b}\int_{-a}^{a}\mathrm{e}^{\,\mathrm{j}k\theta(x\cos\phi+y\sin\phi)}\mathrm{d}x\mathrm{d}y, \end{aligned} \tag{20.13}$$

---

[6] When used at a wavelength of 12 cm, the 210-m diameter illumination on the dish at Arecibo forms a beam whose width between half-power points is only 12/21 000 radians or 0.03 degree, a "pencil beam."

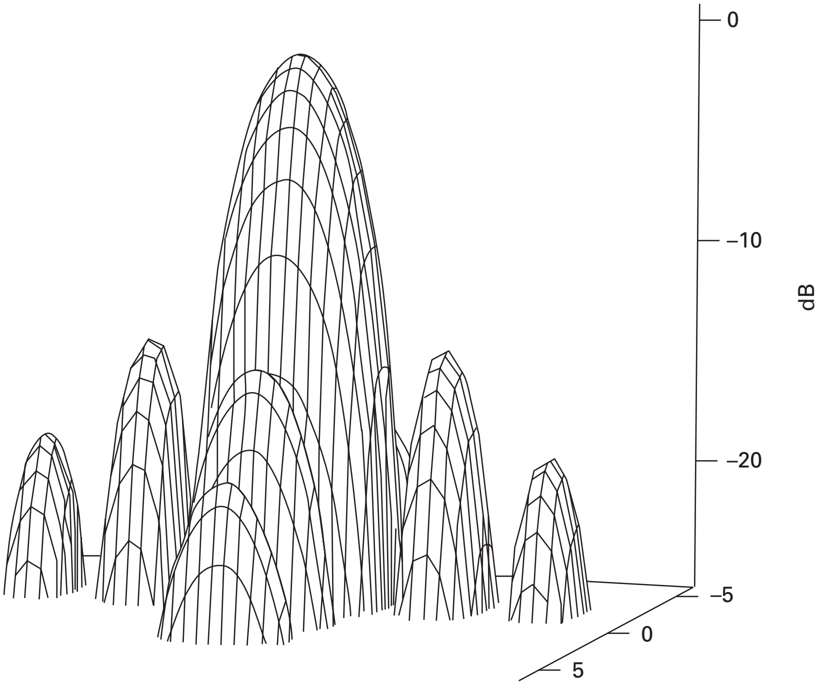

Figure 20.8. Radiation pattern (power in dB) from a rectangular aperture.

where we have replaced $\sin(\theta)$ by θ, again anticipating that the power will be negligible except for the region close to $\theta = 0$. Evaluating the integral we find

$$H(r,\theta,\phi) = \frac{\mathrm{j}kJ_{\mathrm{S}}ab\mathrm{e}^{\mathrm{j}\omega(t-kr)}}{4\pi r}\left(\frac{\sin(ka\theta\cos(\phi))}{ka\theta\cos(\phi)}\frac{\sin(kb\theta\sin(\phi))}{kb\theta\sin(\phi)}\right). \tag{20.14}$$

Since the average power density (watts/m^2) is given by $EH = ½(\mu_0/\varepsilon_0)^{1/2}H^2$, the antenna pattern is proportional to the square of the term in brackets. Figure 20.8 shows the pattern, which has a strong central *main lobe* surrounded by *sidelobes*, which for this $(\sin(x)/x)^2$ power pattern are 13.3 dB below the peak of the main beam.

This plot uses rectangular "sky coordinates," u and v, measured in radians, where $u = \theta\sin(\phi)$ and $v = \theta\sin(\phi)$. The term in brackets is, therefore, $\sin(kau)/(kau)\ \sin(kbv)/(kbv)$. This plot was made for a square aperture; a rectangular aperture produces an elongated beam. For $a < b$, the beam is broader in the u-direction than in the v-direction. We can integrate the power density of the pattern to get the total average power:

$$\begin{aligned}\mathrm{Pwr} &= 1/2\sqrt{\frac{\mu_0}{\varepsilon_0}}\left|\frac{jJ_{\mathrm{S}}kab\mathrm{e}^{\mathrm{j}\omega(t-kr)}}{4\pi r}\right|^2\iint r^2\left(\frac{\sin(kau)}{kau}\frac{\sin(kbv)}{kbv}\right)^2 \mathrm{d}u\mathrm{d}v\\ &= 1/2\sqrt{\frac{\mu_0}{\varepsilon_0}}\left(\frac{J_{\mathrm{s}}kab}{4\pi}\right)^2\frac{\pi^2}{k^2ab}.\end{aligned} \tag{20.15}$$

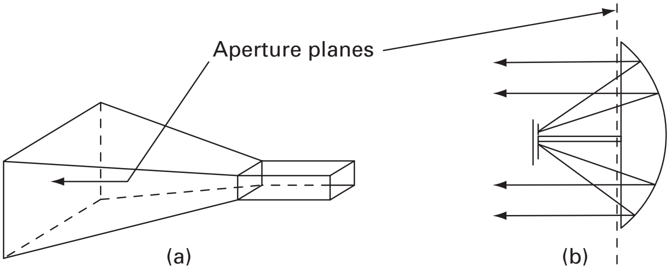

Figure 20.9. Horn and dish antenna aperture planes.

This let us calculate the gain:

$$G = 1/2\sqrt{\frac{\mu_0}{\epsilon_0}}|H(r,0,0)|^2 \div \frac{\text{Pwr}}{4\pi r^2} = \frac{4\pi(4ab)}{\lambda^2} = \frac{4\pi A}{\lambda^2}. \tag{20.16}$$

This example antenna serves to establish the relationship between gain and effective area, $G = 4\pi\ A_{\text{eff}}/\lambda^2$, as long as we can argue that the effective area (capture area) is equal to the actual physical area. To argue this case, consider that a wave transmitted by this antenna is essentially a plane wave as it leaves the large aperture (as contrasted with the spherical wave emitted by a small antenna). Therefore, if we invoke time reversal, the wave entering the antenna would be a plane wave, just as if it had come from a distant transmitting antenna. Since the time-reversed wave is completely "absorbed" by the antenna, the effective area is equal to the physical area, $4ab$.

The integral in Equation (20.13) is just a two-dimensional Fourier transform of the aperture illumination. In this example, we used uniform illumination, so we have transformed the shape of the aperture with uniform weighting. The aperture can have any shape. For example, a circular plate of radius $a \gg \lambda$ produces a field pattern proportional to $J_1(ka\theta)/(ka\theta)$, where J_1 is the first-order Bessel function of the first kind. (The function $J_1(x)$ resembles $\sin(x)[x+1]^{-1/2}$). For any given aperture, uniform illumination produces the highest gain. But "tapered" illumination, where the current density is less near the edges of the aperture, is often used because it reduces the amplitude of the sidelobes.

A simple *microwave horn antenna* is essentially a waveguide funnel, fed at the small end, as shown in Figure 20.9. The other end fans out, usually in both transverse directions, to form a large aperture. The beam radiated from the aperture is comparable to the beam radiated from a dish antenna having equal area. The field distribution in the aperture plane is the same as the field at any cross-section in the waveguide, expanded to fill the aperture.

The horn antenna has no secondary radiators in its aperture plane. Of course there are currents on the inside walls of the waveguide and, in principle, Equation (20.3) can be used to calculate the radiation pattern far out in front of the horn. A much simpler way to find the radiation pattern is to use Huygen's principle, where the aperture *field* is regarded as a *source*, a two-dimensional array of wavelets, each of which re-radiates as if it were a current element.[7] If you know the *E*-field (or *H*-field) in the aperture plane, the squared magnitude of its two-dimensional Fourier transform yields the radiation pattern, just as the squared magnitude of the transform of the currents on a metal plate yielded the radiation pattern in the above example. This analysis technique is also applied to dish antennas. Ray-tracing methods (geometric optics) are used to find the phase and amplitude of the field at an aperture plane – usually just in front of the dish. This field is then regarded as a Huygen's source; its Fourier transform gives the far-field pattern without requiring an intermediate calculation of the currents on the reflector surface. This Fourier transform method is also applied to systems having multiple antennas, such as arrays of dish antennas, used together as an *interferometer* to form an extremely narrow beam.

20.7 Polarization

The elementary dipole of Figure 20.2 produces radiation with *linear polarization*; at any observation point the electric field vector has a fixed direction and an amplitude that oscillates sinusoidally. A dipole receiving antenna would have to be placed parallel to the incoming polarization. If placed perpendicular to the incoming *E* vector, it would pick up no signal. In all the preceding discussions, we have implicitly assumed that the polarization of a receiving antenna was matched to that of a transmitting antenna. *Circular polarization* can be produced with an antenna made of crossed dipoles. The dipoles are fed by signals that are equal in amplitude but 90° out of phase. This results in a transmitted *E* vector that rotates in the plane perpendicular to the direction of propagation. At any observation point, the magnitude of the *E* vector remains constant, but the vector rotates one turn for every period of the wave. A 90° hybrid can be used as a power splitter to feed the two dipoles. An identical antenna (a pair of crossed dipoles with a 90° hybrid as a combiner) makes a polarization-matched receiving antenna. Note that a single dipole can serve as a receiving antenna for circular polarization, but it collects only half the available power. If the incoming *E* field, viewed from the receiving position, rotates in the counterclockwise sense, the radiation has, by definition, *right-hand circular polarization (RCP)*. If the cables from the receiving antennas were to be interchanged at the hybrid, the resulting *LCP* antenna would have the wrong handedness and could receive no power from an RCP transmitting antenna. The most general polarization is elliptical, which is an admixture of linear and circular. Linear and circular polarizations are just special cases of elliptical polarization.

---

[7] See Reference [1] for a theoretical justification of Huygen's principle.

20.8 A spacecraft radio link

Consider the following example of a spacecraft telemetry link for which we wish to find the maximum range. Suppose we have a 1-W telemetry transmitter aboard a spacecraft and that the data rate requires a channel capacity corresponding to a signal-to-noise ratio of at least unity in a 1-Hz bandwidth. This link uses a frequency of 3 GHz (10 cm wavelength). The transmitting antenna on the spacecraft is a 2-m diameter dish. The ground station antenna is a 10-m diameter dish, as shown in Figure 20.10. Assume that both these dish antennas have an effective area equal to 60% of their physical apertures. Assume also that there is no pointing error, i.e., the antennas always point directly at each other and that the system temperature of the ground station receiver is 25 K. (The system temperature is the sum of the equivalent receiver noise temperature, the antenna noise temperature, and the sky noise temperature.)

1. What is the equivalent input noise power of the receiver? Boltzmann's constant, k, is 1.38×10^{-23} W/Hz/K, so the equivalent input noise power, kTB, is $1.38 \times 10^{-23} \times 25 \times 1 = 3.45 \times 10^{-22}$ W.
2. What is the effective area of the receiving antenna? The physical aperture is $\pi \mathrm{R}^2$ so the effective area is $0.60\ \pi R^2 = 0.60\pi 5^2 = 47.1\ \mathrm{m}^2$.
3. What is the gain of the transmitting antenna? The physical aperture is πR^2 and the aperture efficiency is 0.60 so the effective aperture is $0.60\ \pi(1^2) = 1.88\ \mathrm{m}^2$. The gain is $4\pi A_{\mathrm{eff}}/\lambda^2 = 4\pi(1.88)/(0.1^2) = 2369$.
4. What is the maximum range, R, in kilometers for the spacecraft to maintain the required signal-to-noise ratio? Here we simply set $P_{\mathrm{noise}} = P_{\mathrm{received}} = A_{\mathrm{rcvr}}\ P_{\mathrm{trans.}} G_{\mathrm{trans}} / (4\pi R^2)$ from which we have $R^2 = (4\pi)^{-1} P_{\mathrm{trans.}}\ G_{\mathrm{trans}}/P_{\mathrm{noise}}$. Using the parameters calculated above, we have $R = \sqrt{(4\pi)^{-1} \times 1 \times 2369/(3.45 \times 10^{-22})} = 7.4 \times 10^{11}\mathrm{m} = 740 \times 10^6\mathrm{km}$. This is roughly the mean distance to Jupiter.

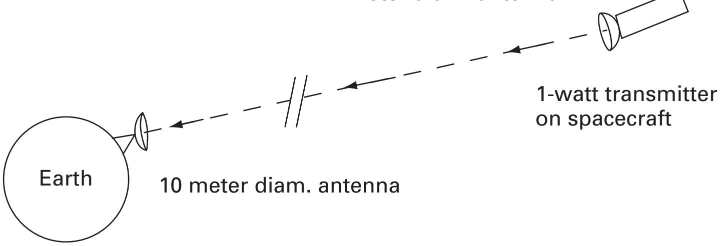

Figure 20.10. A spacecraft telemetry link.

20.9 Terrestrial radio links

VHF and UHF two-way radios used by cellular phones, emergency vehicles, etc. have transmitters with several watts of power but their range is limited by the curvature of the Earth to only a few miles or tens of miles. (Radio waves do not propagate through the highly conductive Earth though they do diffract slightly, so the radio horizon is somewhat beyond the optical horizon.) Mobile radios also use antennas that have gains only of the order of unity so they do not have to be pointed accurately – or even at all. Finally, in ground-to-ground radio links, the signal usually arrives from an angle near the horizon; the receiving antenna will pick up noise from the ground (thermal radiation). In these systems, then, extremely low-noise receivers are of no benefit. Broadcasting stations for FM and television also use VHF and UHF frequencies so their range is also essentially line-of-sight. Long-distance propagation in AM and short-wave broadcasting depends on reflection from the ionosphere.

20.10 The ionosphere

At altitudes above about 60 km the atmosphere is ionized by ultraviolet radiation from the Sun; electrons are stripped from the neutral particles (mostly oxygen atoms and O_2 and N_2 molecules) to produce a mixed electron and ion gas. During the day the density of this ionized gas is highest at around 250 km, the peak of the "F-region." Above the peak the ionization is less because the thinner atmosphere presents fewer particles to be ionized. Below the peak the ionization is less because the denser atmosphere exhausts the supply of ultraviolet photons; the electrons they produce quickly encounter nearby ions and recombine. At night, without sunlight, the ionization rate is zero. Recombination quickly neutralizes the ionization at the lowest altitudes, around 100 km, and depletes the F-region until sunrise.

20.10.1 Wave propagation in the ionosphere

An electromagnetic wave induces electric currents in the electron gas of the ionosphere. (The electrons, by virtue of their low mass, are accelerated by the incident wave to much higher velocities than the ions, so the ion contribution to the current is negligible.) The effective dielectric constant of an electron gas is not difficult to calculate from Maxwell's equations. (We will see that this dielectric constant becomes imaginary below a certain critical frequency which depends on the electron density; below this frequency, then, electromagnetic waves cannot propagate through the plasma.) No longer in a vacuum, we must use the general curl H equation which includes the real electric current, J, in addition to the displacement current:

$$\nabla \times \boldsymbol{H} = \boldsymbol{J} + \epsilon_0 \frac{\partial \boldsymbol{E}}{\partial t}. \tag{20.17}$$

The electrons are in rapid thermal motion, but this motion is random and contributes nothing to the current. Yet all the electrons near any given point are accelerated equally and move together to produce a net current, $\boldsymbol{J} = Nev$, where N is the electron density, e is the electron charge, and v is the component of velocity imparted by the electric field. We will neglect the weak $\boldsymbol{v} \times \boldsymbol{B}$ force from the magnetic field so Newton's second law of motion is just $m\mathrm{d}\boldsymbol{v}/\mathrm{d}t = \boldsymbol{F} = e\mathbf{E}$. For a sinusoidal time dependence, $\mathrm{e}^{\mathrm{j}\omega t}$, we can write this equation of motion as $m(\mathrm{j}\omega\boldsymbol{v}) = e\mathbf{E}$. Substituting $\boldsymbol{J} = Ne\mathbf{v} = Ne^2\boldsymbol{E}/(\mathrm{j}\omega m)$ in Equation (20.17) gives

$$\nabla \times \boldsymbol{H} = \frac{Ne^2\boldsymbol{E}}{\mathrm{j}\omega m} + j\omega\epsilon_0\boldsymbol{E} = \mathrm{j}\omega\epsilon_0\left(1 - \frac{Ne^2}{\epsilon_0 m\omega^2}\right)\boldsymbol{E}. \tag{20.18}$$

Note that the term in brackets is the relative dielectric constant and that it becomes negative for low frequencies, in particular for $\omega^2 < \omega_\mathrm{p}^2$ where $\omega_\mathrm{p}^2 = Ne^2/(\varepsilon_0 m)$. This happens because the conduction current (the electron current) becomes greater than the displacement current. The total current (conduction current plus displacement current) changes sign and has the wrong polarity to source the H field of a traveling wave. This critical frequency, ω_p, is known as the *plasma frequency*. (If the local charge neutrality of an electron–ion gas is disturbed, the densities will oscillate at this frequency the way a spring and mass system oscillates at its resonant frequency.) For a wave to propagate in the plasma, the dielectric constant must be positive; only waves with frequencies lower than the plasma frequency will be reflected. The free-electron gas that gives metals their conductivity is dense enough to reflect visible light but the alkali metals (lithium, sodium, etc.) have relatively lower electron densities and are transparent in the ultraviolet.

20.10.2 Reflection of waves from the ionosphere

The reflection of radio waves is normally a process of refraction because the waves are not vertically incident on the ionosphere. As they travel obliquely upward, the dielectric constant decreases so the phase velocity increases, causing the propagation vector, which is perpendicular to the wavefront, to turn around gradually. This is shown in Figure 20.11.

For signal strength calculations over an ionospheric path the ionosphere can be considered a specular mirror and field strengths can be calculated by taking the inverse square of the total path length of the ray.

20.10.3 Daytime vs. nighttime propagation

Short-wave broadcasts from distant transmitters on the higher frequency bands are not heard at night because the ionospheric electron density is too low for

reflection, i.e., the waves cannot get turned around sufficiently. On the other hand, low-frequency stations, such as those in the AM broadcasting band, are received from great distances *only* at night. During the day their energy is dissipated in the lower ionosphere through collisions between the accelerated electrons and neutral atoms and molecules. Why don't higher frequency waves suffer this daytime attenuation in the lower ionosphere? Consider a low-frequency and a high-frequency wave of equal power, that is, equal field strengths. Both cause the ionospheric electrons to execute synchronized sinusoidal motion as described above. But the low-frequency wave, because its period is long, will produce higher electron velocities; we saw above that $v = Ee/(j\omega m)$. The average kinetic energy of each electron is therefore $m\langle v^2\rangle/2 = m[Ee/(\omega m)]^2/4$ where E is the amplitude of the electric field. All the electrons in the lower ionosphere suffer collisions with the neutral particles (which are present since the ionization is not 100%). The average collision leaves the electron with a random velocity, i.e., its share of the synchronized sinusoidal motion is lost. The frequency of collisions does not depend on the frequency of the electromagnetic wave (or on there being any electromagnetic wave present at all) so the rate of energy loss is inversely proportional to the square of ω, the wave frequency, and long-distance AM listeners have to wait for nighttime.

20.11 Other modes of propagation

Besides reflection by the ionosphere, there are a number of other ways that an electromagnetic wave can get around the curvature of the Earth. These include scattering from the ionized trails of meteors entering the Earth's atmosphere, scattering from irregularities in the ionosphere even when the ionosphere is otherwise not dense enough to turn the waves around by refraction, scattering from density irregularities in the neutral atmosphere (i.e., fluctuations in the index of propagation), and ducting beneath atmospheric temperature inversion layers.

Problems

Problem 20.1. The voltage at the terminals of a receiving antenna is proportional to the E field of an incident electromagnetic wave. The “effective length” (or effective height if the antenna is vertical) is defined as the open-circuit voltage at the terminals divided by the incident E field: volts / (volts/meter) = meters. Show that the effective length is given by

$$\text{effective length} = (4RA_{\text{eff}}/Z_0)^{1/2},$$

where R, the radiation resistance, is the real part of the antenna impedance, A_{eff} is the effective area ($A_{\text{eff}} = G\cdot\lambda^2/(4\pi)$), and $Z_0 = 377$ ohms = $(\mu_0/\epsilon_0)^{1/2}$, the impedance of free space. Find the effective length of a half-wave dipole ($G = 1.6$ and $R = 73$ ohms).

Problem 20.2. Suppose we have a 1-W transmitter connected to a dipole antenna which is aligned to provide the maximum signal strength at a distant receiving antenna. Needing more signal strength, we obtain a second, identical dipole and, using a power splitter, feed each dipole with ½W. We space the second far enough from each other so that they do not interact. We make sure that both antennas are aligned toward the receiver and we also make sure that the cables from the power splitter have equal length. At the receiving antenna, each transmitting antenna provides a field amplitude that is less than the original field by $1/\sqrt{2}$. But the two signals are in phase so the total amplitude is increased by $2/\sqrt{2} = \sqrt{2}$. Squaring this we see that the received signal strength is doubled. Have we gotten something for nothing? Could we repeat this process to increase the received power even more?

Problem 20.3. Let the individual antennas of Problem 20.2 be AM broadcast towers with omnidirectional patterns and vertical polarization. Suppose the spacing between these antennas is $\lambda/2$. As before, they are fed symmetrically, that is, with the same power and same the phase. Find the radiation pattern in the horizontal plane: make a polar plot of the relative field strength vs. azimuth angle for a distance far from the antennas. Hint: at any observation point in the horizontal plane at a distance r from the center of the line joining the two antennas, the total voltage is the sum of the contributions from the two antennas, $e^{j\phi_1}$ and $e^{j\phi_2}$. The phases π_1 and π_2 are the phase path lengths corresponding to r_1 and r_2, the distances from the observation point to the respective antennas. These phase paths are just $2\pi r_1/\lambda$ and $2\pi r_2/\lambda$. The field strength is given by $(|e^{j\phi_1} + e^{j\phi_2}|)$.

Problem 20.4. Consider a pair of crossed dipoles. The first dipole points in the z-direction and carries a current $\cos(\omega t)$. The second dipole points in the x-direction and carries a current $\sin(\omega t)$. Find the type of polarization and the relative power density of the radiation in the $+z$, $-z$, $+x$, $-x$, $+y$, and $-y$ directions. If you have a program like MATLAB or Mathcad, make a three-dimensional surface plot, like Figure 20.3, for which the distance from any point on the surface to the origin is proportional to the radiation power in that direction.

CHAPTER

21 Radar

The idea that radio waves could be used to detect the presence of stationary or moving objects emerged around 1900, almost as soon as radio itself. Christian Hueslmeyer, a German inventor, demonstrated an apparatus in 1904 which, when mounted on a bridge above the Rhine, rang a bell when a ship passed beneath. He used a (now) primitive spark gap RF source and coherer detector. The system may have shown only marginal potential for collision avoidance, as the German Navy demonstrated no interest. Sir Robert Watson-Watt developed meteorological radar in Britain in the 1930s and then a chain of air defense radars during World War II. In the U.S., the MIT Radiation Laboratory, set up to develop military microwave radar systems, had nearly 4000 employees between 1940 and 1945. The acronym RADAR, for Radio Detection And Ranging, has been attributed to U.S. Navy officers F. R. Furth and S. M. Tucker, who introduced it in 1940, though the term remained classified throughout the war.[1]

Today, radar goes beyond aircraft tracking to applications as diverse as space object monitoring, storm tracking, detection of clear air turbulence, and velocity measurements of speeding automobiles and baseballs. In this chapter, we look at some commonly used radars, some general system aspects of radar, and, finally, some RF components and techniques developed specifically for radar.

21.1 Some representative radar systems

Classic surveillance radar

Figure 21.1 is a block diagram of the classic radar system used to monitor air traffic. A rotating antenna sweeps continuously in azimuth while it repeatedly transmits short pulses and receives subsequent echos from targets. As each pulse is transmitted, the beam of the CRT display begins to sweep from the center in a radial direction. The detected signal from the receiver modulates the

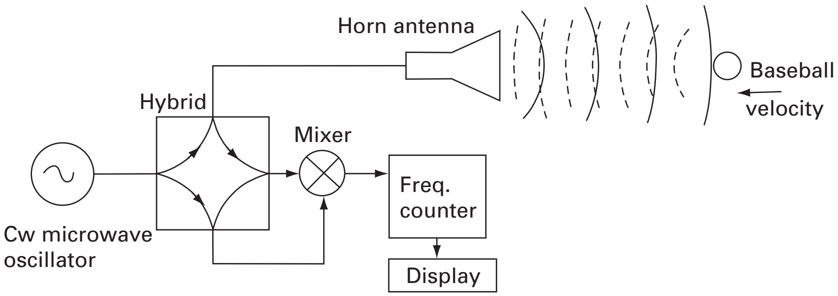
intensity of the spot, rather than causing a deflection perpendicular to the sweep direction. The beam deflection coil is made to rotate continuously around the neck of the CRT, synchronized to the rotation of the antenna, so that the radial sweep direction at any instant is the azimuthal pointing direction of the antenna.

Generally there is a bright area near the center of the CRT, produced by reflections from nearby hills, buildings and towers. The receiver may incorporate an electronic gain control, slaved to the CRT sweep to compensate for the decrease in echo strength with increasing target range. Dashed lines on the figure show the spherical wavefronts for two transmitted pulses and for the reflection (echo) from one pulse, but do not indicate that the intensity of the transmitted waves is sharply concentrated in the forward direction by the high directivity of the antenna.

21.1.1 CW Doppler radar

The classic radar described above uses short pulses for good range resolution. It detects the amplitude of each returning pulse, paying no attention to the phase. Quite the opposite is the radar speed gun, which transmits cw and therefore has no range resolution, but does detect the phase to measure speed. A functional block diagram of the speed gun is shown in Figure 21.2.



Horn antenna
Baseball

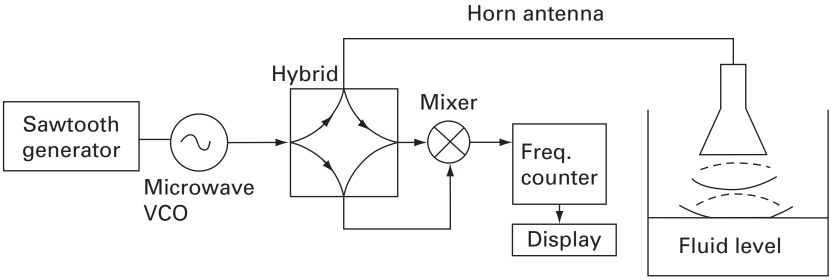
Hybrid
Mixer
Freq. counter
Display
Cw microwave oscillator

Figure 21.2 Radar speed gun.

The signal from a cw microwave oscillator in the 10–20 GHz range (usually a Gunn diode negative resistance oscillator) is split to feed the horn antenna and a mixer (multiplier). The echo from the target also provides a signal to the mixer. A moving target causes a Doppler shift, so the echo has a higher frequency if the target is approaching the radar. The output from the mixer contains a signal whose frequency is equal to the Doppler shift. This frequency is counted and multiplied by the appropriate factor so that the display reads line-of-sight velocity. Note that the Doppler shift depends only on the line-of-sight velocity of the target. This radar is totally insensitive to range.

21.1.2 Chirped cw radar

The radar in Figure 21.3 differs from the radar speed gun only in that its oscillator is a "chirped" VCO, whose output frequency follows a sawtooth control voltage. Here this radar is used to determine the position of a stationary (or very nearly stationary) fluid level in a storage tank.



Horn antenna
Hybrid
Mixer
Sawtooth generator
Microwave VCO
Freq. counter
Display
Fluid level

Figure 21.3 Radar fluid level detector.

The frequency of the tone at the mixer output is given by the frequency difference of the two signals arriving at the mixer inputs. One of these signals is delayed by the round-trip time to the fluid surface, so the lower the level in the tank, the higher the output frequency of the mixer. Note that this radar cannot determine velocity; if the fluid level were changing rapidly, it would create a

Doppler shift that could not be distinguished from a change in fluid level. (Range and velocity are ambiguous for this radar.)

21.1.3 Pulse-Doppler radar

The radar of Figure 21.1 can be modified to sense velocity as well as position. The resulting *pulse-Doppler radar*, when mounted on an aircraft, can distinguish moving targets on the ground from the much stronger "ground clutter" produced by stationary objects. The earliest form of pulse-Doppler radar, called "MTI", for *moving target indicator*, used a mercury acoustic delay line as analog storage for the train of echos received after each pulse. The stored signal was subtracted from the echoes produced by the next pulse to remove the echoes from fixed targets. (This type of delay line, when configured as a recirculating shift register, was used around 1950 as the memory in some of the earliest digital computers.)

Pulse-Doppler radar really became practical with the advent of frequency-stable microwave signal sources (klystron amplifiers, rather than high-power magnetron oscillators), digital storage capability, and digital signal processing. These advances allow coherent signal averaging for increased sensitivity, as well as actual determination of target velocity. Successive received echoes, after being mixed to a low IF frequency, are stored, preserving both amplitude and phase, and then the stored echos are analyzed to see how the phase changes from one pulse to the next. A moving target causes a progressive phase change (Doppler shift) from which the line-of-sight velocity can be determined. When used as a search radar, successive received signals are stored separately for every range. Fourier analysis of the sequence of sampled IF voltages for each range determines whether there is a target at that range and, if so, determines its velocity. A problem that often arises with pulse-Doppler systems involves a range-velocity ambiguity. If target velocities are in the range $\pm v_{\max}$, the corresponding Doppler shift range is $\pm 2f\ v_{\max}/c$, where f is the radar frequency. This produces a total received bandwidth of $4fv_{\max}/c$. If we are to unambiguously determine the frequencies present in this band, the sampling rate, which is the pulse rate, must be at least $8f\ v_{\max}/c$. A high radar frequency and a high maximum velocity may dictate a pulse rate that restricts the maximum unambiguous range. (The echo from a target beyond the maximum unambiguous range arrives after the next pulse has been transmitted, as if it had been reflected from a close-in target.) This problem is discussed in Chapter 26 in the context of planetary radar astronomy.

21.2 Radar classification

Many radar systems are quite different from the classic configuration of Figure 21.1. Radar systems are conveniently classified according to several key system characteristics:

(a) Monostatic or bistatic:
A monostatic radar uses a single antenna for both transmitting and receiving, while a bistatic radar uses two separate antennas. An obvious advantage of the bistatic configuration is that it requires no TR (transmit/receive) switch. A military advantage is that only the transmitting site, which can be unmanned, is vulnerable to attack by a radiation-seeking missile. Bistatic and multistatic radar systems can also be passive, using "transmitters of opportunity," such as television broadcast transmitters.

(b) Coherent (Doppler) or incoherent:
Radars with stable frequency sources for the transmitter and the receiver L.O. can use coherent integration to extract a signal from noise. They can also use the Doppler effect to measure the line-of-sight velocity of a moving target. Incoherent radars detect the power of each pulse, making signal averaging less efficient. They cannot directly detect target velocity though they can, of course, infer velocity by observing successive changes in range.

(c) Pulse or cw:
Short pulses can distinguish closely separated targets, providing range resolution. Long pulses, whose limit is cw (continuous wave), can distinguish target velocity using the Doppler shift. Nevertheless, coherent trains of short pulses and phase-modulated long pulses can provide both range and Doppler resolution.

(d) Search or track:
Aircraft traffic monitoring is normally done with a monostatic search radar, using a rotating antenna that produces a beam pattern that is tall in elevation but narrow in azimuth. Echos from aircraft produce "blips" on a PPI (plan-position indicator) screen which is refreshed on every rotation of the antenna. A tracking radar uses servo motors to keep the antenna pointed at a single, usually fast-moving target.

(e) Mechanical or electronic scanning:
A *phased array* uses a closely spaced two-dimensional array of antenna elements, usually dipoles. Each dipole is equipped with a programmable phase shifter, allowing the array to form a beam in an arbitrary direction. If the signals received from the individual dipoles are made available to the signal processor, the processor can simultaneously form several independent receiver beams. This allows tracking of multiple targets or searching of multiple zones. Phased arrays with three or more faces of elements can be completely stationary.

(f) Detection or imaging:
Conventional radars simply detect the position and/or velocity of targets. Imaging radars make photographic-like reflectivity maps. Imaging systems include airborne side-looking (*synthetic aperture*) radars that map a strip of land parallel to the flight path and "planetary radar" (delay-Doppler) systems that image planetary objects and low-orbit artificial satellites.

21.3 Target characteristics and echo strengths

21.3.1 Radar cross-section

The strength of an echo depends on the nature of the target and on its range from the radar. In general, metal targets with dimensions commensurate with the wave length are good reflectors, especially when their geometry includes linear features. For example, airplane propellers act as dipole re-radiators. A flat metal plate produces a strong specular reflection, if perpendicular to the direction of the radar, but edge currents also produce other, less directional, echoes. Radar engineers define the *radar cross-section* (RCS) of a target, σ, as the collecting area of an object that would produce the target's observed echo strength while *isotropically* re-radiating the intercepted incident radiation. Radar cross-sections for practical targets, such as aircraft, depend on the aspect angle of the target as well as on the target's usually complicated geometry. RCS calculations for such targets are carried out using finite-element electromagnetics modeling programs. Exact expressions have long since been derived for the radar cross-sections of simple objects. A sphere, since it has no aspect angle dependence, makes a good calibration target for measuring radar sensitivity. The RCS of a metal sphere of radius a is just πa^2 (its geometric cross-sectional area) when a is greater than about $5\lambda/\pi$. But when a is less than about $\lambda/(4\pi)$, the RCS is given by the formula: $\sigma = \pi a^2\ [9\ (2\pi a/\lambda)^4]$. Note that the cross-section is proportional to a^6 and to λ^{-4} in this small-target or *Rayleigh scattering* regime.[2]

21.3.2 The radar equation

The definition of radar cross-section lets us write a simple expression for the flux density of a backscattered echo as it returns to the radar antenna

$$S_{\text{received}} = S_{\text{incident}}\sigma/(4\pi R^2), \tag{21.1}$$

where R is the distance to the target. This equation just says that the supposed isotropically scattered power, which is given by $S_{\text{incident}}\ \sigma$, produces a flux density determined by the area of a target-surrounding sphere whose radius is the distance to the radar. From antenna considerations discussed in Chapter 20, we can write the incident flux in terms of the transmitted power as $P_{\text{trans}}\ G/(4\pi\ R^2)$, where G is the gain of the antenna. Of course, this assumes the antenna is pointed directly at the target. Likewise, we can express the capture area of the antenna by $A_{\text{eff}} = \lambda^2 G/(4\pi)$. Putting this together, we obtain an expression for the received power, P_{rec}, which is just $S_{\text{incident}}\ A_{\text{eff}}$ or

---

[2] The reason the sky is not black is that the molecules that make up the atmosphere scatter direct sunlight to produce diffuse sky light. The λ^{-4} dependence of Rayleigh scattering causes sky light to be blue and sunsets to be red.

$$P_{\text{rec}} = [P_{\text{trans}}G/(4\pi R^2)][\sigma/(4\pi R^2)][\lambda^2 G/(4\pi)] = P_{\text{trans}}G^2\sigma\lambda^2/[(4\pi)^3 R^4)]. \quad (21.2)$$

This relation, however written, is known as the *radar equation*, and shows the inverse fourth-power dependence on range. For an aperture antenna, e.g., a dish antenna, the effective aperture is given by $A_{\text{eff}} = \eta_{\text{ap}}\,\pi(D/2)^2$ where D is the dish diameter and η_{a}, the aperture efficiency, is usually around 0.5. Using this, we can write the radar equation as

$$P_{\text{rec}} = P_{\text{trans}}\frac{\pi}{64}{\eta_{\text{a}}}^2\left(\frac{D}{R}\right)^4\frac{\sigma}{\lambda^2}. \quad (21.3)$$

21.3.3 Distributed targets

Targets such as aircraft subtend a solid angle much smaller than the radar beam, but distributed targets, such as rain in the atmosphere or free electrons in the ionosphere, can be much larger than the beam. In these cases the beam actually defines the extent of the target, in as much as there will be radar echoes from throughout the entire volume of the beam. When the individual scattering objects (raindrops and electrons in the above examples) are randomly distributed in space (*incoherent scattering*), the power received by the radar is the sum of the powers of the individual scatterers.[3] For this kind of target, the radar equation must be modified. We first define σ_{V}, the radar cross-section per unit volume of the target, to be $\sigma_{\text{V}} = n\sigma$, where n is the volume density of scattering particles and σ is the radar cross-section of an individual particle. For raindrops, σ is about 41% of the Rayleigh scattering cross-section given above for metal spheres. For individual electrons, $\sigma = [e^2/(4\pi\epsilon_0\, m_{\text{e}}c^2)]$, where e and m are the charge and mass of an electron and c is the speed of light. If we extend the arguments we used for a single particle centered in the beam to include each volume element throughout the beam, we find that

$$P_{\text{rec}} = \frac{P_{\text{trans}}\lambda^2\sigma_{\text{V}}c\tau}{(4\pi)^2 R^2}\frac{1}{4\pi}\int G^2(\phi,\theta)\text{d}\Omega. \quad (21.4)$$

In this radar equation τ is the pulse length, so $c\tau$ is the range depth of the target volume. The cross-range area of the beam is taken into account by integrating over solid angle times R^2, the square of the range. Note that, because the beam determines the target size, the return echo of a distributed target is proportional to R^{-2}, rather than R^{-4}. The last term in Equation (21.4), $(4\pi)^{-1}\int G^2\,\text{d}\Omega$, is the mean square gain, also called the *backscatter gain* of the antenna.

---

[3] The electric field of the radar echo is the sum of the field contributions from the N individual scattering particles illuminated by the beam. If the scatterers have random positions, their E-field contributions have random phases and add in the fashion of a random walk, causing the total E-field echo to be proportional to $\sqrt{N}$. The received power, proportional to the square of the received E field, is therefore proportional to N.

21.4 Pulse compression

Short pulses produce good range resolution, but shortening the pulses reduces the sensitivity of the radar unless the peak power (pulse power) can be increased to maintain the same average power. However, the peak power of any transmitter is eventually limited by voltage breakdown or other device limitations. This constraint led to the development of *pulse compression* schemes in which the transmitted pulses are modulated in such a way that the echoes can be "bunched up" by the receiver as if they had started out as short pulses. The received echo is passed through an appropriate matched filter (often a digital processor) whose output, for a point target, will be a narrow pulse.[4]

One method for pulse compression uses phase coding. The transmitted pulse is divided into N contiguous equal intervals. Each interval or *baud* is assigned a phase value of zero or 180 degrees, which will be the relative phase (and therefore polarity) of the transmitted signal during that interval. These assignments specify the code. Normally every transmitted pulse will have the same code. Figure 21.4 shows how such a code is used for pulse compression. At the receiver, the IF signal from a point target will be a replica of the transmitted pulse. This IF signal travels down a delay line. Taps along the delay line have a delay spacing equal to the baud length. Signals extracted at these taps are weighted (multiplied) by coefficients with values ± 1, whose order duplicates the code. The weighted signals are added together to form the pulse compressor output.

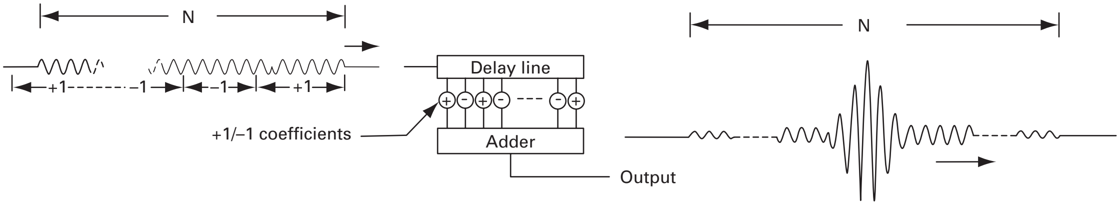


Figure 21.4. A compressor for phase-coded pulses.

Note that, for one position of the signal in the delay line, the multipliers will exactly "undo" the coding, giving the same phase to each of the N input signals to the adder. This alignment will peak at the middle of one baud, as the signal propagates down the delay line, attaining a peak amplitude N times greater than the amplitude of the uncompressed input signal. When the signal in the delay line is not in alignment with the code, there will be some output from the adder unless the code is such that the addends sum to exactly zero. There is no code with this property, though the *13-baud Barker code*, $+ + + + + - - + + - + - +$, produces

---

[4] In general, high range resolution requires that the transmitted signal have a large bandwidth. This bandwidth can be produced by transmitting either short pulses or appropriately modulated long pulses.

("sidelobe") values of only +1 or 0 when the code is not aligned and +13 when it is aligned. When longer codes are needed, it is common to use pseudorandom codes. In this case, the sidelobe levels are determined by random walk statistics; the close-in sidelobes will be less than the main lobe by a factor on the order of $\sqrt{N}$.

An analog surface acoustic wave (SAW) processor can do all the operations shown in Figure 21.4, but it is now more common to use digital processing. Typically, baseband signals are produced by mixing the IF signal, centered at ω_{IF} with $\cos(\omega_{\mathrm{IF}}\ t)$ and $\sin(\omega_{\mathrm{IF}}\ t)$. The resulting I and Q signals are each furnished with a tapped digital delay line/adder pulse compressor. The outputs from the two compressors can be squared and added together for immediate detection, or they can first be Doppler processed.

Pulse compression has other benefits. Because the rapidly changing code spreads the signal's spectrum, it lowers the spectral density. This gives a military radar signal an element of stealth; being less noticeable, it is less likely to provoke a hostile reaction, such as an antiradiation missile. By using different codes with low cross-correlation properties, multiple radars can share the same frequency band. This code-division multiple access property is also used in CDMA cellular telephone systems and in the GPS satellite system, where multiple users (the callers or satellites) share the same band. The GPS system also makes use of the pulse compression property to achieve the high time resolution needed for accurate range resolution (see Chapter 25).

21.5 Synthetic aperture radar

As described above, a phased-array antenna combines the signal from many individual elements to form a beam pattern. Consider a phased array directed toward a point source of cw radiation whose frequency is precisely known. The analog voltage from each element is given a programmed analog phase shift. These voltages then combine to form a vector sum. Note, however, that it is also possible to digitize the voltage (phase and amplitude) from each element and then *compute* the vector sum. If we do this, no hardware phase shifters are needed since, before summing, we can multiply each voltage, V_i by a phase factor, $\mathrm{e}^{\mathrm{j}\phi_i}$, to point the beam in any desired direction. This can be repeated with other sets of phase factors to form a host of beams from the one set of digitized voltages. The echo powers in these beams then form an image if there are multiple targets (assuming they all radiate at the same frequency). Finally, note that we could do all of this with only a *single* array element by moving the element successively from one position to another, recording the voltage (amplitude and phase) at each position. If the set of positions is identical to the element positions in the original phased array, we have effectively used a single small element to *synthesize* a steerable large-aperture antenna.

You can see that this all works out in a radar situation, where all the targets are illuminated by a coherent transmitter signal. The transmitter also provides a

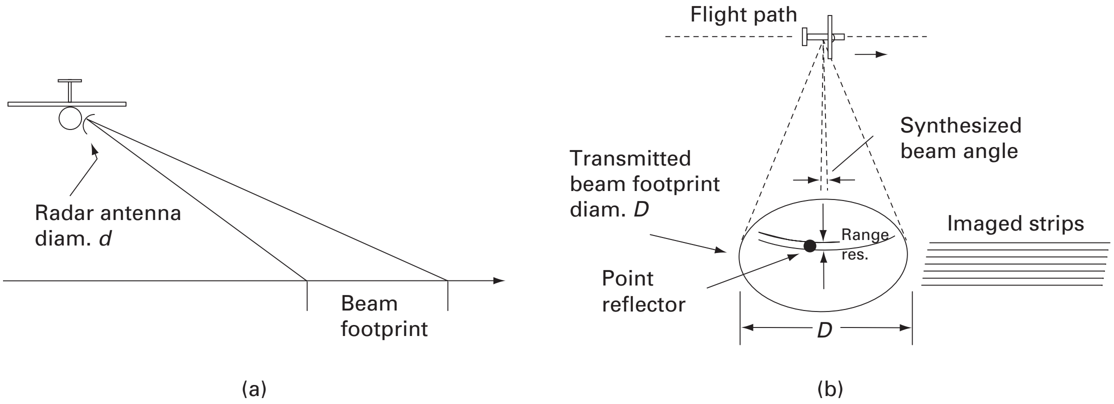

Figure 21.5. Side-looking synthetic aperture radar: (a) elevation view; (b) plan view.

phase reference for the receiver so it is practical to measure both the amplitude and the phase of the return signal at the antenna element. This is the general idea of *synthetic aperture radar* (SAR).[5] Here we assumed that the target was stationary and that the element was stationary, except while being relocated after each voltage measurement. In practice, most SAR techniques involve continuous motion of the elemental antenna, relative to the target. This continuous motion makes it possible to explain the synthesis procedure in terms of Doppler shifts. In addition, most SAR systems transmit short pulses to provide resolution in the down-range (pointing) direction, and use one-dimensional aperture synthesis to provide resolution in the cross-range direction. One of the most common SAR systems is the side-looking radar shown in Figure 21.5.

A small radar antenna of diameter d points outward and downward from the aircraft, which flies a straight-line course. The illuminated patch on the ground, called the *radar footprint*, has a large diameter, D. Since the beamwidth from the radar antenna is given by λ/d radians, we see that D is given by $D = R\lambda/d$, where R is the distance of the footprint from the aircraft. Range resolution is obtained by simply using short radar pulses. In the cross-range direction, the system synthesizes an antenna whose extent in the direction parallel to the flight path is D, since that is the dimension of the footprint that passes over any target feature. The angular size of the resulting synthesized beam is given by $\delta\theta = \lambda/D$. Substituting $D = R\lambda/d$ produces $\delta\theta = d/R$, and the cross-range resolution is therefore $R\delta\theta = d$, the diameter of the small radar antenna. It is interesting to note that the resolution is independent of λ and that making d smaller improves rather than degrades the resolution. Many range strips are observed simultaneously. You can find fascinating side-looking radar (and side-looking sonar) images by searching the internet. A "delay-Doppler" SAR system to image planetary surfaces is discussed in Chapter 26. Another interesting but difficult technique is *inverse synthetic aperture radar* (ISAR) where the aspect of the target (which might be a ship bobbing on the ocean) is variable, not known a priori, and must be inferred from the radar returns as part of the data processing.

---

[5] Synthetic aperture mapping is also possible when the target is not illuminated by coherent radiation, but emits its own wideband radio "noise." In this case, aperture synthesis requires at least two antenna elements. This interferometry technique, used by astronomers to make maps of the radio sky, is discussed in Chapter 26.

21.6 TR switches

Monostatic radars, which transmit and receive with the same antenna, require a TR (transmit-receive) switch. In most radar applications the desired echo arrives so soon after the pulse is transmitted that the TR switch (also known as a *duplexer*) must be electronic rather than a mechanical. Here we will first look at self-duplexing radar techniques based on the use of circular polarization or circulators, then at standard TR switch circuits, and finally at RF electronic switches in general.

21.6.1 Self-duplexing radar techniques

If a radar transmits a circularly polarized signal, reflection by the target changes the sense of polarization from left-hand to right-hand or vice versa. Circular polarization can be produced by transmitting simultaneous crossed linear polarizations 90° out of phase. Figure 21.6 shows how a 90° hybrid not only produces circular polarization of one sense but also routes received circular polarization of the other sense (the return signal) into the receiver.

Note that the x-dipole and the y-dipole, together with the hybrid, are really just equivalent to two separate antennas having opposite circular polarizations. In practice, the isolation between the transmitter and receiver in this scheme is usually no better than about 30 or 40 dB, so a limiter or SPST electronic switch (a *monoplexer*) is installed at the receiver input to protect it from burnout. A waveguide version of this circuit uses a *turnstile junction*, the microwave component shown in Figure 21.7. It is classified as a six-port junction because the round waveguide supports two independent modes: x and y or RCP and LCP or any other pair of orthogonal elliptical polarizations. When two opposite

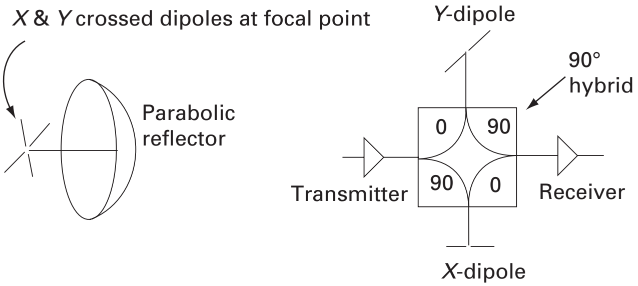

Figure 21.6. A self-duplexing radar using circular polarization.

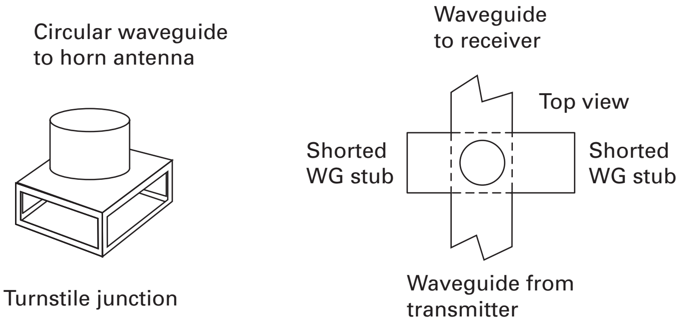

Figure 21.7. A waveguide turnstile junction combines the functions of the hybrid and crossed dipoles.

rectangular ports are fitted with shorts of appropriate lengths, the resulting four-port network is equivalent to the pair of dipoles and hybrid of Figure 21.6. The turnstile junction is described in Volumes 8 and 9 of the Rad. Lab. Series. The transmitter and receiver are connected to the remaining rectangular ports (the pair without shorts) while the antenna, usually a feed horn, is connected to the round waveguide.

A true self-duplexing circuit, shown in Figure 21.8, uses a circulator. The circulator has the property that a signal injected at the transmitter port will exit via the antenna port while a signal injected at the antenna port will exit through the receiver port. (If a signal were injected at the receiver port, it would exit through the transmitter port.) This nonreciprocal action depends on transmission through a nonreciprocal medium which, for the circulator, is a ferrite material, biased by the field of a permanent magnet. This elegant TR system is limited by available circulators to powers of tens of kilowatts.

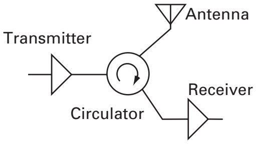

Figure 21.8. A circulator used as a TR switch.

21.6.2 TR switching devices and circuits

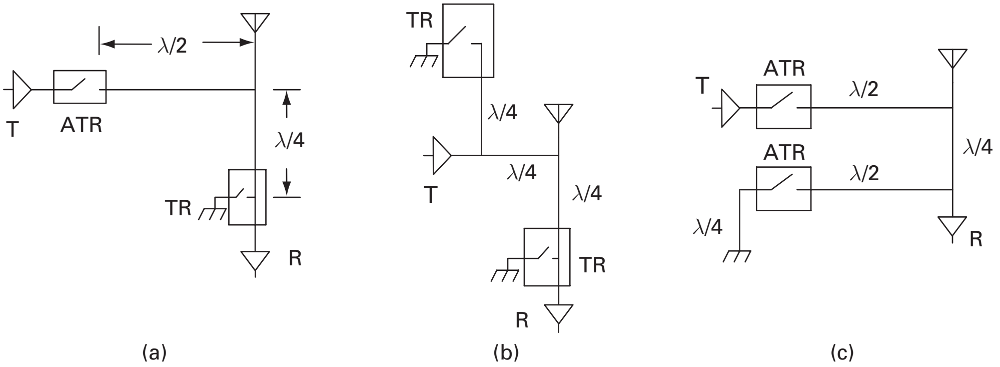
The classic TR circuits developed during WWII use gas discharge tubes or spark gaps and are self-activated by high-power RF on the transmission line. Lower power versions use PIN diode switches, turned on by an external bias circuit. (The radar has a timing generator providing pulses that (1) turn on the TR switch for transmitting, (2) pulse the transmitter, and (3) turn off the TR switch for receiving.) Gas discharge tube switches are usually built into a short piece of waveguide and come in two types: TR and ATR (anti-TR). The distinction is as follows: on transmit a TR device ionizes and presents a low-impedance shunt across the line. The ATR device also ionizes on transmit but it presents a low impedance in series with the line. (Reference [3], Volume 14 of the Rad. Lab. Series, is devoted mostly to these tubes.) There are two general classes of TR circuits, branch line TR switches and balanced TR switches. The former uses segments of transmission line while the latter uses hybrids.

21.6.2.1 Branch line TR switches

Figure 21.9 shows some standard branch line TR Switch circuits using TR, ATR, or both TR and ATR tubes (or PIN diode equivalents).

In the circuit of Figure 21.9(a), the switches are shown in the nonconducting (transmitter off) position. The open ATR switch is connected to the antenna by a half-wave line so it presents the same open circuit to the antenna-to-receiver line. Likewise, the open TR switch does not disturb the antenna-to-receiver line. On transmit, the TR switch places a protective short circuit at the receiver input. This short circuit is transformed by the quarter-wave line into an open circuit which does not affect the connection between the transmitter and the antenna. At high frequencies the switches contain some nonzero path lengths which form part of the half-wave or quarter-wave lines. For low-frequency designs the half-wave lines can be reduced to zero length and the quarter-wave lines can be replaced by lumped-element impedance inverters. You can see from the ways that the TR and ATR elements are used that their names are somewhat arbitrary.

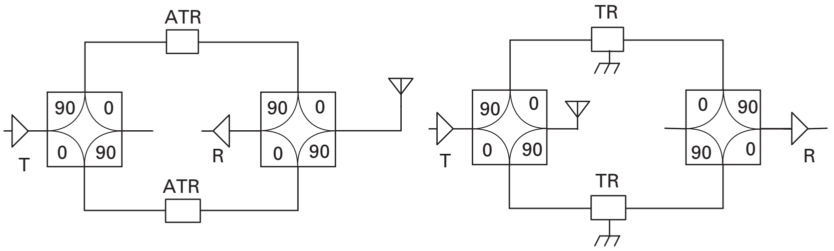
Figure 21.9. Branch line TR switches.



21.6.2.2 Balanced duplexers

Balanced duplexers use hybrids and can have wider bandwidths than the branch line circuits shown above (though more elaborate branch line circuits can have wider bandwidths). Both balanced duplexer circuits shown in Figure 21.10 use two 90° hybrids.

Figure 21.10. Balanced TR switches.



21.7 Diode switches

A single diode shunt switch circuit is shown in Figure 21.11.

Positive control voltage gives the diode a forward bias current to produce a low dynamic resistance, dV/dI. Negative control voltage turns the diode off, making its dynamic resistance very high. Let these dynamic resistance values be denoted respectively by r and R. You can verify (Problem 21.5) that the transmission values (power out/power available) for the switch of Figure 21.11 are given by:

$$\text{Isolation (forward biased state)} = 4r^2/Z_0^2$$
$$\text{Transmission (reverse biased state)} = 1/(1 + Z_0/R).$$

Note from these expressions that you could favor better isolation or lower insertion loss by transforming the line to have a larger or smaller Z_0 at the diode location. Better performance can be obtained with ladder networks analogous to multisection filters. Figure 21.12 shows how a shunt switch can be combined with a series switch to form a two-element ladder network. Isolation is improved since any signal leakage across the open series switch is shorted to ground by the closed shunt switch.

It is often more convenient to use shunt diodes than series diodes, since shunt diodes are easier to bias and to heat sink. Impedance inverters can transform series elements into shunt elements, as we saw when designing coupled

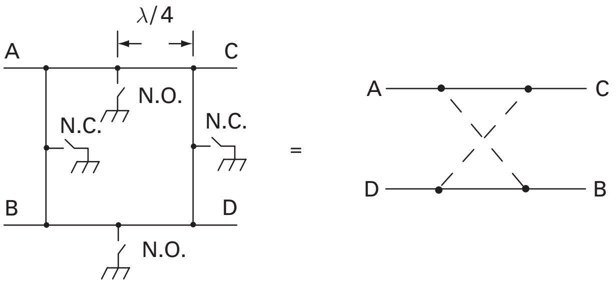

Figure 21.14. Transfer switch using quarter-wave transmission lines.

resonator filters. The switch circuit of Figure 21.13 uses two impedance inverters and three shunt switches.

The switches discussed above are all SPST switches. More complicated switches can be built up from the elementary SPST switch, but special designs can often be made such as the four-diode transfer switch shown in Figure 21.14. When the switches are in the indicated normal positions, the shorted quarter-wave lines appear as infinite-impedance shunts and do not disturb the transmission paths from A to C and from B to D. When the switches are reversed, transmission is from A to B and from C to *D*.

21.7.1 Diodes for RF switching

When ordinary diodes are used in these switching applications, the biases must be enough to keep the diode in the desired state. In particular, when the diode is off, the reverse bias voltage must be greater than the peak RF voltage and, when the diode is on, the forward bias current must be greater than the peak RF current. However, the *PIN diode*, a sandwich of p-type, intrinsic, and n-type semiconductor material, has the remarkable property that, for RF switching, the bias current and bias voltage values can be less than the corresponding RF current and voltage by perhaps an order of magnitude. The operation of the PIN diode (see reference 5) depends on having a large (small) stored charge in the intrinsic region when the diode is on (off). At high frequencies, the time between electric field reversals is much less than the transit time through the intrinsic region, determined by diffusion and drift, so the diode remains in the on (off) state. Finally, a word of caution: diodes, since they are nonlinear circuit elements, have the potential to distort a signal. In particular, they can create intermodulation products between the various signals in a complicated spectrum. For critical applications, e.g., receiver band-changing, diode switches must be turned off and on hard enough to keep any generated intermodulation products at a negligible level.

21.8 Radar pulse modulators

Any cw transmitter can generally be used as a pulse transmitter if a *pulse modulator* is added to provide the rapid turn on and turn off. Tube-type amplifiers can be operated with much higher instantaneous powers when they are pulsed. Tubes are primarily limited by their maximum anode dissipation (heat removal); the dissipation can be the result of either modest cw operation or high-power pulse operation. A cw amplifier can be converted for pulse operation by changing the output matching circuit in order to present a lower load resistance to the tube. Some tubes are available in special pulse-rated versions; they are fitted with high-emission cathodes. Gridded tubes (triodes, tetrodes, and pentodes) can be pulsed by switching the grid bias from negative, for pulse-off, to positive, for pulse-on. The negative bias keeps the tube completely turned off between pulses. Since the grid voltage and current are much smaller than the plate voltage and current, grid control requires only low-power circuitry compared to anode control. At microwave frequencies, magnetrons and klystrons replace gridded tubes. Magnetrons have no control element and therefore require high-power anode pulsers. Klystrons may or may not have a modulating anode ("mod anode") by which the beam current can be cut off. If not, they need high-power pulsers.[6]

Transistor amplifiers, unlike tube amplifiers, can make very little trade-off between duty cycle and peak power. Transistors suffer one type of breakdown or another when operated beyond their maximum continuous ratings. A high-power transistor amplifier for pulse service might differ from a cw amplifier only in that it will dissipate less heat (from the reduced duty cycle) and can therefore get by with a smaller heat sink.

No matter how an amplifier is pulsed, the power supply must furnish high-power pulses with minimum voltage droop. Duty cycles of pulsed transmitters are usually much less than unity so, in addition to at least one switching element, pulse modulators (pulsers) contain some form of energy storage element(s). The simple pulser circuit shown in Figure 21.15(a) stores energy in a capacitor.

---

[6] An air traffic control radar might have a peak power output of 2 MW and an efficiency of 50%. A klystron tube in this service could require 50 kV pulses at 80 amperes.

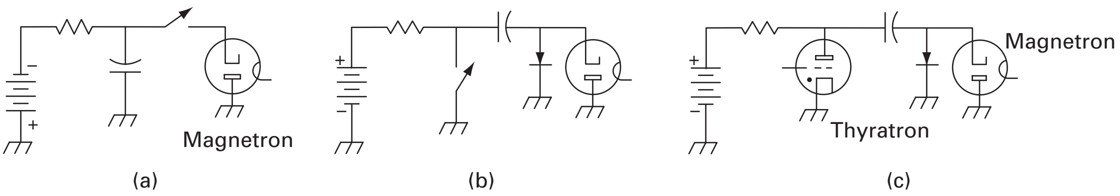

Figure 21.15. Capacitor discharge pulser.

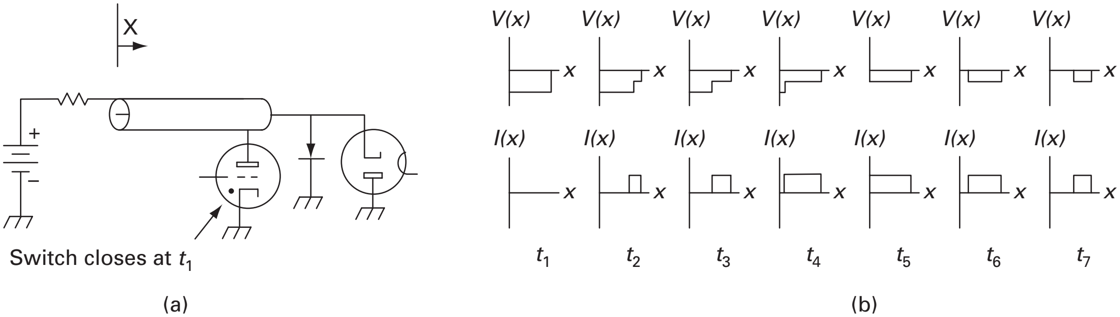
In this circuit the tube (magnetron, klystron, or whatever) is shown as requiring negative voltage. Microwave tubes often use negative supply voltage applied to their cathodes because it is convenient to ground the external heat-dissipating anode. The version of the circuit in (b) allows one side of the switch to be grounded, which is another convenience. The diode provides a charging path for the energy storage capacitor. The circuit of Figure 21.15(c) uses a thyratron (vacuum tube version of the SCR) as the switch.

The simple capacitor discharge modulators in Figure 21.15 have several disadvantages: The voltage droops during the pulse. The droop can be reduced by increasing the size (weight, and cost) of the capacitor. Not much of the stored energy is used. Even if 10% voltage droop is permitted, only 20% of the stored energy is used for each pulse. This might be compared to a car which would not run well if the fuel tank was less than 80% full. They are expensive and heavy, a particular disadvantage for airborne equipment. Despite these disadvantages, capacitor banks are often used, as in the 430-MHZ pulse transmitter used for ionospheric research at the Arecibo Observatory, because a more efficient circuit, the line modulator discussed below, does not easily provide the flexibility needed to change the pulse width.

21.8.1 Line modulators

A length of transmission line (with the far end open) has capacitance and can therefore store electrostatic energy. When the line is discharged into a resistive load equal to its characteristic impedance, it will supply a perfect rectangular pulse rather than a drooping exponential pulse. The constant pulse amplitude during discharge is maintained by the distributed inductance of the line acting together with the distributed capacitance. In Figure 21.16(a), the line is a piece of coaxial cable, replacing the energy storage capacitor. As before, the tube is supplied with a negative pulse. A diode provides a path to recharge the line. Often the load has a higher impedance than the characteristic impedance of the line, and a pulse transformer is required.

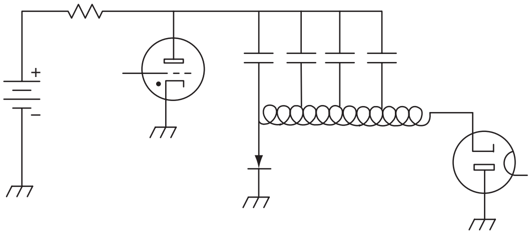
The line supplies a pulse at half the charging voltage since, during the pulse, the charging voltage evenly divides between the load and the equivalent source resistance. The duration of the pulse is the time taken for the current to make a round trip through the line. At the end of the pulse the line is totally discharged; all the stored energy is delivered on every pulse. Figure 21.16(b) shows successive plots of the line's voltage and current distributions. In order to store more



(a) (b)

Figure 21.16. (a) Line-type modulator; (b) line voltage and currents.

Figure 21.17. Pulser using an artificial transmission line (pulse-forming network).



energy, it is common to use an "artificial transmission line" or pulse forming network (PFN) which is a ladder network of inductances and capacitances. A four-section network is shown in the modulator circuit of Figure 21.17.

The network looks like a lowpass filter and it is. Its cutoff frequency is given by $\omega^2 = 4/[LC]$. For frequencies well below cutoff, the network behaves like a transmission line with $Z_0 = \sqrt{L/C}$. Here L and C are in henries and farads rather than henries/meter and farads/meter as in the distributed element transmission line. The one-way time delay on this lumped line is $\sqrt{LC}$ seconds/section.

Let us consider a numerical example: Let us use four sections as in the figure above. Suppose we need a 1 microsecond pulse at 10 kV and 10 amperes. The voltage and current require that $Z_0 = \sqrt{L/C} = 1000$ ohms. We will use four sections which, for the desired one-microsecond round-trip delay, requires that $8\sqrt{LC}$ be equal to $10^{-6.}$ These impedance and time delay equations are satisfied by $L = 125$ μH and $C = 125$ pF. We can verify that the energy stored in the line is indeed equal to the energy delivered by the pulse. The latter is just $(IV)\tau = 10 \times 10\,000 \times 10^{-6} = 0.1$ joule. The former, remembering that we must charge the line to 20 000 V, is $CV^2/2 = 4(125 \times 10^{-12}) \times 20\,000^2/2$ which is also 0.1 joule. As often happens in filter design, these are not particularly practical values; real inductors of 125 μH may well have distributed capacitances that are not negligible compared with 125 pF. We can build the line for a lower

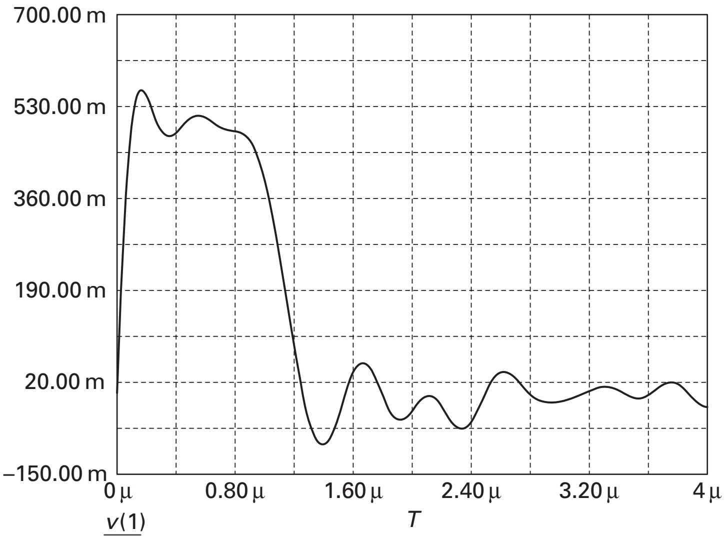


Figure 21.18. Waveform produced by a four-section pulse forming network.

impedance and use a pulse transformer between the line and the magnetron. If we lower the line impedance to 100 ohms, the *L* and *C* values become 12.5 μH and 1250 pF, values that are more practical. Using these values, a SPICE simulation of the discharge produced the voltage waveform shown in Figure 21.18. The voltage scale is normalized, i.e., the capacitors were charged to one volt so the nominal pulse voltage is 0.5 volts. Most pulse forming networks can be tuned slightly to improve the pulse shape; the artificial transmission line is, after all, only an approximation to an ideal transmission line.

The line modulator uses all the stored energy on each pulse but, precisely because of this virtue, deserves a more sophisticated charging circuit than the resistor shown in the circuits above. Remember that when a capacitor is charged through any resistive path from empty (no energy) to $CV^2/2$, the resistor will dissipate this same amount of energy, $CV^2/2$. Here the charging resistor, no matter what value, would dissipate half the power consumed by the radar. The solution to this problem is to charge the line through an inductor instead of a resistor. Figure 21.19(a) shows the voltage waveform on a capacitor as it is *resonantly charged* through an inductor.

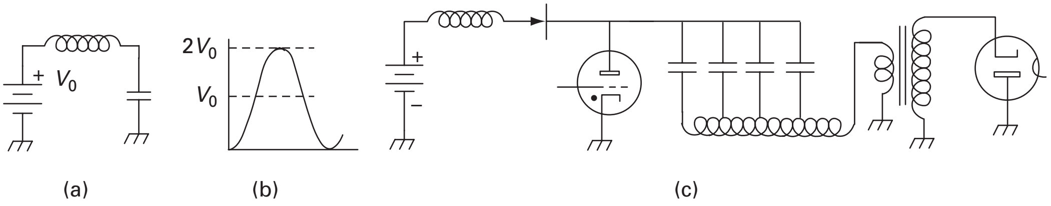

Figure 21.19. Resonant charging.

The voltage is a sinusoid, building up to a maximum of twice the supply voltage. The modulator can be triggered just as the voltage reaches this maximum. The brief pulse discharges the line and the charging curve begins anew. It would seem that the PRF is therefore determined rigidly by the charging time but, if a diode is put in series with the inductor, the charging stops at the maximum voltage and the next pulse can occur anytime. The resonantly charged modulator, with the diode and a pulse transformer, is shown in Figure 21.19(b). Note that the primary of the pulse transformer provides a charging path, eliminating the diode originally in parallel with the magnetron. Also remember that, because of the resonant charging, the supply voltage needs only to be half of the line charging voltage. Line modulators present less risk to tubes than partial-discharge capacitor modulators because there is less stored energy available when an arc occurs in the tube.

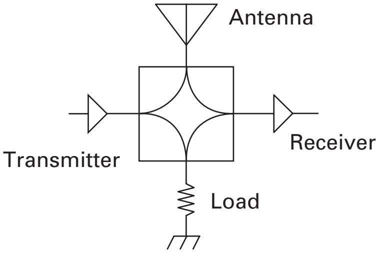
Problems

Problem 21.1. Find the radar cross-section of a flat metal plate of area A that is exactly perpendicular to the radar beam. Assume that $A \gg \lambda^2$. Hint: treat the plate as an aperture antenna with gain $4\pi A/\lambda^2$.

Problem 21.2. Find the lobe pattern produced when a point target is observed by a pulse compression radar using the 13-bit Barker code of Section 21.4. (Convolve the code with itself after padding both ends with zeros.)

Problem 21.3. Why is the side-looking radar antenna positioned to look to one side of the aircraft rather than straight down?

Problem 21.4. If we try to use the hybrid of the circular polarization duplexer as a circulator, we might consider the TR circuit shown below.



Assume the antenna, transmitter, receiver, load, and hybrid all have the same characteristic impedance. This circuit at least protects the receiver from the transmitter. What are its disadvantages (a) when transmitting, and (b) when receiving?

Problem 21.5. Verify the expressions below for $P_{out}/P_{available}$ for the circuit of Figure 21.11.

Diode state	Switch state	$P_{out}/P_{available}$
Foward biased	Isolation	$4r^2/Z_0^2$
Reversed biased	Transmission	$1/(1+Z_0/R)$

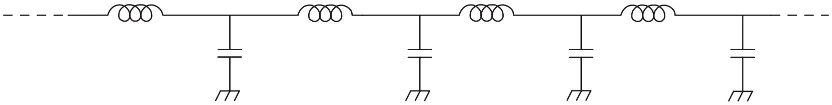
Problem 21.6. Apply your circuit analysis program (Problem 1-3) to the transfer switch circuit of Figure 21.4. Assume a 50-ohm load is connected to Port C, a 50-ohm generator is connected to Port A, and the transmission line sections have a 50-ohm characteristic impedance. Assume also that the internal switches are ideal. Find the transmission coefficient (in dB) over the frequency range from half the design frequency to twice the design frequency. Hint: the closed switches divide the circuit in two so you can ignore the bottom half.

Problem 21.7. Explain the operation of the balanced duplexers shown in Figure 21.10. What restrictions, if any, are there on the lengths of the interconnecting transmission lines?

Problem 21.8. (a) Show that when an uncharged capacitor is brought to potential V by connecting it through a resistor to a voltage source V, the energy supplied by the source is twice the energy deposited in the capacitor (CV^2 rather than $CV^2/2$).

(b) The charging efficiency in (a) is only 50%. Find the efficiency when the capacitor initially has a partial charge, i.e., when the capacitor is initially charged to a voltage αV, where $\alpha < 1$.

Problem 21.9. (a) Find the characteristic impedance of the artificial transmission line shown below. This impedance, Z_0 (which is complex), can be found by adding another LC section to the properly terminated line and noting that the new impedance must still be Z_0.



(b) Use the expression for Z_0 to show that the line has a cutoff frequency, $\omega_c = 2/\sqrt{LC}$, above which signals are reflected rather than transmitted.

Problem 21.10. Show that when $\omega \ll \omega_c$, the propagation delay per section for the artificial transmission line of Problem 21.9 is given by $\tau = \sqrt{LC}$.

Problem 21.11. (a) In a *conial scan* tracking radar, the antenna's feed horn is tilted slightly off center and mechanically rotates around the axis of the parabolic reflector. The antenna beam therefore executes a continuous tight conical scan, centered on the target. Many pulses are transmitted during the course of each scan. Draw a block diagram of circuitry to furnish x and y cross-range position error signals to the antenna's drive system in order to keep the antenna centered on the target. (b) Consider a *monopulse* tracking radar in which the antenna is effectively five antennas: one pointed directly at the target, one slightly above, one slightly below, one slightly to the left, and one slightly to the right. Draw a block diagram of circuitry to combine these five signals to provide x and y error signals.

CHAPTER

22 Digital modulation techniques

Digital modulation is both the newest and the oldest radio technique. Morse code transmissions were strictly binary, with "key down" and "key up" equivalent to multiplying the carrier by one or zero. Many modern systems also use binary keying, but the zero state is usually signaled by reversing the polarity of the signal (*binary phase-shift keying*, BPSK) or by shifting the frequency (*binary frequency-shift keying*, BFSK). This improves the probability of distinguishing zeros from ones in the presence of noise.

In this chapter we look first at some of the methods used for binary and "*m*-ary" modulation. We then see how specially shaped pulses can be used with these methods in order to avoid intersymbol interference when the pulses, dispersed in time, partially overlap at the receiver. The "8-VSB" system used for digital television in the U.S. (see Chapter 19) provides an example of pulse amplitude modulation (PAM). Finally, we discuss two newer digital modulation systems: multicarrier and spread spectrum. A glossary is provided at the end of this chapter, listing the many common abbreviations used (BPSK, BFSK, 8-VSB, PAM, etc.).

22.1 Digital modulators

Digital modulation differs from analog modulation in that only a discrete set of states (in the space of amplitudes, phases, and frequencies) is used, and that the time devoted to any state is always an integral multiple of a basic time-step. The state during this time period constitutes a transmitted "symbol," and the symbol rate is one of the parameters defining a modulation system. Figure 22.1 shows the simple and widely used binary phase shift keying (BPSK) modulation technique. Instead of turning off the carrier to indicate a zero, the carrier phase is flipped 180°. This is equivalent to multiplying the carrier signal by minus one, as shown in the figure. Binary values of 0 or 1 are handled by sending −1 or +1, respectively, to the multiplier. As shown in Chapter 8, the multiplier (mixer) produces a double-sideband suppressed-carrier RF signal.

Figure 22.1. BPSK modulator.

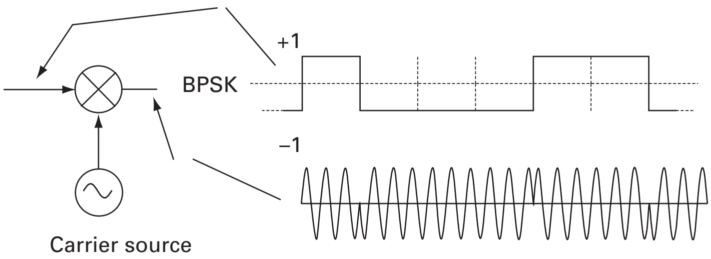

Figure 22.2. *N*-level pulse amplitude modulation (PAM).

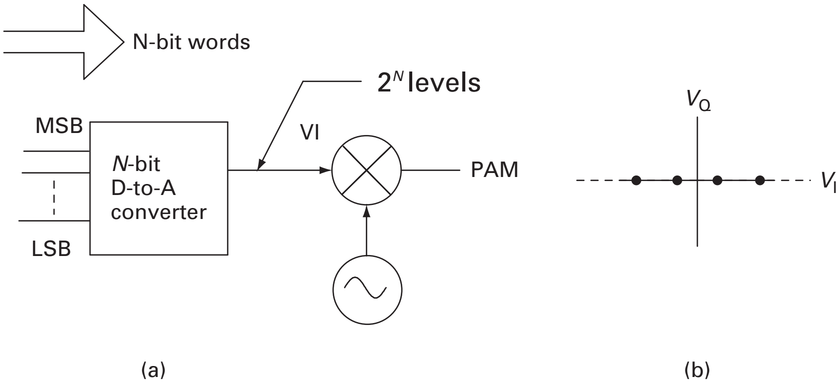

Since the BPSK signal has a nominally constant envelope, the receiver needs a phase-sensitive or "coherent" detector. In contrast, on–off keying (OOK) or frequency shift keying (FSK) can be detected incoherently. The advantage in using coherent systems is one of sensitivity; for a given situation, coherent detection provides a higher signal-to-noise ratio at the detector output. The one-bit BPSK system can be generalized to more than two amplitude levels. We saw in Chapter 21 that the U.S. ATSC digital television system uses eight (2^3) modulation levels in order to send three bits per symbol. Figure 22.2(a) shows an *N*-bit (2^N-level) pulse amplitude (PAM) modulator. The "constellation" shown in (b) shows the signed amplitudes as discrete points on a linear scale. Note that, because the negative amplitudes are produced by changing the phase 180°, PAM requires coherent demodulation.

We saw in Chapter 8 that quadrature AM (QAM) systems can transmit independent information, modulated on a *Q*-carrier which is in quadrature, i.e., 90° out of phase, with respect to the *I* ("in-phase") carrier. This "phase multiplexing" method is commonly used in digital communications. Figure 22.3 shows a "4-QAM" modulator.

The binary (two-level) *I* and *Q* signals result in an *IQ* constellation with four points. In this case, the points on the constellation have four possible phase values, but the amplitudes are equal, since each of the four points lies at an equal distance from the origin. You can see why this scheme is also known as QPSK (quadrature phase shift keying) and 4-PSK (four-state phase-shift keying). Figure 22.4 shows a QAM modulator with four-level modulation on both *I* and *Q* channels, producing a total of 16 states.

The constellation of output signals for this 16-QAM modulator is shown in (b). The 16 binary numbers, 0000 through 1111, could be assigned arbitrarily to the constellation points, but the assignments shown in the figure have the property that nearest neighbors differ by only one bit. As a result, in an environment with only modest noise, errors in transmission will nearly all be single-bit errors. Note that next-nearest neighboring points on the constellation differ by

just two bits. QAM systems can also have constellations in which the points are arranged in polar fashion; a constellation with eight points arrayed on a circle in the I-Q plane is known as 8-PSK. Note that BPSK could just as well be called 2-PSK.

22.2 Pulse shaping

The abrupt reversals in the BPSK waveform of Figure 22.1 result in a signal with an objectionably large bandwidth. The signal is a continuous stream of rectangular RF pulses whose polarity is determined by the data. If the data bits are random, with equal probabilities of being a one or a zero, these rectangular pulses produce a power spectrum proportional to $[\sin(\pi f T)/(\pi f T)]^2$, where T is the duration of a symbol, the "baud" length. This spectrum is plotted in Figure 22.5.[1] On this graph, frequency is in units of $1/T$, and the zero is at the nominal carrier frequency.

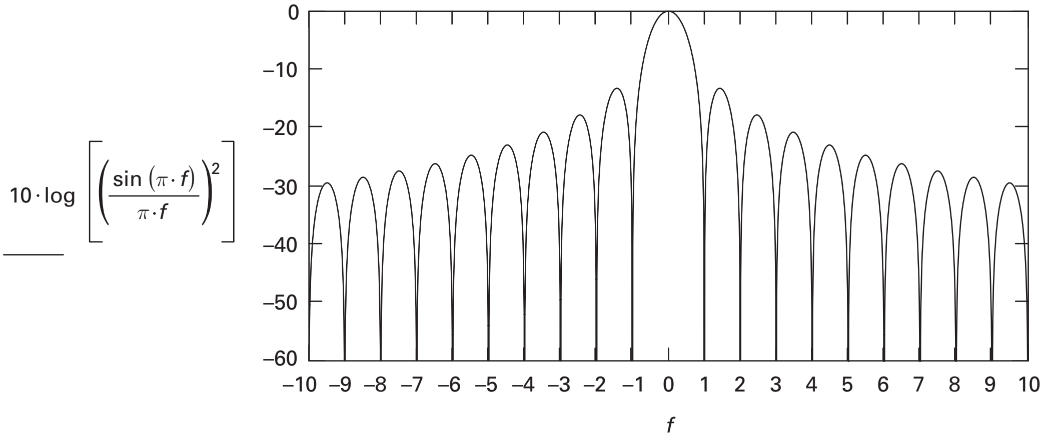

Figure 22.5. Power spectrum of a BPSK signal with random data and rectangular pulses. Frequency is in units of $1/T$, and the zero is at the nominal carrier frequency.

This wide spectrum applies to all the digital modulators discussed above, and is clearly unacceptable if other users are to use nearby frequency channels. Bandpass filtering at the transmitter, or otherwise transmitting a pulse shape whose spectrum is band-limited, solves this problem, but there is a complication – limiting the bandwith causes a widening of each pulse in the sequence so that, at the receiver, a currently arriving pulse will be contaminated by remnants or precursors of nearby pulses. This effect is known as *intersymbol interference* (ISI). However, there exists a class of pulse shapes, *Nyquist pulses*, for which (a) the bandwidth is limited and (b) there is no ISI, despite the fact that the pulses do spread into each other. One such pulse shape is $V(t) = \sin(\pi t/T)/(\pi t/T) = \mathrm{sinc}(t/T)$, the normalized sinc function. This pulse shape is the impulse response of a

---

[1] The power spectrum is calculated from the signal's average autocorrelation function (see Chapter 27).

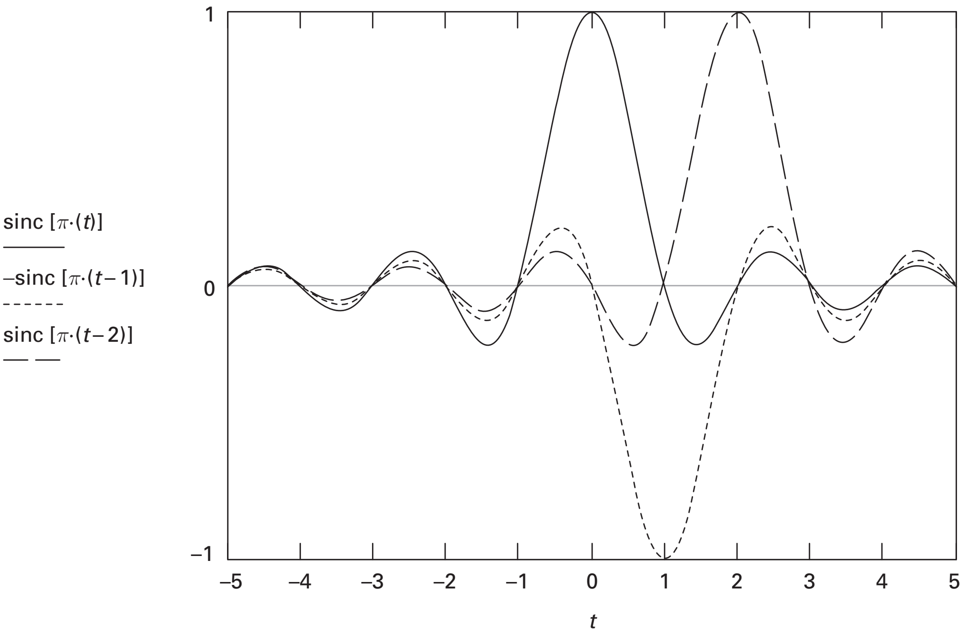

Figure 22.6. Successive $\sin(\pi t)/(\pi t)$ signaling pulses.

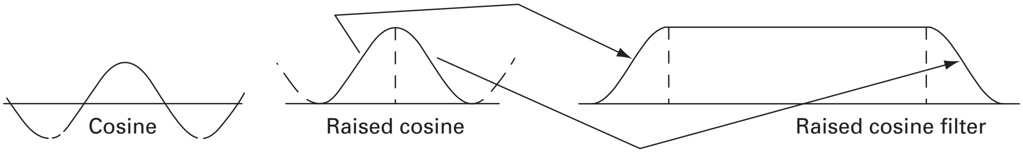

Figure 22.7. Construction of the raised cosine filter; $H(\omega)$ is the voltage response.

rectangular lowpass filter with a cutoff frequency of 1/(2T)Hz. This filter confines all the power to a bandwidth of 1/(2T). Successive output pulses for a 101 data string are plotted in Figure 22.6. The third pulse reaches a maximum at $t = 2$, the instant at which we sample it. Neither of the two previous pulses has yet died out but, at $t = 2$, both are crossing zero and thus contribute no interference to the sampled value of the desired pulse.

The same holds true for the contributions from all the other pulses, of any amplitude and either polarity, allowing us to transmit data pulses at a rate 1/T without intersymbol interference.

Pulses with this property are said to be *orthogonal* to one another. While they do invade each other's space, they do not create intersymbol interference. The $\sin(\pi t/T)/(\pi t/T)$ pulse is an extreme case; bandwidth is minimized, but the pulse is widely spread out in time. In practice, other orthogonal pulse shapes are chosen, which have somewhat greater bandwidth but are only modestly spread in time. One frequently used pulse shape is the impulse response of the *raised-cosine* filter. Figure 22.7 shows how this filter shape is produced by replacing the vertical sides of the rectangular filter with smooth roll-offs formed from quarter cycles of the cosine function, raised by 1/2 in the y-direction.

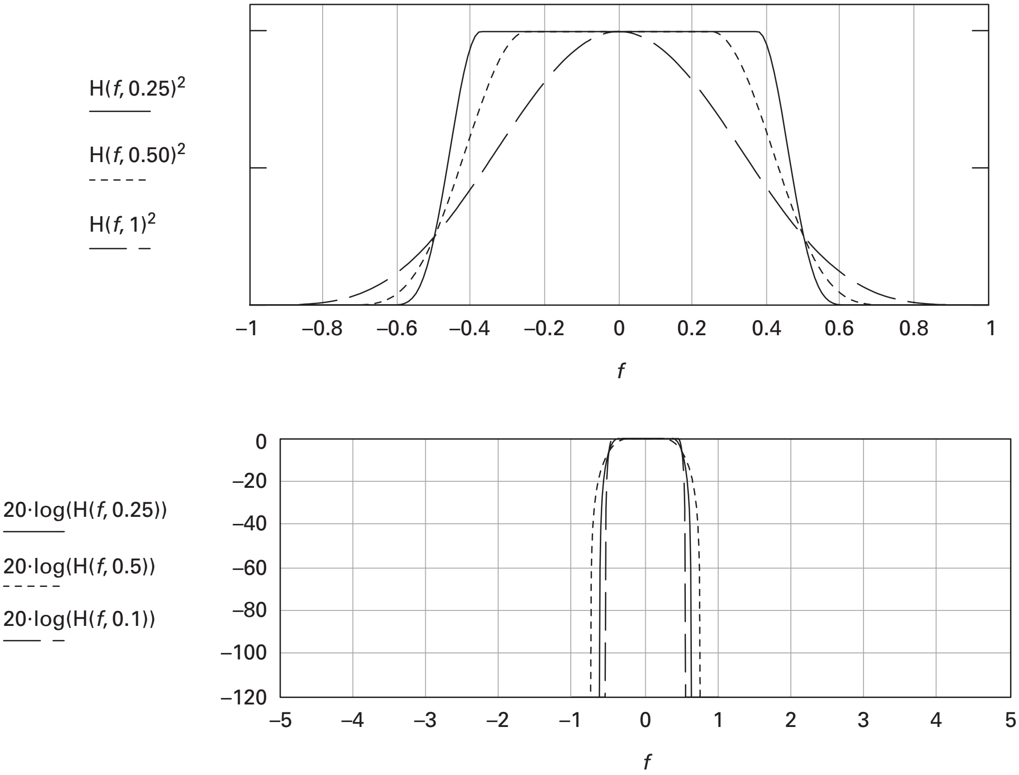

Figure 22.8. Power response, |*H* (*ω*)|2, of raised cosine filter for *α* = 0.25, 0.5, and 1.0.

We can express this filter shape as

$$H(f,\alpha)=\begin{cases} T: & 2|f|T\le 1-\alpha \\ \dfrac{T}{2}\left[1+\cos\left(\dfrac{\pi T}{\alpha}\left(|f|-\dfrac{1-\alpha}{2T}\right)\right)\right]: & 1-\alpha\le 2|f|T\le 1+\alpha \\ 0: & 2|f|T1+\alpha, \end{cases} \tag{22.1}$$

where α, a roll-off factor between zero and one, determines the width of the raised cosine edge sections. Note that the $\alpha = 0$ case is just the rectangular filter discussed above. This filter's power response, $|H(f,\alpha)|^2$, for $\alpha = 0.25$, $\alpha = 0.5$ and $\alpha = 1$ (pure raised cosine with no flat center section) is plotted in Figure 22.8(a) with a linear power scale and Figure 22.8(b) with a dB power scale.

The impulse response of this filter, i.e., the Fourier transform of $H(f,\alpha)$, often called by extension a "raised-cosine pulse," is given by

$$h(t,\alpha)=\frac{\sin(\pi t/T)}{\pi t/T}\cdot\frac{\cos(\pi\alpha t/T)}{1-(2\alpha t/T)^2}. \tag{22.2}$$

The zeros of the first term, $\sin(\pi t/T)\,/(\pi t/T)$, give this pulse shape the same orthogonality property as $\sin(\pi t/T)\,/(\pi t/T)$ alone. Figure 22.9 shows three

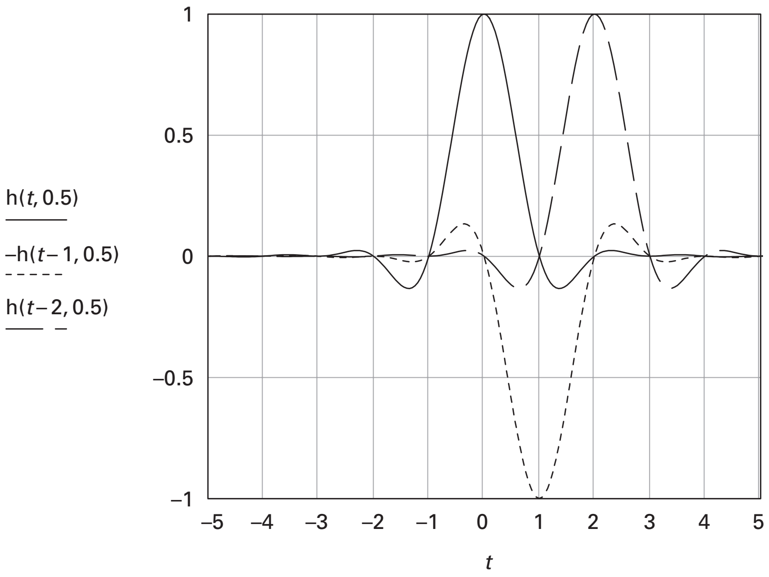

Figure 22.9. Successive raised-cosine signaling pulses.

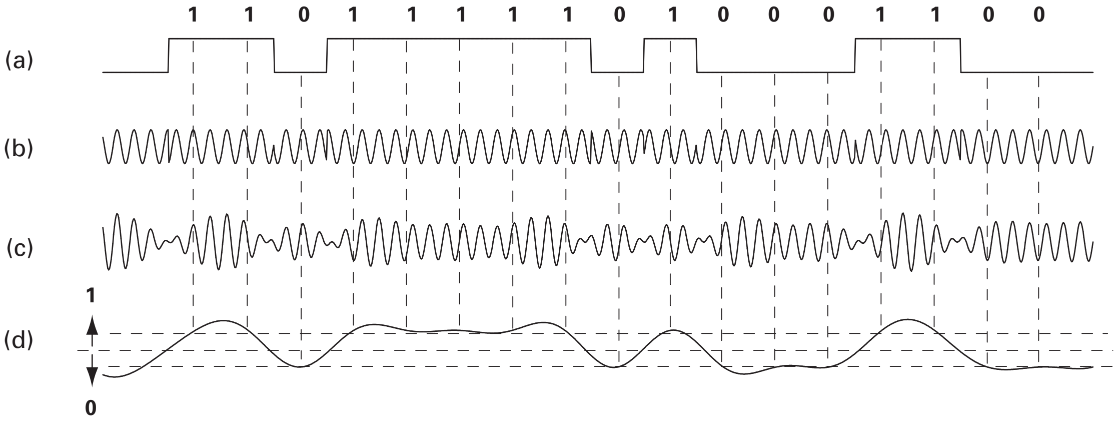

Figure 22.10. BPSK waveforms: (a) input data; (b) bi-phase modulated carrier; (c) modulated signal after raised-cosine filtering ($\alpha = 0.22$); (d) coherently detected signal.

consecutive $\alpha = 0.5$ raised cosine pulses. Note that these pulses, like the sin $(\pi t/T)/(\pi t/T)$ pulses of Figure 22.6, produce no intersymbol interference, but unlike those pulses, these are only modestly spread out in time.

Despite the bandwidth advantage, there are two penalties associated with choosing a low value for α. First, the impulse response duration of the filter is longer, requiring more computations per symbol when the filter is implemented digitally. Second, the increased ringing means that the received signal must be sampled with higher timing accuracy to avoid ISI.

The successive processes of BPSK modulation, pulse shaping, and detection are shown in Figure 22.10. The data string to be transmitted is shown in (a). In (b), the sinusoidal carrier has been multiplied by the data, producing phase

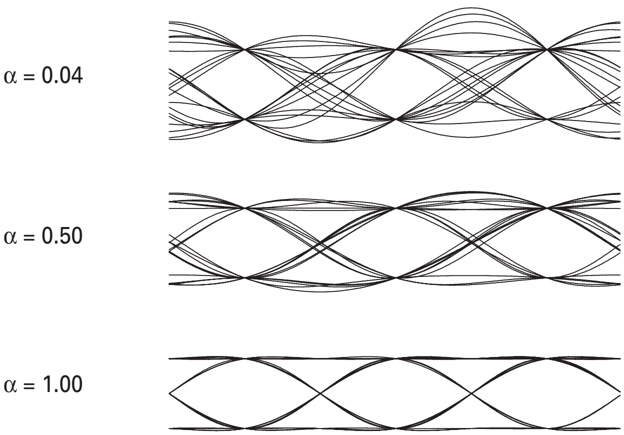

Figure 22.11. BPSK eye diagram.

reversals. In (c), the modulated signal has been band-limited by a raised-cosine filter of $\alpha = 0.22$. In this simulation the modulation rate is high, causing obvious variations in the envelope of the filtered signal. Finally, in (d), the filtered signal has been coherently detected, i.e., multiplied by a replica of the original sine wave carrier and then lowpass filtered to remove the components at twice the carrier frequency. Note that, at the sampling instants, the sampled values are exactly the same 0's and 1's of the original data, i.e., there is no intersymbol interference. Note: for clarity in alignment with the original data, no filter delay has been added to the waveforms in (c) and (d), so they appear noncausal.

If the detected data is displayed versus time for many sweeps on a storage oscilloscope that is synchronized to the data, we obtain the well-known "eye" diagram, shown in Figure 22.11. You can see that, at the sampling instants, the value of the waveform is either zero or one; there is no intersymbol interference. Eye diagrams are presented for three values of α. You can see that, for smaller values of α (narrower bandwidths), the sampling instants must be increasingly accurate to obtain only the values zero and one, whereas larger values of α make the system more tolerant of sampling "jitter."

22.3 Root raised-cosine filter

Any receiver must contain a bandpass filter to reject unwanted signals (i.e., signals as well as noise on nearby frequencies). If the receiver filter has a rectangular shape whose bandwidth is equal to or greater than the signal bandwidth, Nyquist pulses will pass through undistorted, maintaining their orthogonality, i.e., their freedom from intersymbol interference. However, a basic result from signal processing theory (see Chapter 23) is that the overall signal-to-noise ratio of a communication link is maximized when the receiver uses a *matched* *filter*, which is a filter whose impulse response is proportional to the time-reversed waveform of the incoming signal pulse. Let us apply this consideration to the two pulse shapes discussed above. For the $\sin(\pi t/T)/(\pi t/T)$ signaling pulse, the matched filter is just the rectangular filter which might have been used to produce the pulse. The cascade of two rectangular filters is equivalent to a single rectangular filter, and the pulse shape is preserved. For a raised-cosine signaling pulse, however, the matched filter is the raised-cosine filter of Equation 22.1. If we put this filter at the input of the receiver, the overall response will be the *square* of the raised-cosine shape. The signaling pulses will take on the shape of a raised-cosine squared filter – a shape that is not free of intersymbol interference. To avoid this, it is common to transmit "root raised-cosine" signaling pulses, i.e., pulses whose shape is the impulse response of a filter whose amplitude response is the square root of the raised-cosine filter. A root raised-cosine filter is used at the input of the receiver as a matched filter. The pulses exiting the receiver filter will therefore have the "raised-cosine pulse" shape shown in Figure 22.9, and there will be no intersymbol interference. The frequency response of the root raised-cosine filter is given by Figure 22.8(b), if you relabel the y-scale to go from 0 to – 60 dB instead of 0 to −120 dB.

Let us summarize this section. So-called Nyquist pulses can be transmitted without intersymbol interference up to a maximum rate of B pulses per second using double-sideband AM modulation within an RF bandwidth of at least B Hz. A second carrier, at the same frequency, but phase shifted by 90°, can be used simultaneously to transmit independent pulses. When the pulses are identical except for 0° or 180° phase changes, the system is called BPSK (one carrier only) or QPSK (pulses on both I and Q carriers). Synchronous detection, i.e., phase-sensitive detection, makes this 0° and 180° phase modulation equivalent to amplitude modulation in which the sign of the signal is preserved. If the I and Q components of a QPSK signal are each allowed to take on four values, the modulation forms a 4×4 constellation and is referred to as 16-QAM. (It would be convenient if the term "AM" always referred to this kind of sign and magnitude modulation. BPSK could be called "sign modulation." Traditional AM could be called "magnitude modulation".)

Note that in the above analysis we have not needed to bother with including a phase factor in the filter amplitude response functions. These particular filter functions are purely real, except for this omitted factor, $e^{-j\omega T_{\text{delay}}}$, where T_{delay} is a frequency-independent time delay. Neglecting this factor is equivalent to setting the delay equal to zero, which causes the impulse responses to begin at non-causal negative times.

22.4 8-VSB and GMSK modulation

The U.S. digital television system, discussed in Chapter 19, modulates an I-carrier with three-bit digital data in the form of eight evenly spaced amplitude levels whose nominal values are 7, 5, 3, 1, −1, −3, −5, and −7. A bias of 1.5 is added to these levels to create a small pilot carrier (a phase reference for the receiver) resulting in five transmitted levels that are positive and three that are negative. This is a PAM system (see Figure 22.2). The resulting double-sideband suppressed carrier signal is bandpass filtered to eliminate all but a vestige of the lower sideband, reducing the bandwidth by factor of almost 2. This modulation is called 8-VSB (eight levels, vestigial sideband). Because the signal had no Q-component before filtering, the lower sideband was the mirror image of the upper sideband and contained redundant information. With a general QAM signal (using both I and Q), the lower and upper sidebands are different and both are needed. But, as a result of filtering away the lower sideband, a transmitted VSB signal acquires a Q component, making the "Q-space" unavailable for the transmission of a second television signal.

The modulation method used in GSM cellular telephones is known as *GMSK* (*Gaussian minimum shift keying*), and works as follows. A standard QPSK modulator is used, summing the signal from an I mixer with the signal from a Q mixer. But the input signals to these mixers are such as to cause the sum signal to rotate smoothly from one point on the constellation to an adjacent point during the baud time. The rotation is 90°, clockwise or counterclockwise, depending on the binary data bit. The rotation takes place at a uniform rate. Since frequency is the time derivative of phase, this modulation is actually BFSK. In addition, smoothing, derived from a Gaussian filter shape, is applied to the phase command, so that the time derivative of the frequency is continuous during the transitions between the two nominal frequencies. This system is designed to minimize bandwidth, allowing closer channel spacing to accommodate more users. Bandwidth reduction comes from using both I and Q, from changing the phase slowly and smoothly, and from allowing some intersymbol interference (which is almost all from the immediately preceding baud and can be compensated for by the receiver).

22.5 Demodulation

Synchronous demodulation is required for the BPSK and QAM systems discussed above. This requires that the receiver be able to synthesize a replica of the carrier. This carrier recovery, which takes place in the presence of data, can be done, for example, using a squaring PLL (see Chapter 12). A standard PLL suffices if a pilot carrier is transmitted. The receiver contains a matched filter, followed by a mixer whose L.O. signal is the recovered carrier. The baseband output of the mixer is sampled at the signal baud rate. The signal may include a periodic synchronizing pattern to assist the receiver in establishing the correct phase for the sampler. A digital matched filter is often used. When realized as a weighted sum of signals from a tapped delay line (a transversal FIR filter), such a filter illustrates how a matched filter is equivalent to a correlator, finding the best alignment (match) of the signal to a replica of the signaling pulse.

Sometimes a free-running L.O. will be close enough to the carrier frequency that the dephasing over a data word or packet is significantly less than $\pi/2$. In this situation, differential modulation can be used whereby, for example, a “one” is signaled by flipping the phase of a BPSK signal, while a “zero” is signaled by leaving the phase at its prior value. If both I and Q channels are implemented, the phase changes can be reliably sensed and the data can be reconstructed. In a QPSK system, both I and Q channels are always implemented and the receiver can sense differential changes between points on the modulation constellation. Differential modulation, however, results in a higher error rate than coherent demodulation.

22.6 Orthogonal frequency-division multiplexing – OFDM

OFDM is a relatively new modulation technique in which the digital data stream to be transmitted is divided into N separate parallel data substreams, each having a data rate that is $1/N$ times the data rate of the original stream. Each substream independently modulates a separate RF carrier. The modulation scheme can be any of the schemes described above, except for FSK and MSK, where the phase does not remain constant throughout the duration of a symbol. At the receiver, the N substreams are demodulated in parallel and then combined to produce the original data stream. Applications of OFDM include 802.11*a* , *g*, and *n* Wi-Fi modems, DAB (digital audio broadcasting) in Europe and Canada, Digital Radio Mondiale short-wave broadcasting, HD (hybrid digital) radio broadcasting on the U.S. AM and FM bands, and European DVB-T (terrestrial digital television broadcasting). The number of carriers used in these systems varies from tens to thousands.

22.6.1 Advantages of OFDM

The system is bandwidth neutral, occupying about the same bandwidth as the traditional modulation systems it replaces. Its main advantage comes from its ability to deal with multipath propagation and channel equalization. Consider the problem of equalization. The propagation channel for a digital signal should have a specific amplitude and phase response, such as the raised-cosine shape discussed above. There are several propagation effects that can distort the shape. Receiving antennas are not always flat in frequency and linear in phase, so they can modify the channel response. Constructive and destructive interference of multipath components are frequency dependent and modify the channel response. Television receivers for 8-VSB use time correlation to detect multipath components and then subtract or realign them. This process, while essential, is not simple, and is particularly difficult in a mobile environment where the multipath situation is constantly changing. At fast baud rates, new multipath components are still arriving at the time the baud ends. With the slow data rates on the individual OFDM carriers, the baud can extend far beyond the time needed for all the multipath components to arrive. Dispersion is also a classic problem in wired data links.[2] Fast DSL (*digital subscriber line*) data links over ordinary telephone circuits have to deal with cable dispersion, poorly controlled impedances, and multipath echos caused by haphazard terminations and discontinuities. An early application of OFDM was in "discrete multi-tone" DSL modems of the early 1990s. While the principles of OFDM date back to the 1960s, practical implementations had to await the advent of fast digital signal processors. Most OFDM system incorporate coding and decoding for forward error correction and are known as COFDM (coded OFDM). As in digital TV transmission, the coding usually encloses the inner modulation/demodulation "physical layer."

22.6.2 Single-frequency broadcasting networks

The essentially perfect ability of OFDM to deal with multipath propagation can be exploited in single-frequency networks, in which broadcasting transmitters, all on the same frequency, serve overlapping areas of coverage. When the identical transmitted signals are synchronized in time and frequency (which can be done using GPS satellite signals), the signals arriving at any given site are indistinguishable from multipath signals originating from a single transmitter. At any given site, the receiving antenna is aimed at the strongest signal. The weaker signals, depending on their phase, increase or decrease the signal strength. They also shift the phases of the recovered Fourier coefficients, but this is not a problem because OFDM channels can be individually equalized via an occasional "training" sequence sent by the transmitter or by using a set of pilot carriers. Single-frequency networks allow efficient use of the spectrum, since the same television or radio channels can be used in adjacent areas – something like solving the classic map coloring problem with a single color. It is assumed that 8-VSB broadcasting could also use single-frequency networking, given echo cancellers of sufficiently high performance. Same-frequency fill-in or "booster" stations with well-synchronized frequencies have been used occasionally for conventional analog AM, FM, and television, but, without echo cancellation, they produce video echos ("ghosts").

---

[2] The earliest trans-Atlantic telegraph cable, over its great length, accumulated so much dispersion that baud rate had to be slowed down to where the received signal was traced out by a chart recorder. Likewise, early overland telegraph lines were too dispersive to support baseband telephony. The first solution, series loading coils, was a product of the then recent theory of waves on transmission lines, which showed that the reactance per unit length had to be increased, relative to the resistance per unit length.

22.6.3 Implementation of OFDM

The key to practical implementation of OFDM is the discrete Fourier transform (DFT) and its inverse (IDFT), which, in practice are implemented using FFT algorithms. At the transmitter, the data is arranged as a stream of data blocks, each containing N pairs of digital numbers. Each pair of numbers can be considered as the real and imaginary parts of a complex number. Let the complex data numbers in a given block be denoted as D_n, for $n = 0$ to $N-1$.

Figure 22.12. OFDM transmitter block diagram.

Figure 22.12, a block diagram for an OFDM transmitter, shows that these numbers are first inverse Fourier-transformed as follows:

$$V_m = \sum_{n=0}^{N-1} D_n e^{j2\pi mn/N}. \tag{22.3}$$

The resulting set of N complex numbers, V_m, for $m = 0$ to $N - 1$, is read out serially at a rate N/T, where T must be no greater than the spacing between blocks of input data. If V_0 appears at $t = 0$, we can express the output numbers as a function of time:

$$V(t_m) = \sum_{n=0}^{N-1} D_n e^{j2\pi n t_m/T} = \sum_{n=0}^{N-1} D_n e^{j\omega_n t_m}, \tag{22.4}$$

where ω_n is $2\pi n/T$. Note that this is just the sum of N carriers at equally spaced frequencies, ω_n, and that each carrier is multiplied (amplitude modulated) by a coefficient, D_n.

This set of N modulated carriers is converted from baseband to a QAM signal at RF by using a “cosine mixer” for the real part and a “sine mixer” for the imaginary part. Of course the real and imaginary outputs of the IDFT must be converted to analog voltages before they are applied to the mixers. These (suppressed) carriers are often called subcarriers, although they are not part of the sideband structure of some main carrier. Figure 22.13 shows an OFDM

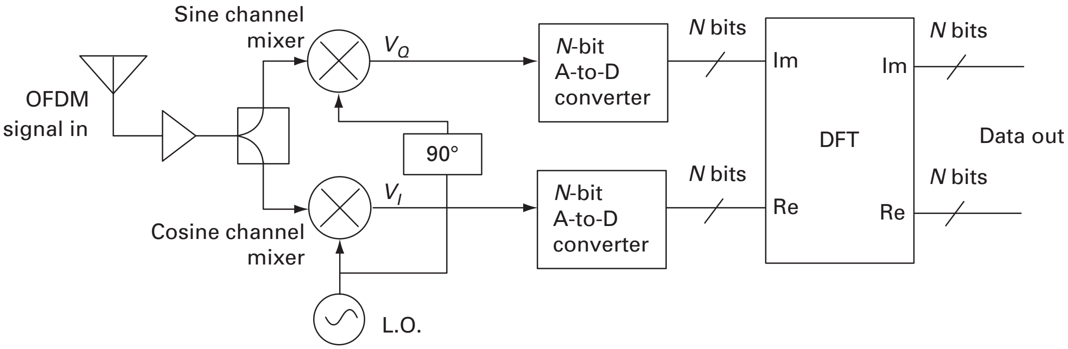

Figure 22.13. OFDM receiver block diagram.

receiver. Note that it is a mirror image of the transmitter. The operations done by the transmitter are undone in the reverse order by the receiver. I and Q samples from the cosine and sine mixers are digitized and combined to from the sequence of complex numbers, V_m, which is Fourier transformed to recover the date (the complex amplitudes of the subcarriers),

$$\frac{1}{N}\sum_{m=0}^{N-1} V_m\, \mathrm{e}^{-\mathrm{j}2\pi nm/N} = D_n, \qquad (22.5)$$

and we see that the data has indeed been recovered from the separate carriers. Thus the inverse Fourier transform effectively acts as N carrier oscillators and N mixers to create N modulated carriers while the Fourier transform at the receiver acts as N L.O.'s and N mixers to detect the (complex) amplitude of each carrier. During the interval T, the n-th carrier has constant amplitude; it is an RF pulse with a rectangular envelope. The Fourier transform of this pulse has the shape $\sin(\Delta\omega T/2)/(\Delta\omega T/2)$, where $\Delta\omega$ is the offset from ω_n. The shape plotted in Figure 22.5. We see that the spectrum for any one of the carriers has considerable overlap with the spectra of nearby carriers. Nevertheless, at the nominal frequency of any one of the carriers, the power spectrum of any other carrier is crossing through zero. For this reason, the carriers are said to be orthogonal in the frequency domain, analogous to Nyquist pulses in the time domain, whose maximum value occurs at an instant when the voltage from any earlier pulse is crossing zero.

22.6.4 OFDM guard interval

The key to dealing with multipath in OFDM is the use of a guard interval after every T-second transmission of the group of multicarrier signals. To see that this is necessary, consider the situation shown in Figure 22.14, where no guard interval is used. In the figure, the data is advancing in time toward the right. Ideally we would receive N signal samples from a

direct signal during the time interval 0 to t and then apply the Fourier transform to this set of numbers. But signals arriving on paths other than the direct path will arrive somewhat later, as shown in the figure, where the signal from the farthest path arrives late by about $0.2T$. A set of voltage samples taken from $t=0$ to T will be the sum of the signal voltages from the various paths so the first 20% of the samples will be contaminated by data from the previous signal interval, arriving via the farthest path and the first 5% or so will be contaminated by the previous signal arriving over all the delayed paths.

Now let us add a guard interval of length αT, as shown in Figure 22.15(a). The contributions from the delayed paths during the interval $t=0$ to T will now be from whatever has been placed in the guard intervals. You might think of zeros as a possible choice; at least they contain no data from the previous signal. However, they would compromise the orthogonality property. A much better scheme is to extend the data cyclically into the guard intervals, as shown in Figure 22.15(b). Data from the first part of the sequence is pasted into the guard interval so that when the guard interval advances into the sampler, the data sequence for the data interval begins over again. The result is that each multipath signal is properly demodulated over a complete interval and orthogonality is maintained. The overall system works as follows. Blocks of $2N$ real numbers are considered as blocks of N complex numbers. Each arriving block is subjected to an inverse DFT, whose output is also a block of N complex numbers. These output blocks are cyclically extended from length N to length $N(1+\alpha)$.

The numbers are converted to analog voltages and fed to a QAM modulator at a rate $N(1+\alpha)/T(1+\alpha) = N/T$. The receiver takes a burst of N samples every $T(1+\alpha)$ seconds, nominally aligned with the frame of data arriving over the direct path. Sampling bursts are separated by a time interval αT. The frames of N samples are Fourier-transformed to yield the complex amplitude of each carrier. This set of amplitudes is the original data. Many methods are possible to get the proper framing at the receiver and to regenerate the carrier for coherent detection. DAB audio broadcasting uses differential PSK modulation in order to tolerate carrier phase errors. DVB-T television, however, uses PSK with coherent detection.

22.6.5 Disadvantages of OFDM

One disadvantage of OFDM is that the signal has a high dynamic range, requiring that the transmitter have excellent linearity. (The same is true for any transmitter that transmits the sum of many independent signals, e.g., a cellular telephone base station transmitter.) Another potential problem is use in a mobile environment where different multipath signal components will generally have different Doppler shifts, as when the receiver is moving away from the transmitter but is moving toward a reflective object (maybe a building or tower) which provides a strong additional signal. The spacing between OFDM subcarriers would have to be considerably greater than the Doppler spread of the multipath signals. But, if there are appreciable differences in the time delays of the multipath components, the carriers must be closely spaced. This conflict is less severe at low radio frequencies, since Doppler shifts are proportional to frequency.

22.7 Spread-spectrum and CDMA

Best known now for its application in CDMA cellular telephony, spread spectrum was originally developed to provide secure communications links by using signals spread out in frequency and, therefore, reduced in spectral amplitude below the noise level of common intercept receivers. Besides being hard to detect, the signals cannot be demodulated without finding the long code word used in the spreading process. In addition, spreading makes the signals hard to jam.

22.7.1 Direct sequence spreading

Figure 22.16 shows how a rapidly changing binary pseudorandom code sequence multiplies a data stream to produce a signal whose bandwidth is determined by the "chip"[3] length of the code, rather than by the relatively slow data baud.

---

[3] Code elements, unlike signal elements, carry no information and are called "chips" rather than "bauds."

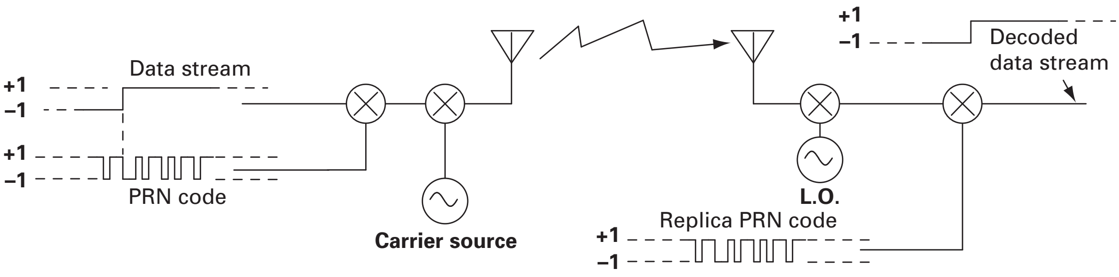

Figure 22.16. Pseudonoise spread spectrum.

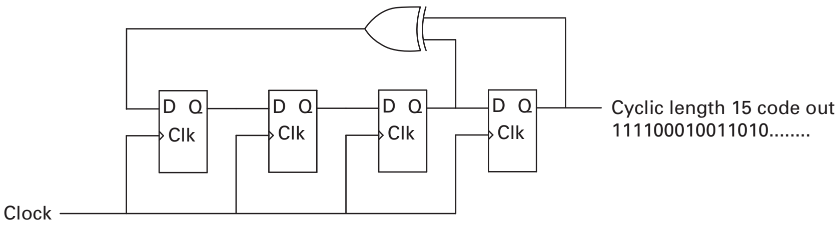

Figure 22.17. Four-stage maximum length shift register code generator.

This system is known as a *direct-sequence* spread spectrum (DSSS). We saw the same circuitry in Chapter 21, where its purpose was to produce a wide radar pulse with modest power that could be decoded (decompressed) to form a narrow high-power pulse. The purpose there was to get around the peak power limitation of the transmitter, but the system also provides the radar with a signal that is harder to intercept and jam. We will encounter the circuit again in Chapter 25, where its use in GPS satellites provides the high range resolution of pulse compression radar as well as multi-access – allowing all the satellites to transmit on the same frequency.

The pseudonoise or "direct sequence" spreading used in Figure 22.16 often uses *maximum length shift register sequences*, which are pseudorandom codes of length $2^N - 1$ generated by a circuit made of an N-stage shift register and a two (or more)-input modulus 2 adder. Figure 22.17 shows a four-stage generator and its 15-chip sequence. For this four-stage generator, only two feedback taps are needed, so the modulus-2 adder is a simple exclusive-OR gate. You can see that, for this kind of code generator, the shift register will never contain all zeros, as that state would then repeat endlessly. All other states do occur, so the length of the sequence is 2^N-1. A sequence of length $2^{32}-1$ can be generated by a 32-stage shift register with taps at stages 32, 31, 30, and 10. These taps can be added with a cascade of three ex-OR gates. With a 1-MHz clock, this generator would run for more than an hour before the sequence starts to repeat. For a given value of N, there are usually several sets of taps, each of which will yield a different maximum length sequence. The key property of the maximum length sequences is that they are noise-like. There is essentially zero correlation between different codes or between a code and a time-shifted version of itself.

The power spectrum of the signal transmitted by this system has a $[\sin(\pi f T)/(\pi f T)]^2$ shape, where ω is the offset from the carrier frequency and T is the chip length. Thus, the bandwidth is about $1/T$, independent of the code length. Longer codes, however, provide better security against interception. This system uses coherent detection; there must be provision for the receiver L.O. to acquire the correct phase (and, therefore, frequency) and for the replica code generator to acquire the phase for alignment with the incoming signal.

Wide frequency spreading requires a short chip time which, in turn, requires a high-precision time alignment of the replica code. Another spreading technique, *frequency hopping*, requires less alignment precision.

22.7.2 Frequency-hopping spread spectrum (FHSS)

In this system, the transmitter carrier frequency “hops” pseudorandomly from one frequency to another throughout the band. The timing of the hops is usually regular, though it, too, could be pseudorandom. An advantage of the hopping scheme is that the bandwidth is determined primarily by the assignment of hopping frequencies and not by the chip time – the time between hops. A convenient scheme is to hop to a new frequency for each data baud. These systems usually use incoherent detection since, until the advent of the direct digital synthesizer (DDS), it was difficult to achieve phase-coherent changes in frequency. One modulation scheme uses frequency shift keying. At the transmitter, the FSK signal is up-converted to the RF band by a frequency hopping carrier generator. At the receiver, a synchronized hopping L.O. converts the signal down to a constant IF frequency. The FSK IF signal can then be demodulated by an ordinary incoherent FM discriminator.

22.7.3 CDMA in cellular telephone systems

By itself, a direct sequence spread spectrum link is as power-efficient as a narrowband link, but deliberately has low spectral efficiency (data rate/RF bandwidth). However, the low cross-correlation property of the codes makes it possible for many users to have spread spectrum links operating in the same band. To each user, the signals from the others appear as random noise. This is known as *code-division multiple access* (CDMA). One advantage of CDMA is that no synchronization is required between users, in contrast to conventional time division and frequency multiplex systems where users must occupy scheduled frequencies and time slots. Another advantage is that the CDMA system quality degrades gracefully; as users are added, each user sees the background noise increase somewhat and experiences a lower signal-to-noise ratio. In time division and frequency division multiplexing, the maximum number of users is strictly limited by the number of frequency and time slots. For the same reason, in a CDMA cellular telephone system, adjacent cells can use the same band. Signals from adjacent cells will be, on average, weaker, and contribute only modestly to the background noise. Moreover, since a mobile user moving from one cell to another stays on the same frequency, there is a "soft handoff" from one base station to the next, rather than a momentary disconnection while new time or frequency slots are allocated.

Problems

Problem 22.1. Show that the impulse response of the filter function of Equation (22.1) is indeed the pulse shape of Equation (22.2).

Problem 22.2. Show that the filter whose frequency response is the *square* of that of the raised-cosine filter will produce intersymbol interference, i.e., show that such a filter, when excited by delta function at $t = 0$, will have an impulse response that is not identically zero at $t = T$.

Problem 22.3. Consider the simple single-frequency "network" for traditional AM broadcasting in which a single "booster" transmitter site is located at the fringe of the coverage area of the main transmitter. Describe what a listener, midway between the sites, could experience if (a) the carrier frequencies differ by 400 Hz; (b) the carrier frequencies differ by 0.1 Hz; (c) the carriers are locked to the same frequency.

Problem 22.4. Write a program to simulate the pseudonoise code generator of Figure 22.15 but use 10 stages, rather than four. One input to the ex-OR gate is the output of the tenth stage. Find which stage should be connected to the other input of this gate to produce a sequence of length 1023.

Hint: Start with the shift register in the all-ones state. Count the clock pulses needed to bring it back to this state. Do this for different taps until you find one that requires 1023 pulses.

Glossary

ATSC	Advanced Television Systems Committee: developed the ATV standard for US digital television broadcasting.
BER	Bit Error Rate: probability that a received "one" is deemed a zero or vice versa
BFSK	Binary Frequency-Shift Keying.
BPSK	Binary Phase-Shift Keying.

CDMA	Code Division Multiple Access: spread spectrum modulation that allows multiple users to share the same nominal frequency.
COFDM	Coded Orthogonal Frequency Division Multiplexing: multicarrier modulation system suited to multipath propagation environments. Includes coding for forward error correction.
DAB	Digital Audio Broadcasting standard used in Europe and Canada.
DDS	Direct Digital Synthesizer: frequency synthesizer with phase-continuous frequency transitions (see Chapter 12).
DFT	Discrete Fourier Transform, equivalent to a matrix multiplication that converts a set of N complex numbers to another set of N complex numbers.
DSL	Digital Subscriber Line: Telephone company high-speed digital service
DTV	Digital Television
DSSS	Direct Sequence Spread Spectrum: frequency spreading done via multiplication with pseudorandom ±1 sequence.
DVB-T	Digital Video Broadcasting – Terrestrial: European over-the-air digital television.
FEC	Forward Error Correction
FDM	Frequency Division Multiplexing: users are assigned different frequencies
FHSS	Frequency Hopping Spread Spectrum: transmitted signal "hops" rapidly between pseudorandomly chosen frequencies.
FIR	Finite Impulse Response: FIR filters are often based on a weighted sum of the signals from a tapped delay line.
GMSK	Gaussian Minimum Shift Keying: a particular frequency shift keying with smooth transitions between ones and zeros.
GPS	Global Positioning System: satellite navigation system.
GSM	Global System for Mobile Communications: the dominant cellular phone system.
HD radio	Hybrid Digital radio: a transition U.S. radio broadcasting standard in which COFDM digital signals share frequency channel assignments with AM and FM signals.
IDFT	Inverse Discrete Fourier Transform: equivalent to a matrix multiplication that inverts (undoes) a discrete Fourier transform.
ISI	Intersymbol Interference: self-interference caused by spreading of nearby pulses.
PAM	Pulse amplitude modulation
OFDM	Orthogonal Frequency Division Multiplexing: multi-carrier modulation system suited to multipath propagation environments.
OOK	On–Off Keying
QAM	Quadrature Amplitude Modulation: system in which two independent baseband signals are transmitted at the same frequency. One is up-converted to an "in-phase" carrier $\cos(2\pi f_{\mathrm{RF}}\, t)$, while the other is up-converted to a "quadrature" carrier $\sin(2\pi f_{\mathrm{RF}}\, t)$.
QPSK	Quadrature Phase Shift Keying: QAM using BPSK on both I and Q carriers.
TDM	Time Division Multiplexing: users on a single frequency channel have assigned time slots.
VSB	Vestigial Sideband: The remaining vestige of the lower sideband of an AM signal after asymmetric bandpass filtering.

CHAPTER

23

Modulation, noise, and information

In this chapter we examine how noise degrades the accuracy of digital data transmission and the fidelity of analog transmission. We begin with an explanation of matched filtering, a subject which came up in Chapter 22. We show that, for binary data links using matched filtering and coherent detection, the probability of error depends only on the noise level at the input of the receiver and on the energy, but not the shape, of the transmitted pulses. We look at two example systems: BPSK (binary phase-shift keying) with coherent detection and OOK (on–off keying) with envelope detection. The error rates and channel capacities (maximum error-free data rates when using forward error correction coding) are calculated and compared with Shannon's expression for the capacity of a bandlimited channel. Finally, traditional AM and FM are examined with respect to their noise characteristics.

23.1 Matched filtering

We stated in Chapter 22 that, in the presence of noise, the post-detection signal-to-noise ratio is maximized when the predetection bandpass shape of the receiver is that of a *matched filter*.

A matched filter is one whose impulse response is proportional to the time-reversed waveform of the incoming signal pulse, as will be shown below. For example, if the input signal is a pulse whose shape is the same as the symmetric impulse response of a root raised-cosine filter, then the receiver should use a root raised-cosine filter or an equivalent cascade of filters. Sometimes we deal with complicated pulses, such as the biphase coded pulses used in pulse compression radar. In these cases, it is common to use a front-end bandpass filter which is a matched filter for the individual subpulses, followed by coherent detection and then a decoder which undoes the plus/minus phase coding. Here the cascade of the front-end filter and the decoder is equivalent to a matched filter for the coded pulses. Note that coherent detection is down-conversion to baseband, a linear operation. We can think of the entire matched filter as the actual detector, whose output samples are the received symbols.

Let D denote the output of the receiver's filter (which we have just defined as the "detector" output) and let $h(t)$ be the impulse response of this filter, a real function. For a signal pulse unaccompanied by noise, the output from the filter is given by

$$D_S = \int_{-\infty}^{\infty} h(t) V_S(-t)\mathrm{d}t, \tag{23.1}$$

where we have assumed the pulse position to be such that the filter output should be sampled at $t=0$. The output signal power, in units of volts^2, is given by $P_S = D_S{}^2$. The noise output of the filter can be written in terms of N_0, the standard one-sided noise density, in units of volts^2/Hz, as

$$P_N = \frac{N_0}{2} \int_{-\infty}^{\infty} |H(\omega)|^2 d\omega, \tag{23.2}$$

where $H(\omega)$ is the filter transfer function, i.e., the Fourier transform of $h(t)$. Note that we have assumed that N_0 is a constant (white noise). Using Parseval's theorem, we can write P_N in terms of $h(t)$:

$$P_N = \frac{N_0}{2} \int_{-\infty}^{\infty} h(t)^2 dt. \tag{23.3}$$

With these expressions for P_S and P_N, we can write the output signal-to-noise ratio as

$$\mathrm{SNR} = \frac{P_S}{P_N} = \frac{\left(\int_{-\infty}^{\infty} h(t) V_S(-t)\mathrm{d}t\right)^2}{\frac{N_0}{2}\int_{-\infty}^{\infty} h(t)^2 \mathrm{d}t}. \tag{23.4}$$

At this point, we invoke Schwarz's inequality[1] which gives us

$$\mathrm{SNR} \le \frac{\int_{-\infty}^{\infty} h(t)^2 \mathrm{d}t \int_{-\infty}^{\infty} V_S(-t)^2 \mathrm{d}t}{\frac{N_0}{2}\int_{-\infty}^{\infty} h(t)^2 \mathrm{d}t} = \frac{1}{N_0}\int_{-\infty}^{\infty} V_S(-t)^2 \mathrm{d}t = \frac{1}{\frac{N_0}{2}}\int_{-\infty}^{\infty} V_S(t)^2 \mathrm{d}t. \tag{23.5}$$

---

[1] Schwarz's inequality is written as $|\int f(x)g(x)\mathrm{d}x|^2 \le \int |f(x)|^2 \mathrm{d}x \int |g(x)|^2 \mathrm{d}x$. This can be seen by considering the integral of fg to be the dot product of a multidimensional vector, while the integral $\int |f(x)|^2 \mathrm{d}x$ is the length of the vector f and $\int |g(x)|^2 \mathrm{d}x$ is the length of the vector g. For two vectors $\boldsymbol{A}$ and $\boldsymbol{B}$, we know that $|\boldsymbol{A}\bullet\boldsymbol{B}|^2 \le |\boldsymbol{A}\bullet\boldsymbol{A}||\boldsymbol{B}\bullet\boldsymbol{B}|$.

Looking at Equation (23.4), we see that if $h(t) = \beta V_S(-t)$, where β is any constant, then the SNR will be equal to its maximum possible value, the right-hand expression in Equation (23.5). This is the matched filter. Note that, with a matched filter, the signal-to-noise ratio for a pulse is independent of the pulse shape and is simply the time integral of $V_S(t)^2$, i.e., the energy of the pulse, $\mathscr{E}_S$, divided by the noise spectral density N_0. (N_0 has units of volts^2/Hz, which is the same as volts^2 sec.) Thus, when a matched filter is used,

$$\mathrm{SNR} = \frac{1}{N_0/2}\int_{-\infty}^{\infty} V_S(t)^2 \mathrm{d}t = \frac{2\mathscr{E}_s}{N_0}. \tag{23.6}$$

23.2 Analysis of a BPSK link

Coherent detection makes the BPSK link especially easy to analyze. The signal at the output of the matched filter is just the sum of the signal voltage and the noise voltage, which we will assume to have a Gaussian distribution, characteristic of thermal noise. The detected signal voltage will be either A or $-A$, so the Gaussian noise distribution will be centered at either A or $-A$, as shown in Figure 23.1. The one/zero decision threshold will, of course, be set at $V = 0$ for this symmetric situation.

The probability distribution for a zero (the solid curve) is the normal Gaussian distribution function, $p_0 = (2\pi\sigma^2)^{-1/2} \exp[-(V+A)^2/(2\sigma^2)]$. By inspection of the figure we can write

$$p_\mathrm{e} = \int_0^{\infty} \frac{\mathrm{e}^{-(V+A)^2/2\sigma^2}}{\sqrt{2\pi\sigma^2}} dU = \int_A^{\infty} \frac{\mathrm{e}^{-V^2/2\sigma^2}}{\sqrt{2\pi\sigma^2}} \mathrm{d}U = \frac{1}{\sqrt{2\pi}}\int_{\frac{A}{\sigma}}^{\infty} \mathrm{e}^{-u^2/2}\mathrm{d}U. \tag{23.7}$$

Now let us relate this probability of error to the signal-to-noise ratio. We saw in the previous section that, at the output of a matched, the ratio of the square of the signal portion of the sampled output to the average square of the noise portion is $2\mathscr{E}_S/N_0$, where $\mathscr{E}_S$ is the energy of the pulse, i.e., the time integral of the V_S^2, and

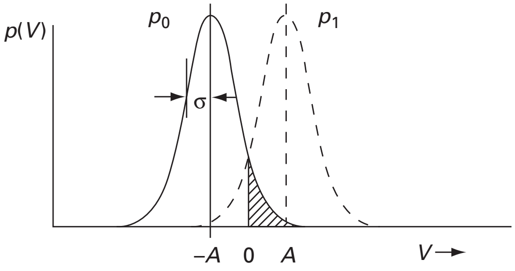

Figure 23.1. Gaussian voltage probability distributions for received BPSK ones and zeros for $A = 1.5\sigma$ (SNR = 1.5^2). The shaded area in the figure is the probability p_e of a transmission error, i.e., the probability that a received zero will be interpreted as a one or that a received one will be interpreted as a zero.

N_0 is the noise power density. Therefore $A^2/\sigma^2 = 2\mathscr{E}_S/N_0$, and we can rewrite Equation (23.7) as

$$p_e = \frac{1}{\sqrt{2\pi}} \int_{\sqrt{2\,\mathscr{E}_S/N_0}}^{\infty} e^{\frac{-u^2}{2}} du. \tag{23.8}$$

We have been implicitly working at baseband, i.e., assuming that the signal (and the noise) have been converted down from an RF carrier frequency, ω_0, through multiplying the modulated RF signal by a sine wave in phase with the (normally suppressed) carrier. This, as we have seen, constitutes synchronous detection. In this common situation, the matched filter is a baseband filter.

It is interesting to note that we could alternately have used a matched filter at the RF (or some IF) frequency. In this case, the output of the filter is an RF sine wave, multiplied by the baseband pulse. We can sample this directly, but the sampling must be very precise, so that the samples are taken at points that, with a dc pulse, would be at the peaks of the RF sine wave. The SNR will be the same as for the synchronous conversion to baseband because even though the RF bandwidth is twice the baseband bandwidth and contains twice as much total noise power, the synchronous sampling will respond to only half this noise, e.g., the "cosine" component.

If symbols are arriving at the rate $1/T$ in the minimum baseband bandwidth of $1/(2T)$ that eliminates intersymbol interference (see Chapter 22), then $2\mathscr{E}_S/N_0 = (\mathscr{E}_S/T)/(N_0/[2T]) = P_S/P_N = SNR$ the signal-to-noise ratio. This probability of error from Equation 23.8 is plotted vs. SNR in Figure 23.2.

This figure displays the well-known "dropout" effect in digital communications systems. If, for example, the input SNR drops from ten to five, a factor of only 2, the error rate increases by a factor of 100. The probability of error for the BPSK distributions shown in Figure 23.1, where A/σ = 1.5, is 0.067.

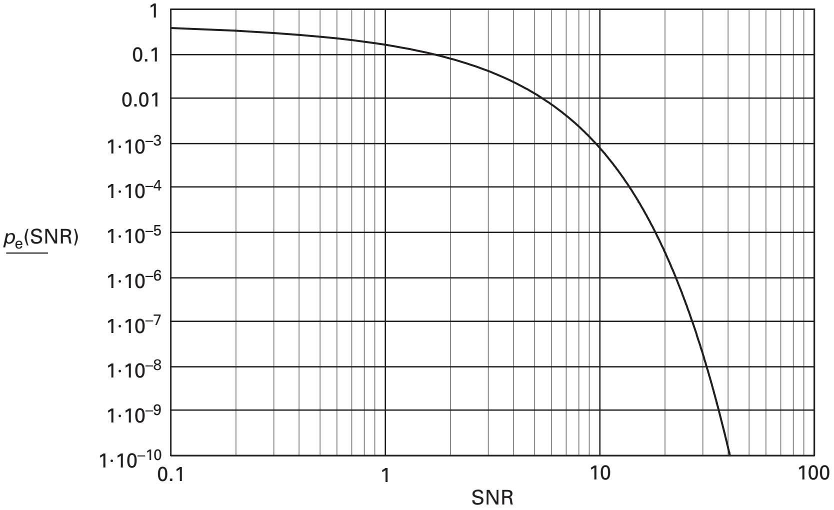

Figure 23.2 Envelope probability distributions $P(E, A, \sigma)$, *for* $\sigma = \sqrt{2}$ and $A = 0$ *or* $1.5\sqrt{2}$.

23.3 On–off keying with envelope detection

The BPSK system discussed above, using coherent detection, is suited for data transmission under low signal conditions. (When there is ample signal power, multilevel "M-ary" modulation can obviously transmit data at a faster bit rate.) But let us now consider simple on–off keying with envelope, i.e., noncoherent detection. Before we can calculate the probability of error, we must find the distribution function of the output voltage from the envelope detector.

23.3.1 Envelope probability distributions

As we have seen, the IF signal, containing random noise, is a random variable with Gaussian probability distribution. The presence of a signal offsets the Gaussian curve. The output of the envelope detector is also a random variable. Let us find the probability distribution of the envelope, first without the presence of a signal. Figure 23.3(a) shows the in-phase and quadrature components, $\boldsymbol{N}_I$ and $\boldsymbol{N}_Q$. of the IF noise voltage. The length of their vector sum is $\boldsymbol{E}$, the envelope voltage.

Since the I and Q noise components are uncorrelated, their joint probability distribution is the product of their individual Gaussian distributions.

$$p(V_I, V_Q) = \frac{\mathrm{e}^{-V_I^2/2\sigma^2}}{\sqrt{2\pi\sigma^2}} \times \frac{\mathrm{e}^{-V_Q^2/2\sigma^2}}{\sqrt{2\pi\sigma^2}} = \frac{\mathrm{e}^{-(V_I^2+V_Q^2)/2\sigma^2}}{2\pi\sigma^2} = \frac{\mathrm{e}^{-E^2/2\sigma^2}}{2\pi\sigma^2}. \tag{23.9}$$

To obtain the distribution in terms of E and θ, we note that

$$p(E,\theta)E\mathrm{d}\theta\mathrm{d}E = \frac{\mathrm{e}^{-E^2/2\sigma^2}}{2\pi\sigma^2}E\mathrm{d}\theta\mathrm{d}E, \tag{23.10}$$

from which we identify

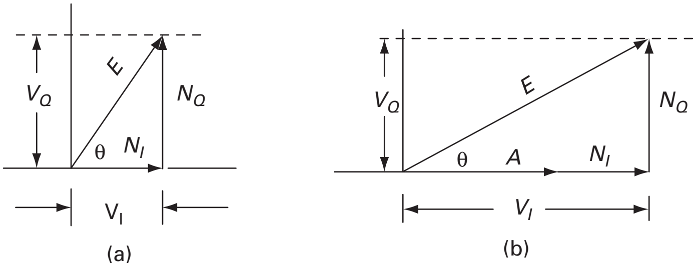

Figure 23.3 (a) *I* and *Q* noise phasors alone; (b) noise phasors together with a sine wave of amplitude *A*.

$$p(E,\theta)=\frac{E\mathrm{e}^{-E^2/2\sigma^2}}{2\pi\sigma^2}. \tag{23.11}$$

Integrating over θ, from 0 to 2π, we find $p(E)$, the envelope probability distribution:

$$p(E)=\int_0^{2\pi}P(E,\theta)\mathrm{d}\theta=\frac{E\mathrm{e}^{-E^2/2\sigma^2}}{\sigma^2}. \tag{23.12}$$

This function is known as the Rayleigh probability distribution. Note: for both the I and the Q noise components, the variance is σ^2. Therefore, the total noise power, which is the expectation of E^2, is $2\sigma^2$.

Now we must find the envelope distribution function when the IF signal is the superposition of noise plus a sinusoidal carrier. This is shown in Figure 23.3(b). Again, both noise voltages, N_I and N_Q, have Gaussian distributions, but now the distribution for N_I is centered at A, the amplitude of the carrier, so we can write

$$\begin{aligned}p(V_I,V_Q)&=\left[\sqrt{2\pi\sigma^2}\right]^{-2}\mathrm{e}^{[-(V_I-A)^2+V_Q^2]/2\sigma^2}\\&=(2\pi\sigma^2)^{-1}\mathrm{e}^{[-(E\cos(\theta)-A)^2+E\sin(\theta)^2]/2\sigma^2}.\end{aligned} \tag{23.13}$$

Expanding the argument of the exponential on the right-hand side we have

$$p(V_I,V_Q)=(2\pi\sigma^2)^{-1}\mathrm{e}^{-(E^2+A^2)/2\sigma^2}\mathrm{e}^{-2AE\cos(\theta)/2\sigma^2}. \tag{23.14}$$

Following the steps used in the carrier-free case, and integrating over θ, we find

$$\begin{aligned}p(E,A,\sigma)&=\frac{E\mathrm{e}^{-(E^2+A^2)/2\sigma^2}}{\sigma^2}\frac{1}{2\pi}\int_0^{2\pi}\mathrm{e}^{-AE\cos(\theta)/\sigma^2}\mathrm{d}\theta\\&=\frac{E\mathrm{e}^{-(E^2+A^2)/2\sigma^2}}{\sigma^2}I_0(AE/\sigma^2),\end{aligned} \tag{23.15}$$

where I_0 is the modified Bessel function of order zero. This function, $p(E,A,\sigma)$, known as the *Rician* distribution, is plotted in Figure 23.4 for $A=0$ (the envelope distribution of noise alone) and for $A=1.5\sqrt{2}$, for the same noise power and average transmitted power (assuming equal probabilities for transmitted ones and zeros) used for the BPSK example of Figure 23.1.

Let us calculate the probability p_e that a bit is received incorrectly when we have (arbitrarily) set the decision threshold at the intersection of the ON and OFF envelope distribution functions, which we will denote as E_t. We will also assume that we transmit, on average, equal numbers of ones and zeros. The probability of error is, therefore, $\frac{1}{2}p_{\mathrm{e}0}+\frac{1}{2}p_{\mathrm{e}1}$, where $p_{\mathrm{e}0}$ is the probability that a transmitted zero is received incorrectly and $p_{\mathrm{e}1}$ is the probability that a transmitted one is received incorrectly or

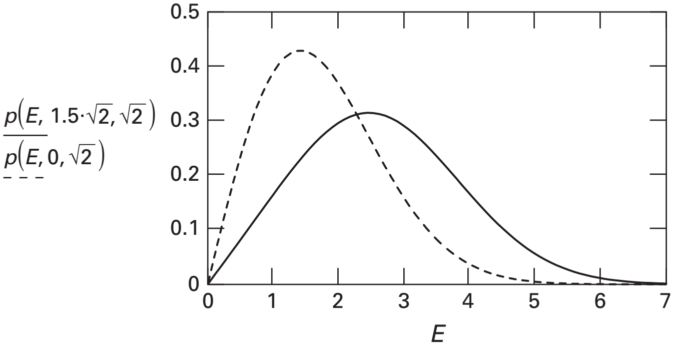

Figure 23.4 Probability distribution $p(E,A,\sigma)$, for the envelope of a signal that is the sum of a sine wave of amplitude $A = 1.5\sqrt{2}$ plus noise with $\sigma = 2$.

$$p_{\mathrm{eOOK}}(A,\sigma) = 1/2 \int_{E_t}^{\infty} p_0(E,A,\sigma)\mathrm{d}E + 1/2 \int_{0}^{E_t} p_1(E,A,\sigma)\mathrm{d}E. \tag{23.16}$$

Evaluating P_{eOOK} for A $= 1.5\sqrt{2}$ and $\sigma = \sqrt{2}$ for comparison with the BPSK example of Figure 23.1 (same average transmitted power, but twice the noise power (quadrature as well as in-phase components), yields $P_{\mathrm{eOOK}} = 0.34$ for a threshold $E_{\mathrm{t}} = 2.3$, compared to only .067 for P_{eBPSK}.

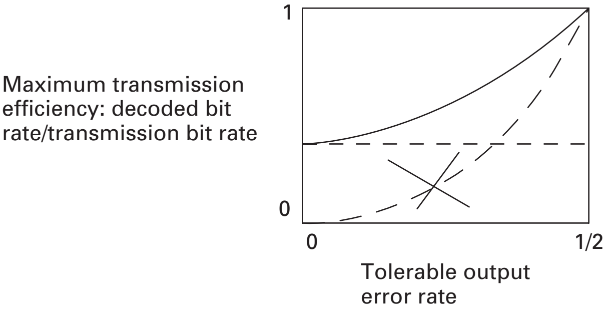
Channel capacity

We have seen how to calculate the expected bit error rate as a function of the signal and noise powers for two example situations, coherently-detected PSK and envelope-detected on–off keying. We also know that data error rates can be reduced by expanding (encoding) the data so that it contains redundancies.[2] Of course, the net data rate slows when redundant bits are transmitted. These redundancies may be crude, such as transmitting a packet of data several times, or elegant, such as the nested combination of block codes and convolutional codes used in data links and digital broadcasting systems. Given a particular communications link with an optimal encoding scheme, it is obvious to ask how many bits must be transmitted, on average, for each data bit, if we are willing to tolerate a certain average data error rate. One might expect that, as the error tolerance is reduced to zero, the optimal transmission efficiency would also go to zero, i.e., that an infinite number of bits would have to be transmitted for each recovered data bit, as indicated by the crossed out curve in Figure 23.5. Shannon's remarkable "noisy channel theorem" showed that this is not so. For any given communications link, there must exist coding schemes that will permit data transmission with an arbitrarily low error tolerance while still

---

[2] Making the data redundant enough so that errors can be detected and corrected at the receiver is known as forward error correction (FEC). In reverse error correction, the receiver can only detect errors. To make corrections, it must request repeat transmissions.

Figure 23.5 Transmission efficiency vs. tolerated output error rate when using optimum channel encoding.



achieving a non-zero efficiency. This situation is shown by the solid curve Figure 23.5, which shows the efficiency for a link using an optimum error coding scheme.

The maximum efficiency is unity if we are willing to tolerate an output error rate of 1/2, but this is the point at which no net information is transmitted since a one is randomly declared a one or a zero and vice versa. But as the error rate tolerance is lowered to zero, the maximum efficiency approaches an asymptotic *non*zero value. This asymptotic maximum efficiency value is called the *channel capacity* (bits/bit) and, when multiplied by the bit rate, in bits/sec, the result, in units of bits/sec, is a rate and is also referred to as the channel capacity. (Context usually resolves any confusion between the two.) The ususal statement of Shannon's theorem is that it is possible to transmit data at a rate equal to or less than the channel capacity, with an arbitrarily low data error rate. While Shannon's work shows that optimum codes must exist, it does not show how to construct then. However, it does show how to calculate the channel capacity for a given link, the highest standard against which we can judge the efficiency of any coding scheme proposed for the link. If the arbitrarily low data error rate is set too low, the encoded data must be in the form of extremely long blocks. Fortunately, acceptably low error rates can be achieved with acceptably short data blocks.

Binary symmetric channel

The coherent BPSK link discussed above is an example of a *binary symmetric channel*. The transmitted symbols are either one or zero, and every received signal is deemed either a one or a zero. From the symmetry of Figure 23.1, it is obvious that the probability p_e that a transmitted one will be received in error as a zero is equal to the probability that a transmitted zero will be received in error as a one, as indicated in Figure 23.6. This figure, a sort of probability flow graph for a binary channel, is equivalent to a 2×2 matrix whose coefficients are probabilities. The binary symmetric channel corresponds to a symmetric channel matrix.

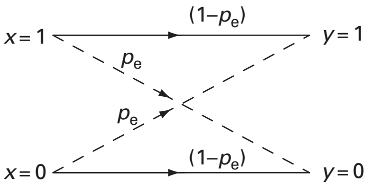


Figure 23.6. Binary symmetric channel: p_e is the probability that a symbol x_i is wrongly received as a symbol y_j.

The channel capacity for this link, which depends only on p_e and on p_i, the probability that the i-th transmitted bit is a one, is given by

$$\begin{aligned} C(p_e, p_i) &= p_e \log_2(p_e) + (1 - p_e)\log_2(1 - p_e) \\ &\quad - p_i \log_2(p_i) - (1 - p_i)\log_2(1 - p_i). \end{aligned} \tag{23.17}$$

This expression is always greatest for $p_i = 1/2$ (equal probability of transmitted ones and zeros). Figure 23.7 shows C(p_e,1/2) plotted versus p_e.

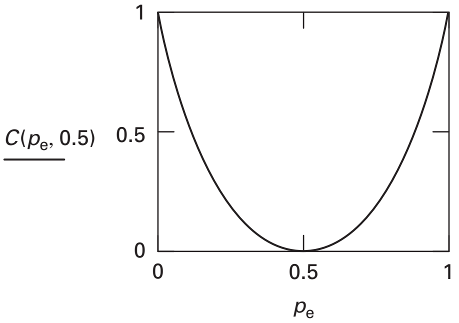

Figure 23.7 Channel capacity of a binary symmetric channel vs. transmission error rate, assuming ones and zeros are transmitted with equal probability.

Note that the channel capacity falls to zero at $p_e = 1/2$, where the receiver is equally likely to interpret a transmitted one as a zero and vice versa. Then C rises again to unity for $p_e = 1$, where the receiver always mistakes a one for a zero and zero for a one. In this case, the message is transmitted faithfully, assuming the receiver realizes that it should complement the bits. (It takes only a single transmitted bit to resolve this ambiguity.)

The reader will find excellent treatments of information theory, channel capacity, and coding in the texts listed at the end of this chapter but the origin of Equation (23.17) warrants at least a brief discussion, in the limited context of a binary channel. The discussion should at least serve to show that, while the concepts are subtle, the mathematics is simple. In the binary channel, the transmitter sends a symbol which is denoted either x_1 (a one) or x_2 (a zero). The *information* in a transmitted symbol is defined as $I(x_i) = \log_2 (p(x_i)^{-1})$, where $p(x_i)$ is the probability of x_i. Note that if $p(x_i)$ is nearly one, the information contained in x_i is nearly zero. If the transmitted symbols are almost always ones (or zeros), very little information is transmitted by sending a one (or zero), as we would have expected the one (or the zero). But if $p(x_i)$ is a very small number, the occurrence of x_i is highly informative, as we would not have expected it. A second definition is that of *mutual information*,

$I(x_i; y_j) = \log_2[p(x_i|y_j)|p(x_i)]$, where $p(x_i|y_j)$ is the conditional probability that x_i was transmitted, given that y_j was received. Note that while the distribution of transmitted symbols is generally flat (uniform), the distribution of $I(x_i; y_j)$ for a given j is not uniform, but peaked around the value of i most likely to have resulted in y_j.

The expected value of the mutual information is the sum of the $I(x_i; y_j)$'s, weighted by their probabilities, i.e.,

$$\langle I(x_i; y_j)\rangle = \sum_i \sum_j p(x_i, y_j) I(x_i; y_j), \tag{23.18}$$

where $p(x_i, y_j)$ is the joint probability of x_i and y_j, i.e., $p(x_i\, y_j) = p(x_i)\, p(y_j|x_i)$. For the binary symmetric channel discussed above, $p(y_j, x_i) = p_e$ for $i \neq j$ and $(1 - p_e)$ for $i = j$. The channel capacity is given by the maximum value of $\langle I(x_i; y_j)\rangle$ with respect to the set of values $p(x_\text{i})$, by

$$C = \max\langle I(x_i; y_j)\rangle \text{ w.r.t } \{p(x_i)\}. \tag{23.19}$$

For the binary symmetric channel, the maximum occurs when equal numbers of ones and zeros are transmitted, i.e., when $p(x_1) = p(x_2) = 1/2$. Evaluation of Equation (23.19) yields Equation (23.17), the expression for the channel capacity. Note that the channel capacity is based on the relative frequency of transmitted ones and zeros and on the values of $\text{p}(y_j \mid x_i)$, which is the conditional probability that the receiver produces y_j when the transmitter sent x_i. However, to calculate the values of $I(x_i; y_j)$, we need to know $\text{p}(x_i \mid y_j)$, the conditional probability that when the receiver produces y_j, the transmitter had sent x_i. The two conditional probabilities are related through Bayes' theorem: $p(x_i, y_j) = p(x_i)\, p(y_j \mid x_i) = p(y_j)\, p(x_i \mid y_j)$.

Channel capacity of the BPSK and OOK example channels

For the BPSK example shown in Figure 23.1, with $A/\sigma = 1.5$, we found the probability of error to be $p_\text{e} = .067$. Using this value in Equation 23.17, the channel capacity is 0.645 data bits/transmitted bit. For the comparable asymmetric OOK channel of Figure 23.4 the two integrals in Equation 23.16 are, respectively, the probability that a transmitted zero is received as a one and vice versa. If we calculate the channel capacity using Equation 23.19, we find that it maximizes at about $\text{C} = 0.08$, if the threshold is set at $E_\text{t} = 2.5$ and the proportion of transmitted zeros is 52%. In addition to low channel capacity, another disadvantage of the OOK system is that the threshold must be changed when either the signal or noise level changes.

Channel capacity of a bandpass channel

Shannon also presented a formula for the *maximum* channel capacity for a band-limited channel with added Gaussian white noise – the channel most amenable to analysis, and a channel often encountered in practice, for example, in spacecraft telemetry links. This formula states that the maximum channel capacity is given by

$$C = B\log_2[1 + S/N] = B\log_2[1 + S/(BN_0)] \tag{23.20}$$

where S is the received signal power, N is the noise power which is equal (for white noise) to BN_0, where B is the channel bandwidth, and N_0 is the noise spectral density at the receiver in Watts/Hz. The figure of merit for any particular modulation scheme is how close its channel capacity approaches this ideal maximum channel capacity. To see that Equation 23.20 is reasonable note that, when S/N is high, it is essentially the practical number of quantization levels, n, and $\log_2(n)$ converts this into bits. The bandwidth factor, B, will be the symbol rate or close to it.

For illustration, suppose the signal power available from a spacecraft is 10^{-16} Watts, contained within a bandwidth of 100Hz, and the noise density at the receiver input is 4×10^{-19} Watts/Hz. With these numbers, Equation 23.20 produces $C = 181$, which is the maximum rate (bits/sec) at which information could be transmitted over the channel at an arbitrarily small error rate, if the modulation scheme and signal coding are optimum.

Let us look at our example BPSK channel in the light of Equation 23.20. In that example, the SNR at the output of the detector was $(A/\sigma)^2 = 1.5^2$. If we are using a matched filter, we saw that $(A/\sigma)^2$ be equal to $2\mathscr{E}/N_0$. Let us assume we transmit bits at a rate of $1/T$ and use receiver bandwidth of $1/(2T)$. The received power is $S = \mathscr{E}/T$ and the noise at the receiver is $N_0/(2T)$, from which we have $S/N = 2\mathscr{E}/N_0$. Using Equation 23.20, we see that the maximum channel capacity will be $C = 1/(2T)^{-1}\log_2(1 + 2\mathscr{E}/N_0) = .850/T$ bits/sec. But, from the bit error probability, a function of A/σ, we had calculated the actual channel capacity of this BPSK link to be .645 bits/bit. If we multiply this by the bit rate, $1/T$, the channel capacity becomes $.645/T$ bits/second. This BPSK link, therefore, has $.645/.850 = 76\%$ of the maximum possible channel capacity.

For much larger values of S/N, we would find that, while the ideal channel capacity increases, our BPSK channel capacity saturates at the value $1/T$. This is simply due to staying with two-level binary modulation, as opposed to N-level PAM modulation.

Noise in analog FM and AM systems

Let us first look at the noise produced at the output of an FM receiver. The instantaneous received signal voltage, V_{SIG}, is accompanied by noise, V_N, as shown in Figure 23.8.

This is the same as the diagram in Figure 23.3(b), except that now we are interested in the phase angle rather than the magnitude of the vector sum of the signal plus noise. This "phase noise," ϕ_N, will cause noise in the detected output of an FM or PM detector. Clearly the angle ϕ_N becomes smaller if the signal strength is increased. But there is another way to defeat the noise. The signal-to-noise ratio at the detector output depends on the ratio of the signal's modulation phase excursions to the phase noise. If the modulation level is increased, even without increasing the signal strength, the output signal-to-noise ratio will be improved.

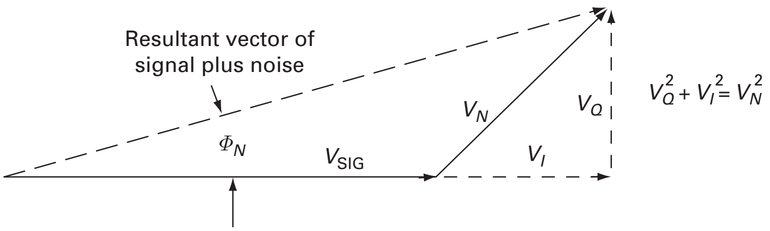

Figure 23.8. Signal and noise voltages.

If, for example, the rms phase noise is 1/10 radian and the modulation index is 1 radian, the phase SNR is 100. If the deviation is increased to produce a modulation index of 5 radians, the phase SNR increases to 2500. The improvement has been obtained not by increasing the signal power but by increasing the signal bandwidth. In the case of amplitude modulation, the SNR depends on the noise modulating the length of the vector $V_{\mathrm{SIG}} + V_N$. Since V_{N} is fixed in any given situation, the only way to improve the SNR in AM is to increase V_{SIG}, i.e., increase the transmitted power.

Analysis of the SNR improvement in FM

A quantitative analysis of the SNR improvement in FM is simpler if we take the noise to be the background noise produced by the detector when the signal is unmodulated, i.e., the total power in the hiss coming from the loudspeaker or other output device. For the signal we will take an audio sine wave with 100% modulation (maximum deviation). We can represent the noise, V_N, by in-phase (I) and quadrature (Q) noise components, V_I and V_Q where $V_I^2 + V_Q^2 = V_N^2$ as shown in Figure 23.8. Both V_Q, and V_I are phasors rotating at ω_0, the frequency of the unmodulated carrier. Their amplitudes are random and independent. The I component of the noise is the most effective in causing amplitude fluctuations and therefore contributes noise in AM demodulation. But it is mostly the Q component, since it is perpendicular to V_{SIG}, that causes angle fluctuations and therefore contributes noise in the FM demodulation. For $V_N \ll V_{\mathrm{SIG}}$, the instantaneous angle noise, $\phi_N(t)$, is just $V_Q(t)\,/V_{\mathrm{SIG}}$ radians. Since V_{SIG}, the carrier amplitude, is constant, the power spectrum of ϕ_n (call it S_ϕ) is proportional to the power spectrum of V_Q. The spectral distribution of V_Q can be assumed uniform (white) so S_ϕ is also uniform. The integral of S_ϕ over the IF band gives the mean square phase fluctuation, $\langle(\phi_n(t))^2\rangle$, so we can write $S_\phi = \langle(\phi_n(t))^2\rangle/B_{\mathrm{IF}} = \langle V^2{}_Q(t)\rangle/(V^2{}_{\mathrm{SIG}}B_{\mathrm{IF}}) = \langle V^2{}_N(t)/2\rangle/(V^2{}_{\mathrm{SIG}}\,B_{\mathrm{IF}})$ where B_{IF}, the IF bandwidth, is twice the maximum deviation. An FM demodulator produces an output spectral density proportional to the time derivative of the phase, $\langle(\mathrm{d}\phi_n(\mathrm{t})/\mathrm{d}t)^2\rangle$. The spectral density of the noise in the (one-sided) audio band at the detector output is therefore given by $2\omega_a{}^2 S_\phi(t)$, and the total noise power is the integral of this spectral density over the output bandwidth of the detector, i.e., the audio band (0 to B_a radians):

$$\text{Output noise power} = \int_0^{B_\mathrm{a}} 2\omega^2 S_\phi \mathrm{d}\omega = S_\phi \int_0^{B_\mathrm{a}} 2\omega^2 \mathrm{d}\omega = \frac{2}{3} S_\phi {B_\mathrm{a}}^3 \\ = \frac{{B_\mathrm{a}}^3}{6k_\mathrm{osc}A_\mathrm{MAX}} \frac{\langle {V_\mathrm{N}}^2 \rangle}{V_\mathrm{SIG}^2}. \tag{23.21}$$

The maximum amplitude of the sine-wave signal at the output of the detector is $k_\mathrm{osc}A_\mathrm{MAX}$, the maximum deviation, so the maximum signal power is just $P_\mathrm{SIG} = {k_\mathrm{osc}}^2{A_\mathrm{MAX}}^2/2$. Taking the noise power from Equation (23.21), the signal-to-noise ratio at the detector output is:

$$\text{Maximum output SNR} = 3\left(\frac{k_\mathrm{osc}A_\mathrm{MAX}}{B_\mathrm{a}}\right)^3 \frac{V_\mathrm{SIG}^2}{\langle {V_\mathrm{N}}^2 \rangle}. \tag{23.22}$$

Note that the output SNR improves as the cube of the ratio of the maximum deviation to the full audio bandwidth.

Output signal-to-noise ratio for an AM signal with the same carrier power

Let us consider an AM system with the same carrier power and the same audio bandwidth, in order to compare its output SNR to that of the FM system. Again the modulation will be a single sine-wave tone and the amplitude of the carrier will be V_SIG. At 100% modulation, the amplitude of the sine wave modulation envelope will also be V_SIG so the audio signal power at the AM detector output will be ${V_\mathrm{SIG}}^2/2$. For the AM system, the IF bandwidth needs to be only $2B$, twice the audio bandwidth (wide enough to accommodate the highest audio frequency but, to minimize noise, no wider). The noise voltage at the detector output will be V'_I, the in-phase component of V'_N, where the primes distinguish the noise voltages in the AM IF band from the noise voltages in the wider FM IF band. The noise power will be given by $\langle {V'_\mathrm{I}}^2 \rangle = \langle {V'_\mathrm{N}}^2 \rangle/2$. The SNR at the AM detector output is therefore

$$\text{AM output SNR} = \frac{{V_\mathrm{SIG}}^2}{\langle {V'_N}^2 \rangle}. \tag{23.23}$$

Comparison of noise, FM vs. AM under strong signal conditions

All that remains in order to compare the FM and AM systems is to note that the ratio of the IF noise powers is just the ratio of the IF bandwidths, i.e.,

$$\frac{\langle {V_N}^2 \rangle}{\langle {V'_N}^2 \rangle} = \frac{2kA_\mathrm{max}}{2B_\mathrm{a}} = \frac{kA_\mathrm{max}}{B_\mathrm{a}}. \tag{23.24}$$

Using Equations (23.22)–(23.24), we can write

$$\frac{\text{FM SNR}}{\text{AM SNR}} = \frac{3{k_\mathrm{osc}}^2 {A_\mathrm{MAX}}^2}{{B_\mathrm{a}}^2} = 3(\text{Deviation ratio})^2. \tag{23.25}$$

In FM broadcasting the deviation ratio is about five so the output SNR for a maximum-amplitude audio tone will be higher with FM than with AM by a factor of $3{\cdot}5^2 = 75$ or about 19 dB. The FM sound in television uses a deviation ratio only 1/3 as large as that of FM broadcasting so the signal-to-noise improvement is correspondingly less. Remember that the above analysis is only for the situations of high signal-to-noise. When the signal is comparable to or lower than the noise, the phase is almost totally determined by the noise and the FM system is useless.

FM, AM and channel capacity

The improvement in a signal-to-noise ratio that is possible with wideband FM is an example of increasing the channel capacity of a communications channel by increasing the bandwidth.

Note that S/N_O has units of bandwidth and can be considered a "natural" bandwidth for a given N_0 and S. N_0 is determined by the noise added along the channel, such as atmospheric noise and noise added by the receiver. The signal power, S, is determined by the transmitter power, transmitter and receiver antenna gains, and propagation loss. Channel capacity, from Equation (23.20), vs. bandwidth is plotted in Figure 28.9. Both are normalized to S/N_0.

Note that, for $b > 1$, the channel capacity has essentially reached an asymptotic value of 1.44 S/N_0. If we are below the knee of the curve, we can increase the channel capacity significantly at no cost in transmitter power by (somehow) using more bandwidth. We have seen that FM broadcasting does just this. On the other hand, Equation (23.20) shows that it is expensive (and ultimately impractical) to increase channel capacity by increasing power since the log term increases slowly.

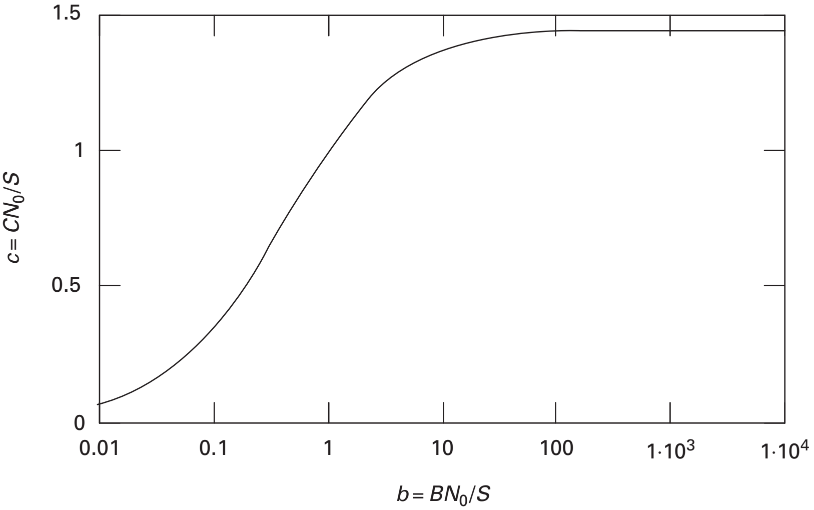

Figure 23.9. Channel capacity vs. bandwidth (both are normalized to S/N_0, the "natural bandwidth").

In AM, the bandwidth is fixed by the highest modulation frequency; the total bandwidth in standard full-carrier DSB AM is twice the highest modulation frequency. When a weak AM station is received, the signal-to-noise ratio is low enough to put us beyond the knee of the channel capacity vs. bandwidth curve and there would be no gain in going to a modulation scheme that increases the bandwidth. But if the station is strong, we are probably far below the knee of the curve. In this case, changing to FM modulation (without changing transmitter power) can bring us up the curve where the higher channel capacity allows a higher signal-to-noise ratio.

Problems

Problem 23.1. Show that the differential equation $x^2y'' + xy' - x^2y = 0$ (modified Bessel's equation of order zero) is satisfied by the function

$$I_0(x) = \frac{1}{2\pi}\int_0^{2\pi} \mathrm{e}^{x\cos(\theta)}\mathrm{d}\theta.$$

Problem 23.2. Consider an asymmetric binary channel in which the probability that a one is correctly received is 0.9 but the probability that a zero is correctly received is 1/2. (A transmitted zero is equally likely to be declared a zero or a one.) Suggest a simple coding method to transmit data reliably through this channel.

Problem 23.3. Consider the situation where a rectangular pulse of length T is transmitted, but the receiver instead of using a $\sin(1/2\ \omega T)/(1/2\ \omega T)$ matched filter, uses a rectangular filter of bandwidth β/T. The noise at the input is Gaussian. Find the value of β that maximizes the SNR at the output of the filter. Compare this to the value that would have been obtained if the matched filter had been used.

CHAPTER

24 Amplifier and oscillator noise analysis

A fundamental limitation in amplifiers and oscillators is the internally generated random noise whose physical causes are shot noise in semiconductors and thermal noise (Johnson noise) in resistors. Amplifier noise is a practical concern whenever this noise level is comparable to the signal being amplified. Oscillator noise, characterized as phase or frequency fluctuations, adds noise to FM systems, limits how closely carriers may be spaced in frequency division multiplexing (FDM), and limits the length of signal averaging times in coherent communication systems. In this chapter we discuss the way transistor noise is characterized, treating the transistor itself as a two-port network, and how these characteristics are taken into account to design low-noise circuits.

24.1 Amplifier noise analysis

In Chapter 17 we quoted a formula showing how the noise figure of any active two-port device depends on the impedance of the signal source:

$$F = F_{\min} + (R_n/G_s)|Y_s - Y_{\text{opt}}|^2. \tag{24.1}$$

Here $F_{\min}$ is the minimum noise figure; $Y_s = G_s + jB_s$ is the source admittance, $Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}}$ is the source admittance that produces $F_{\min}$, and R_n is a real parameter known as the *noise resistance*. Equation (24.1) applies as well to audio and instrumentation amplifiers as to radio and microwave amplifiers, as long as the four noise parameters of the device, $F_{\min}$, R_n, G_{opt}, and B_{opt}, are known for the frequency in question. While Equation (24.1) requires some effort to derive, its use is simple, at least with RF (narrowband) amplifiers.

24.1.1 Noise matching

To design a low-noise RF amplifier, we get out the data sheet for the transistor, find the value of Y_{opt} for the desired frequency, and design an input network to convert the impedance of the intended source (probably 50 ohms) into $1/Y_{\text{opt}}$.

Figure 24.1. Input network to convert a 50-ohm source impedance to $G_{OPT} + jB_{OPT}$.

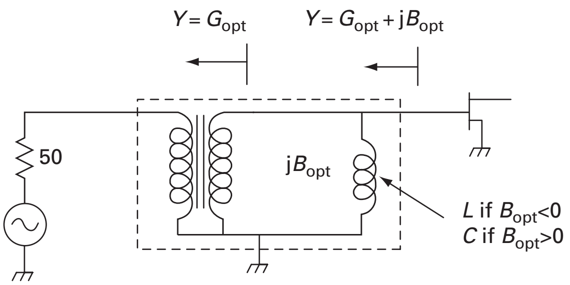

Figure 24.1 shows how a transformer and a reactor can form the matching network. (Of course there are many equivalent networks.)

With this input network, the transistor is said to be "noise matched," because the noise figure of the overall amplifier will be F_{min}. The input network that provides noise matching generally does not provide impedance matching, i.e., it does not convert the source impedance into the complex conjugate of the amplifier's input impedance. The resulting power mismatch means we will have less signal at the amplifier output than with a conjugate impedance match. But converting the source impedance into $1/Y_{opt}$, rather than into $1/Y^*_{in}$, will reduce the transistor noise more than the mismatch reduces the signal power. The net effect is to maximize the signal-to-noise ratio, i.e., provide the minimum possible noise figure.

(Note: In some cases simultaneous noise matching and impedance matching can be achieved or at least approached. If the device has a nonzero reverse transfer coefficient, the amplifier's input impedance is not fully determined by the input network. Depending on the transistor characteristics, a designer might find an output network to make the input impedance of the amplifier approach Z_0 while using an input network that provides noise matching. The use of feedback can provide additional degrees of freedom with which to pursue simultaneous matching.)

24.1.2 Equivalent circuits for noisy two-port networks

Equation 24.1 was derived by Rothe and Dahlke [4] who pointed out that a noisy two-port network (transistor, amplifier, etc.) can be modeled, for small signals, as an ordinary passive linear two-port with two external frequency-dependent noise sources. These noise sources can be series voltage generators at the input and output, shunt current generators at the input and output, a current source at one end and a voltage source at the other end, or, finally, both a voltage source and a current source at the same end. Figure 24.2 shows these equivalent circuits.

Note that when a current generator and a voltage generator appear on the same side they can be interchanged without changing their parameters, so Figures 24.2(e) and (f) (or g and h) are actually the same circuit.

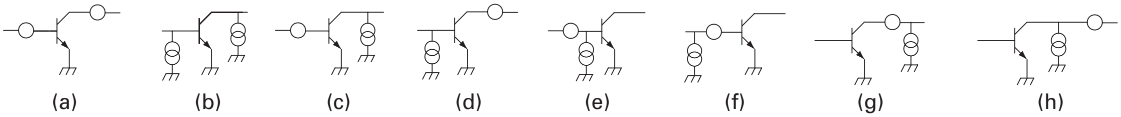

Figure 24.2. Equivalent representations of a noisy transistor as a noiseless transistor with two external noise generators.

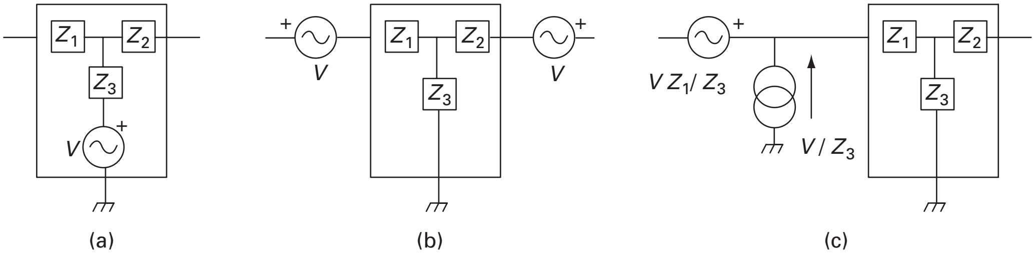

Figure 24.3. (a) An arbitrary two-port network with an internal voltage source; (b) and (c) networks equivalent to (a), but with external sources.

Note: Replacing internal sources with equivalent external sources is a sort of generalization of Thévenin's theorem and Norton's theorem, from one-port networks to two-port networks. Figure 24.3(a) shows an arbitrary two-port network with an internal voltage generator. Both (b) and (c) are equivalent to (a). In this example, the network is passive, but it can just as well be active, containing dependent voltage and current sources. When the internal source is a sine-wave source, the external generators are specified by complex amplitudes. When the internal source is a noise source, the external sources are specified by their rms values and the correlation between them. For example, if the external sources are a voltage source and a current source, the correlation is the complex number $\langle iv^* \rangle$, the time average of the product of the complex amplitude i and the complex conjugate of the complex amplitude v. When a two-port has multiple internal noise sources,[1] the resulting external sources can be consolidated into two external sources.

24.1.3 Noise figure of the equivalent circuit

Figure 24.2(e) (or 24.2f) is the easiest equivalent circuit to analyze for noise figure. Since both noise sources are placed at the input, the transfer characteristics (Z, Y, or S parameters) of the two-port will not come into play. In Figure 24.4, the circuit to be analyzed, the amplifier block can represent a transistor, a tube, or a complete amplifier. The two external noise sources, v and i, are equivalent to the device's internal sources of noise, whatever their number and physical nature. The other current source, i_T, represents the thermal

---

[1] A circuit model for a transistor usually contains several noise sources.

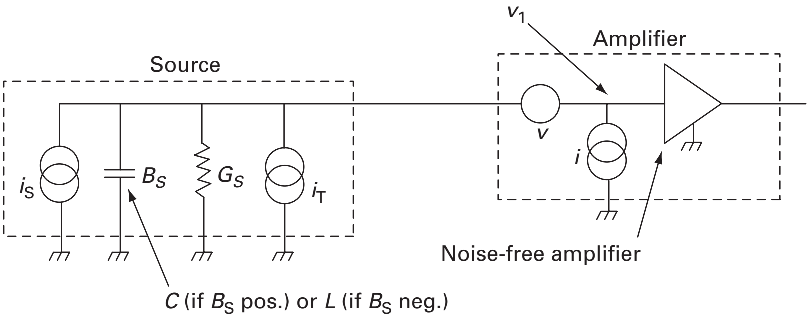

Figure 24.4. Signal source and noisy amplifier – equivalent circuit.

noise of the source, i.e., $\langle i_T\rangle^2 = 4kTG_s$. Since there are four noise parameters to be determined, we need more than just $\langle i^2\rangle$ and $\langle v^2\rangle$. The other two parameters come from the fact that i and v are generally not independent but are correlated. The part of i that is correlated with v defines the "correlation admittance," Y_c, through the relation $i_c = Y_c\, v$. Thus

$$\langle iv^*\rangle = \langle (i_c + i_u)v^*\rangle = \langle i_c v^*\rangle = \langle Y_c|v|^2\rangle = Y_c\langle |v|^2\rangle (G_c + jB_c)\langle |v|^2\rangle. \quad (24.2)$$

To find an expression for the noise figure, we must find the voltage v_1 at the input of the device and use the definition of noise figure to find the ratio of the average of $\langle |v_1|^2\rangle$ to the part of $\langle |v_1|^2\rangle$ attributable to the source. The result is independent of the input impedance of the device since, using superposition, we can find v_1, considering the noise sources one at a time. They all have the same effective source impedance, $1/Y_s$. For convenience, then, we can take the device to have an infinite input impedance. It follows immediately that

$$v_1 = (i + i_T)/Y_s + v. \quad (24.3)$$

To get the equivalent input *power* we use the average squared magnitude of v_1:

$$\langle |v_1|^2\rangle = (\langle |i|^2\rangle + \langle |i_T|^2\rangle/|Y_s|^2 + \langle |v|^2\rangle + (\langle iv^*\rangle/Y_s) + (\langle i^*v\rangle/Y_s^*). \quad (24.4)$$

Here we have used the fact that there is no correlation between i and i_T or between i_T and v. The noise figure is given by this total power divided by the part due to the noise current of the source:

$$F = \frac{((\langle |i|^2\rangle + \langle |i_T|^2\rangle))/|Y_s|^2 + \langle |v|^2\rangle + ((\langle iv^*\rangle/Y_s + \langle i^*v\rangle/Y_s{}^*)}{\langle |i_T|^2\rangle/|Y_s|^2} \quad (24.5)$$

or

$$F = 1 + \langle |i|^2\rangle/\langle |i_T|^2\rangle + ((\langle |v|^2\rangle/\langle |i_T|^2\rangle))|Y_s|^2(1 + Y_c/Y_s + Y_c^*/Y_s^*). \quad (24.6)$$

The noise current of the source is given by $\langle |i_T|^2\rangle = 4kT_0G_s$. It is convenient now to introduce the terms "noise conductance," g_n, and "noise resistance," R_n, which are defined by

$$\langle |i|^2 \rangle = 4kT_0 g_n \quad \text{and} \quad \langle |v|^2 \rangle = 4kT_0 R_n. \tag{24.7}$$

(The lower-case g_n follows the original notation of Rothe and Dahlke who reserved G_n for the part of i that is correlated with v.) In terms of these parameters we have

$$F = 1 + (g_n/G_\mathrm{s}) + (R_n/G_\mathrm{s})|Y_\mathrm{s}|^2(1 + Y_\mathrm{c}/Y_\mathrm{s} + Y_\mathrm{c}^*/Y_\mathrm{s}^*). \tag{24.8}$$

Replacing Y_s by $G_\mathrm{s} + \mathrm{j}B_\mathrm{s}$ and Y_c by $G_\mathrm{c} + \mathrm{j}B_\mathrm{c}$, this becomes

$$F = 1 + (g_n/G_\mathrm{s}) + (R_n/G_\mathrm{s})(G_\mathrm{s}^2 + B_\mathrm{s}^2) + 2(R_n/G_\mathrm{s})(G_\mathrm{c}G_\mathrm{s} + B_\mathrm{c}B_\mathrm{s}). \tag{24.9}$$

Differentiating with respect to B_s and setting the derivative to zero, we find the optimum source susceptance,

$$B_\mathrm{opt} = -B_\mathrm{c}. \tag{24.10}$$

Differentiating next with respect to G_s and setting that derivative equal to zero gives the optimum source conductance:

$$G_\mathrm{opt} = \sqrt{g_n/R_n - B_\mathrm{c}^2}. \tag{24.11}$$

After a few more steps we find

$$F = 1 + 2R_n(G_\mathrm{c} + G_\mathrm{opt}) + (R_n/G_{\mathrm{s})})([G_\mathrm{s} - G_\mathrm{opt}]^2 + [B_\mathrm{s} - B_\mathrm{opt}]^2), \tag{24.12}$$

which is the desired relation, the Rothe–Dahlke formula.The first term on the right is just T_min. Summarizing these relations between the equivalent external noise generators and the standard noise parameters we have

$$R_n = \frac{\langle |v|^2 \rangle}{4kT_0} \tag{24.13a}$$

$$B_\mathrm{opt} = \frac{-\mathrm{Im}\langle iv^* \rangle}{\langle v^2 \rangle} \tag{24.13b}$$

$$G_\mathrm{opt} = \sqrt{\frac{\langle |i|^2 \rangle}{\langle |v|^2 \rangle} - \left(\frac{\mathrm{Im}\langle iv^* \rangle}{\langle |v|^2 \rangle}\right)^2} \tag{24.13c}$$

$$F_\mathrm{min} = 1 + \frac{2\langle |v|^2 \rangle}{4kT_0}\left(\frac{\mathrm{Re}\langle iv^* \rangle}{\langle |v|^2 \rangle} + G_{opt}\right). \tag{24.13d}$$

The inverse relations are

$$\langle |v|^2 \rangle = 4kT_0 R_n \tag{24.14a}$$

$$\langle |i|^2 \rangle = 4kT_0({G_\mathrm{opt}}^2 + {B_\mathrm{opt}}^2) \tag{24.14b}$$

$$\mathrm{Im}\langle iv^*\rangle = -B_{\mathrm{opt}}\langle |v|^2\rangle \tag{24.14c}$$

$$\mathrm{Re}\langle iv^*\rangle = 4kT_0R_n\left(\frac{F_{\mathrm{min}}-1}{2R_n} - G_{\mathrm{opt}}\right). \tag{24.14d}$$

24.1.4 Devices in parallel

Noise matching allows us to realize the best noise figure, F_{min}, from a transistor. We saw earlier that multiple devices in series (an amplifier cascade) result in an unavoidable increase in noise figure. What about amplifiers in parallel? Identical transistors might be literally paralleled, emitter-to-emitter, base-to-base, and collector-to-collector. Or amplifiers might have their inputs directly connected and their outputs combined with a hybrid coupler. The result for two devices in parallel (see Problem 24.4) is that the resulting amplifier, compared to the individual amplifiers, has half as much noise resistance, twice as much noise conductance, and twice as much correlation admittance. This leaves F_{min} unchanged. It does, however, double Y_{opt}, making it easier to noise match to a low-impedance source, and can be a useful technique, for example, at very low frequencies where transformer matching is impractical.

24.1.5 Noise measure

We pointed out earlier that an amplifier with a good noise figure is of little value if its gain is low (a piece of wire has a perfect noise figure, unity, but has no gain). The application of negative feedback may lower the noise figure of a given transistor but at the same time it will reduce the gain. To recover the lost gain we can cascade two or more amplifiers. We saw in Chapter 17 the expression for F_∞, the noise figure of a cascade of identical amplifiers:

$$F_\infty - 1 = \frac{F-1}{1-1/G}. \tag{24.15}$$

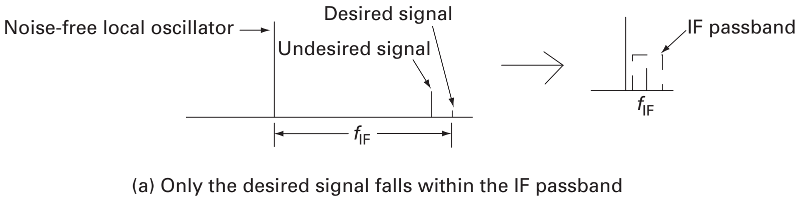
This quantity, called *noise measure*, is a better figure of merit than noise figure in that a low-gain amplifier scores low, even if its noise figure is good. The optimum input network should, therefore, minimize F_∞ rather than F. But the gain, G, depends also on the output network. Haus and Adler [1] showed that the *minimum noise measure* is a fundamental invariant when the gain, G, is taken to be the "available gain" of the device (the maximum gain that can be obtained by varying the output match while leaving the input untouched). Minimum noise measure, like minimum noise figure, is therefore determined by the input network. Haus and Adler proved that the minimum noise measure of a device is left unchanged when the device is embedded in an arbitrary network of lossless reactances. It had been noticed earlier that the noise figure of a device could sometimes be lowered by using feedback. Haus and Adlers' results showed that any improvement in noise figure must be accompanied by a decrease in gain such that the minimum noise measure remains constant. A corollary is that changing the orientation of the device (common-emitter, common-collector, common-base) does not change the minimum noise measure. Circuit techniques, then, cannot produce a breakthrough low-noise amplifier. Any standard configuration can have the best possible noise performance. Circuit techniques, however, can improve bandwidth and stability. If we know the characteristics of a given device, we can calculate the minimum noise measure (best possible noise performance) at every frequency. There is, however, no theory available that tells us how well we can do over a given frequency band. R. N. Fano showed how well impedance matching can be done over a given band but no one has done the same for noise matching.

24.2 Oscillator noise

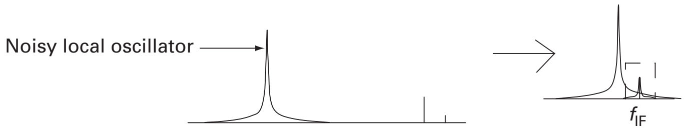
The frequency stability of an oscillator is determined by changes in ambient temperature and humidity, mechanical vibration, component aging, power supply variations, load variations, and finally, random noise generated by the circuit components – primarily the active element (transistor, tube, op-amp, etc). Except for noise, these effects are systematic, i.e., nonrandom, and can, in principle, be eliminated by using constant-temperature chambers, thermal compensation schemes, and shock mounting. But even when the systematic variations have been reduced to an acceptable level, random variations remain and determine the power spectrum of an oscillator (called "line shape" in spectroscopy). An ideal oscillator would have a power spectrum that is a delta function, i.e., an infinitely narrow unmodulated carrier. Noise broadens the spectrum of any real oscillator. In some applications the concentration of power is important; a specification might state, for example, that at least 90% of the power must be contained in a band within 0.01 Hz of the nominal frequency. More often it is only necessary that the spectral density beyond some distance from the center frequency be very low. In such a case it might be specified that "the noise power in a 1-Hz bandwidth centered 1 kHz from the carrier must be at least 60 dB below the total power." Spectral energy outside the narrow band containing most of the power is referred to as "sideband noise."

In a superheterodyne receiver the noise sideband power of the local oscillator can mix with an incoming signal that is nominally outside the IF passband to produce noise that falls within the passband, as shown in Figure 24.5. An undesired signal that is translated to a frequency outside the IF passband will normally be rejected by the IF bandpass filter. But a noisy L.O. will add noise sidebands to this signal that extend into the bandpass. If the undesired signal is near the bandpass and if it is much stronger than the desired signal, this noise can override the desired signal.

Figure 24.5. Translation of phase noise into the passband of a receiver.



(a) Only the desired signal falls within the IF passband



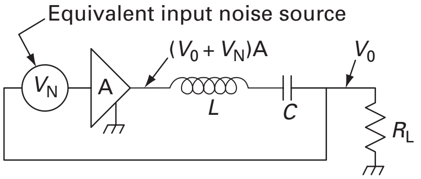
(b) Oscillator noise sidebands on the undesired signal fall within the IF passband

A similar situation occurs in MTI (moving target indicator) radar where the Doppler effect is used to distinguish moving objects from background "clutter" (the ground and stationary objects). Moving targets can be identified as spectral components shifted away from the frequency of the strong clutter echo. But, in as much as the transmitter's master oscillator or the receiver's local oscillator is noisy, moving targets with small velocities will be buried in the broadened clutter return. Good subclutter visibility therefore requires low-noise oscillators.

24.2.1 Power spectrum of a linear oscillator

In the simplest analysis, an oscillator is considered to be a linear system with just enough positive feedback to sustain oscillation. We have already used this approach to design a feedback oscillator. Here we will present a simple analysis [2, 3] that predicts the shape of the spectral line. This shape does not depend on the circuit configuration so here we will consider the simple series-mode oscillator presented in Chapter 11. This circuit, shown in Figure 24.6, uses a noninverting voltage amplifier having voltage gain, *A* (independent of frequency), infinite input impedance, and zero output impedance.

Figure 24.6. Prototype oscillator for phase noise analysis.



We will put an equivalent generator at the input to account for the noise produced by the amplifier. As long as the amplifier is linear, we need only consider the amplifier's noise spectrum in the vicinity of the oscillation frequency. The feedback voltage is taken from the load resistor forming the bottom leg of a voltage divider whose top leg is the series *LC* circuit. By inspection of Figure 24.6, we can write the loop equation:

$$V_0 = \frac{(V_0 + V_N)AR}{R + \mathrm{j}X} \tag{24.16}$$

where A is the voltage gain of the amplifier and $X = \omega L - 1/(\omega C)$. Note that V_0 and V_N are spectral densities, i.e., their units are volts $/\sqrt{Hz}$. Solving for V_0 we have

$$V_0 = \frac{V_N AR}{R(1 - A) + jX}. \tag{24.17}$$

Expanding X around the resonant frequency, we let $\omega = \omega_0 + \omega'$, where $\omega_0{}^{-2} = LC$. The reactance, X, then simplifies to $X \approx 2\omega' L$ and Equation (24.17) becomes

$$V_0(\omega') = \frac{-V_N A}{(A - 1) - 2\mathrm{j}\omega' L/R}. \tag{24.18}$$

The value of A is determined by the condition $\int |V_0{}^2(\omega')|/R \, \mathrm{d}\omega' = P$, where P is the total output power:

$$P = \frac{1}{R}\int V_0^2(\omega')\mathrm{d}\omega' = \frac{1}{R}\int_{-\infty}^{\infty} \frac{A^2 V_N^2 \mathrm{d}\omega'}{(A-1)^2 + 4\omega'^2 L^2/R^2} = \frac{\pi A^2 V_N^2}{2(A-1)L}. \tag{24.19}$$

Solving for $(A-1)$ we find

$$\frac{A - 1}{A^2} = \frac{\pi V_N^2}{2PL}. \tag{24.20}$$

Note that $A-1$ can be very small; the voltage gain is only slightly greater than unity. Using Equation (24.20) and the fact that A is approximately unity, Equation (24.18) gives the power spectrum:

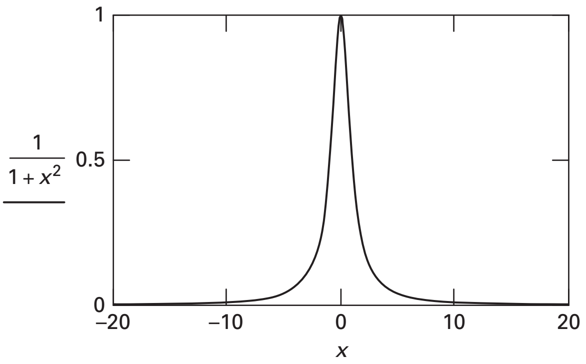
$$S(\omega) = \frac{|V_0(\omega')|^2}{R} = \frac{4P^2 Q^2 R^2}{\pi^2 V_N^2 \omega_0^2} \frac{1}{1 + (\omega'/\Delta)^2} \tag{24.21}$$

where Δ, the half-width of the line, is given by

$$\Delta = \frac{\pi V_N^2 \omega_0^2}{4PQ^2 R}. \tag{24.22}$$

The $1/(1+x^2)$ "Lorenztian" line shape of Equation (24.21) gives the bell-shaped curve shown in Figure 24.7.

Figure 24.7. Lorentzian line shape.



24.2.2 Sideband shape

As explained earlier, it is often important that the far-out sideband noise be low compared to the carrier power. If we assume $\omega' \gg \Delta$ then Equations (24.21) and (24.22) reduce to

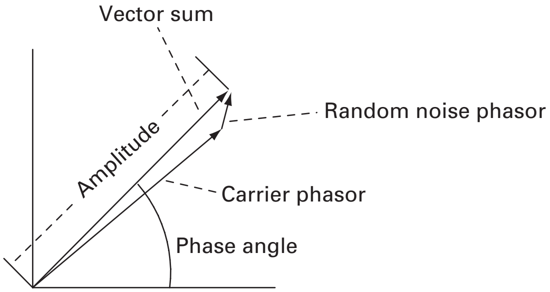
$$\frac{S(\omega')}{P} = \frac{\omega_0^2 V_N^2}{\omega'^2 4Q^2 RP}\ \mathrm{Hz}^{-1}, \tag{24.23}$$

and we see that the far-out sideband noise falls off as $1/\omega'^2$.

Phase noise

So far, the oscillator noise has the same character as if it had been produced by amplifying white noise and passing it through a very narrow filter. The oscillator output voltage is equivalent to the sum of a noiseless phasor, i.e., the carrier, and a random noise phasor, as shown in Figure 24.8.

Figure 24.8. Vector diagram showing oscillator noise.



When the noise component is parallel to the carrier, the vector sum has the correct phase but an altered amplitude. When the noise is perpendicular to the carrier, the result is mostly just a phase error. The signal can be passed through an amplitude limiter to remove the amplitude fluctuations. This leaves only the perpendicular noise components, i.e., the phase noise. The parallel and perpendicular noise signals are uncorrelated, so if the amplitude variations are removed, the total noise power is cut in half. The symbo $\mathscr{L}(\omega')$ is often used to represent the phase noise power in a 1-Hz bandwidth at an offset of ω' from the nominal carrier frequency:

$$\mathscr{L}(\omega') = \frac{\omega_0^2 V_N^2}{\omega'^2 8Q^2 RP}\ \mathrm{Hz}^{-1}. \tag{24.24}$$

We can express the noise power $V_N^2(\omega')/R$ as FkT where F is the noise figure of the amplifier, k is Boltzmann's constant, and T is the reference temperature, 290 K:

$$\mathscr{L}(\omega') = \omega_0^2 \frac{FkT}{\omega'^2 8Q^2 P}\ \mathrm{Hz}^{-1}. \tag{24.25}$$

This result shows that best performance is obtained by using a low-noise device, by running it at high power, and by maximizing the loaded Q (by using a high-Q resonator with light loading).

24.3 Effect of nonlinearity

The analysis given above actually gives a lower limit for the noise. Very close to the carrier, oscillators depart from the predicted Lorenztian line shape and, as the offset frequency approaches the carrier, phase noise increases faster than ω'^{-2}. This additional noise is usually attributed to nonlinearity in the active device. We have made the assumption that the device is linear but some nonlinearity *must* be present in any actual oscillator or its amplitude would either decay or increase without limit. The nonlinearity can translate baseband $1/f$ noise up to the radio frequencies.

Problems

Problem 24.1. A transistor with noise parameters, F_{min}, G_{opt}, B_{opt}, and R_{n}, is provided with a noise matching network to produce an amplifier with $F'_{\mathrm{min}} = F_{\mathrm{min}}$, $B'_{\mathrm{opt}} = 0$, and $G'_{\mathrm{opt}} = 1/50$. What is the value of R'_n?

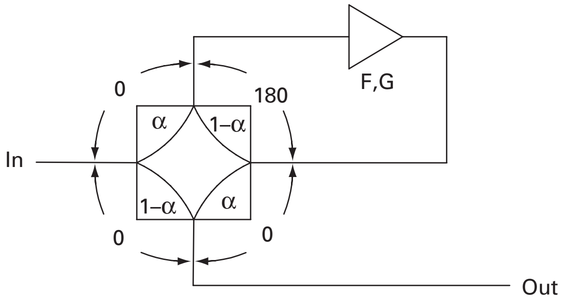
Problem 24.2. Can a transistor be fitted with an input network such that the correlation admittance, Y_{c}, is zero for the overall amplifier?

Problem 24.3. The portion of the noise current, i_{c}, that is correlated with the noise voltage cannot exceed the total noise current, i.e., $\langle |\, i_{\mathrm{c}}|^2 \rangle \leq \langle |\, i|^2 \rangle$. Use this to prove the following inequality:

$$F_{\mathrm{min}} - 1 \leq 4 R_n G_{\mathrm{opt}}.$$

Problem 24.4. Show that when two identical transistors are paralleled, the minimum noise figure of the combination is the same as the minimum noise figure of the individual transistors.

Problem 24.5. A standard amplifier for use in 50-ohm systems has a gain G and a noise figure F. This amplifier is combined with a 50-ohm directional coupler to form the feedback amplifier shown below. The 180° coupler has a power gain of α in its "main channel" and therefore a power gains of $1-\alpha$ in the adjacent arms. The 180° path of the coupler provides the negative feedback. (Assume that the amplifier has zero phase shift.)



(a) Find the gain, G', of the feedback amplifier.
(b) Find the noise figure, F', of the feedback amplifier.
(c) Combine the results of (a) and (b) to show that the noise measure of the feedback amplifier is the same as the noise measure of the imbedded amplifier, i.e., show that

$$\frac{F'-1}{1-1/G'}=\frac{F-1}{1-1/G}.$$

This problem provides a simple demonstration of noise measure remaining invariant when an amplifier is imbedded in a lossless network. The negative feedback reduces the noise figure but it also reduces the gain and the noise measure stays the same. (What would positive feedback do − short of causing oscillation?)

Problem 24.6. It is certainly possible (and common) for an amplifier to have a noise temperature less than its physical temperature. Is it possible to build an *electronic cold load*, i.e., an active one-port circuit whose impedance is resistive but which generates less noise power than a resistor at ambient temperature?

Problem 24.7. A differential amplifier, e.g., an op-amp, is a three-port device (output and two inputs). Find an equivalent circuit which represents an op-amp as a noiseless device with three external noise sources. Arrange for these noise sources to be on the input side of the amplifier.

Problem 24.8. Which of the following statements best describes the operation of an oscillator?

(a) Noise is necessary to get an oscillator started. Once running, the oscillation is self-sustaining and noise plays no role.
(b) The output of an oscillator consists of amplified noise; the very narrow line shape derives from a resonator whose high loaded Q is effectively increased by the circuit's positive feedback.

Problem 24.9. Discuss the consequences (sound or picture quality) of a noisy oscillator used as a local oscillator in (a) an AM receiver; (b) an FM receiver; (c) an NTSC television receiver; (d) an ATSC television receiver.

Problem 24.10. Sketch a design for an oscillator that somehow regulates its own gain in order to stay as linear as possible, i.e., runs with just enough gain to maintain oscillation.

CHAPTER

25

The GPS navigation system

The basic idea of GPS navigation is simple. A GPS receiver simultaneously monitors ("tracks") the signals from four GPS satellites. Using a highly accurate onboard clock, each satellite effectively stamps its signals with the time at which they are transmitted. The receiver has an internal clock and can, therefore, determine the apparent travel time of the signals from each satellite. Let τ_i denote the travel time of the signal from the i-th satellite. The receiver contains a database and can look up the position of the i-th satellite, x_i, y_i, and z_i, corresponding to the time of transmission. Let x, y, and z represent the (unknown) position of the receiver. For each of the four satellites, *distance = rate × time*, so we can immediately write four equations:

$$\begin{aligned}(x-x_1)^2+(y-y_1)^2+(z-z_1)^2 &= c^2(\tau_1-\Delta)^2\\ (x-x_2)^2+(y-y_2)^2+(z-z_2)^2 &= c^2(\tau_2-\Delta)^2\\ (x-x_3)^2+(y-y_3)^2+(z-z_3)^2 &= c^2(\tau_3-\Delta)^2\\ (x-x_4)^2+(y-y_4)^2+(z-z_4)^2 &= c^2(\tau_4-\Delta)^2,\end{aligned} \tag{25.1}$$

where c is the speed of light and Δ is the offset (error) in the receiver's clock (the same error that made determination of longitude a challenge for early navigators). Because there are four equations and four unknowns, a unique solution can be found for x, y, z, and Δ, thus determining both position and time from scratch. (The receiver's clock error does not matter.) While these equations are nonlinear, the ample processing power available, even in hand-held receivers, makes the solution process easy. An obvious method is to begin with an estimated position, e.g., the last determined position, and then linearize and solve Equations (25.1) in the vicinity of this position.

25.1 System description

The GPS system is operated by the U.S. Department of Defense. In 1993 the system began running a full complement of 24 active satellites, with four satellites

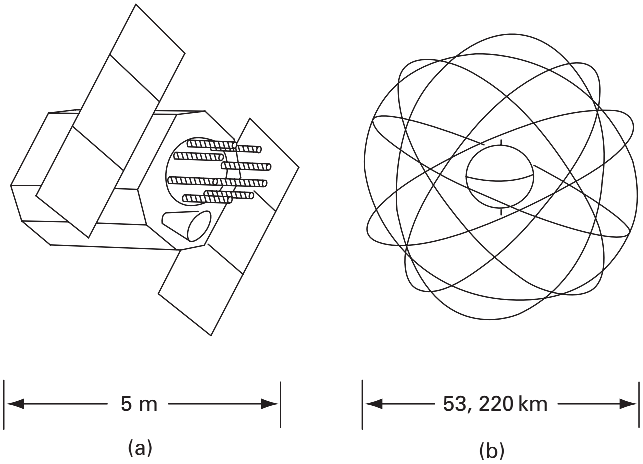

Figure 25.1. (a) Block IIa GPS satellite, 1816 kg; (b) GPS satellite orbits.

in each of six orbital planes, inclined at 55° with respect to the equatorial plane. The satellites were in 12-hour circular Earth-centric orbits, 20 200 km (3.17 Earth radii) above the surface of the Earth as shown in Figure 25.1.

At any point on the Earth, from six to twelve satellites will be above the horizon at any time. As the number of active satellites was increased to 31, the constellation was modified to provide better availability in the event of satellite failures. Orbits are adjusted once a year. The satellites have had operational lifetimes of approximately 10 years.

25.2 GPS broadcast format and time encoding

The system uses two L-band frequencies, 1575.42 MHz ("L1") and 1227.6 MHz ("L2"). Each satellite transmits on both of these frequencies using CDMA (code division multiple access) modulation. The L1 signal contains a "navigation message," described below, which is transmitted repeatedly as a continuous 50-Hz bit stream. Before transmission, this slow bit stream is exclusive-ORed (modulus-2 added) with a one-bit pseudorandom noise (PRN) sequence (the CDMA code) having a high clock rate. This produces a fast bit stream, spread out in bandwidth to approximately the clock rate ("chip" rate) of the PRN code. The L2 signal may also be modulated by the data stream, but is usually modulated only by the PRN code, equivalent to sending a data stream of all 1's. Each satellite is assigned a unique PRN code. In order to receive data from the *i*-th satellite the receiver converts the incoming signal L1 to baseband and multiplies it with a replica of that satellite's PRN code. When the replica, whose binary levels are ±1, is precisely positioned (phased), in order to decode or "strip" the code from the signal, it reproduces the original 50-Hz bit stream, as shown in Figure 25.2.

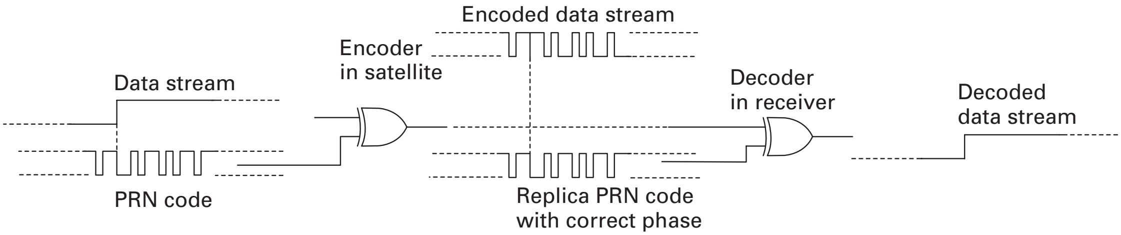

Figure 25.2. CDMA coding (spreading) and decoding (de-spreading).

If the phase of the replica code is shifted off by as little as one chip, the decoder output will be as random and as spread in frequency as its input. This decoding process is the way the receiver selects the desired signal. Signals from other GPS satellites will also be superposed in the received signal, but they have different PRN codes which, when multiplied by the selected code, average to zero for any value of phase shift. Thus, other signals appear as added noise. This added noise is insignificant, in that the received signal is already less than the thermal background noise by some 20–30 dB.[1]

The 50-Hz data streams contain the GPS time,[2] orbital corrections, satellite clock correction, propagation delay effects, and satellite condition, as well as an almanac of long-term satellite data and an auxiliary service, the current difference between GPS time and UTC time. But the precise time of transmission is inferred not from the data but from the phase of the PRN code. We saw in Chapter 21 that just such codes are used for pulse compression in radar to achieve high time resolution (and hence high range resolution) without using narrow high-power pulses. When PRN codes are correlated (convolved) with themselves, a sharp peak is formed, allowing precise time resolution. Thus, PRN coding does double duty in the GPS system; it provides multiple access (many satellites using the same frequency) and it also provides pulse compression for timing accuracy. The *P-code* (*P*recision), a high rate code transmitted on both L1 and L2, has a seven-day period. Therefore, a receiver that has successfully delayed the output of its replica code generator to match the incoming signal, i.e., to acquire the signal, can use that delay value to estimate the signal travel time. The P-code was originally intended only for military use.[3] The other transmitted code is the *C/A-code* (Coarse ranging and Acquisition). This code, always present, along with the P-code, on L1, has a 1.023-MHz chip rate vs. 10.23 MHz for the P-code. It therefore nominally provides only one-tenth the range resolution of the P-code. The C/A code is intended for civilian use; consumer GPS receivers use only the C/A code on L1. The C/A-code repeats every millisecond. This makes acquisition easier, but introduces a

---

[1] Assuming a receiving antenna with a gain of 3dB, the received power of a GPS signal is -160 dBW(10^{-16} watts).

[2] GPS time increases continuously, unlike Universal Coordinated Time (UTC) which is occasionally adjusted by a leap second. GPS and UTC coincided at the start of Jan. 6, 1980, UTC.

[3] Usually the P-code is referred to as the *P*(*Y*)-code because the published P-code can be replaced by a classified *Y-code* for military security.

1-msec ambiguity in the time, which must be resolved using time information transmitted in the data stream.

25.3 GPS satellite transmitter

Figure 25.3 is a functional block diagram of the transmitter aboard a GPS satellite and shows the signals that modulate L1 and L2. All signals are derived from an onboard 10.23-MHz atomic frequency standard. Newer satellites carry two rubidium and two cesium frequency standards. A data formatter produces the continuous one-bit data stream at a 50-Hz baud rate (20 msec/baud). This stream is exclusive-ORed separately with the C/A code and the P-code to create two-bit streams, with respective (main lobe) bandwidths of 1.023 MHz and

10.23 MHz. The streams are offset to be symmetric about zero volts (indicated by a coupling capacitor on the diagram) and then multiplied by sine waves at 154×10.23 MHz =1575.42 MHz, one shifted 90° with respect to the other. These products are summed to form the L1 signal. The output of each multiplier is a double-sideband suppressed carrier (DSSC) signal. The sum of these two signals, as we have seen, is known as quadrature AM modulation (QAM).[4] The modulating signal fed to each mixer has only two values, $+V$ or $-V$, which determine the polarity of the mixer output, so these mixers can also be called BPSK (binary 0 and 180° phase-shift keying) modulators. The L1 C/A "Civil GPS" signal path is indicated on the diagram.

The original L2 signal is produced by a single mixer, whose signal input can set by the ground control station to be the C/A code, the P-code, or the exclusive-OR of the data and the P-code. Normally the P-code is selected and the L2 signal provides dual-frequency operation for ionospheric delay correction (described below). Newer satellites also provide an "L2C" civil L2 signal, as shown in dotted lines. This signal will provide civil users with dual-frequency capability for high-precision surveying.

25.4 Signal tracking

To see how tracking can be done, we will first consider the case of the L2 signal carrying only the long PRN code and no navigation data. We will then describe the somewhat more complicated case of tracking a signal containing the navigation data, exclusively-ORed with the short C/A code.

25.4.1 Tracking the L2 signal

Figure 25.4 is a block diagram of a hypothetical receiver set up to track this signal. The IF band, which is 20.46 MHz wide to contain the P-coded signal, is established by a bandpass filter which precedes the mixer but follows the low-noise amplifier (LNA), in order that the filter loss not degrade the receiver's noise figure.

Surface acoustic wave (SAW) filters are common in this very small fractional bandwidth application. A 20-MHz lowpass filter (LPF), probably not extending down quite all the way to dc, further defines the bandpass and eliminates the sum frequency component from the mixer. The IF signal is sampled at 41 MHz

---

[4] QAM is normally used to transmit two independent signals which will be independently recovered. In this case, however, the two signals have been made independent by the coding, so they could be algebraically added, with the sum feeding a single mixer. This would introduce "self noise," but a GPS receiver is dominated by thermal noise, so the system performance would not suffer. The QAM system has the advantage of producing a constant-amplitude signal which does not require a linear power amplifier.

(Nyquist sampling at twice the signal bandwidth to avoid aliasing). From this point on, the receiver uses all-digital processing.

The digital portion of the block diagram includes the blocks necessary to track the L2 signal from one satellite. This entire section would be duplicated n times in a receiver that receives signals simultaneously from n satellites. The receiver synchronously (coherently) detects the signal by stripping off the PRN code and also mixing down to dc (stripping off the carrier). These operations can be done in either order. Once these stripping operations are working properly, the phase of the replica code will be aligned with the code on the incoming signal, allowing the time of transmission to be inferred, as described above. The L.O. used to strip the carrier is the *carrier NCO*, a numerically controlled oscillator in a digital phase lock loop. To convert the signal to precisely zero frequency, the receiver must tune the carrier NCO to compensate for Doppler shift, caused by line-sight-velocity, and by inevitable error in the first L.O. frequency.

Mixer M1 (a digital multiplier) multiplies the digital IF signal by a correctly phased replica of the ±1 PRN code for the desired satellite. This strips the code from the signal, leaving just the $\approx$ 10.23 MHz carrier signal. This carrier signal feeds mixer M2, as the reference signal for the PLL. Two additional code stripper mixers are provided. One is fed by the replica code, advanced by half a chip (*early* code), while the other is fed by the replica code, delayed by half a chip (*late* code). The outputs of these code strippers are mixed down to dc. The carrier NCO is part of a conventional PLL, so its phase is in quadrature with the phase of the reference. Therefore, a version shifted by 90° (the "cosine" output) is provided to synchronously demodulate the code-stripped early and late signals. When the code is in perfect alignment with the satellite signal, the demodulated early and late signals will have equal average values, half the value they would have if they had been on time ("prompt"). But if the alignment shifts slightly, the demodulated early and late signals will be different. A subtractor forms this difference and uses it to increase or decrease the frequency of the *code NCO*, which is the time base for the code generator. Thus, the code loop is also a conventional PLL.

Note that the two loops, while they can run independently, are related. Suppose that, while both loops are tracking a satellite signal, the line-of-sight velocity suddenly increases. The increase in Doppler shift causes the carrier loop to shift the L.O. by an amount $\Delta\omega/\omega_0 = \Delta v/c$. Since range = velocity × time, we can expect that the code tracking loop will shift the code NCO by the same fractional amount. In fact, the code loop can be assisted by properly scaling the carrier NCO frequency control value and adding it directly to the code NCO's frequency command. The scaling is chosen to make the fractional frequency shifts equal. Using this *assisted tracking* technique, the bandwidth of the code loop can be narrowed, for more accurate tracking. Note that it does not matter that the carrier NCO frequency is determined partly by frequency error in the first L.O., because the code NCO loop will pump up a bias to counteract this non-Doppler component.

25.4.2 Tracking the C/A code on the L1 signal

Figure 25.5 shows a hypothetical consumer GPS receiver tracking the L1 short C/A code-plus-data signal on L1. The RF section is tuned to L1, and, for the slower chip rate code, the IF bandwidth is now just 2.046 MHz. The presence of the 50-Hz data stream will cause the polarity of the carrier stripper outputs to change sign, according to whether a given data bit is a one or a zero. This will defeat the operation of the conventional PLLs used above for a signal with no data. A remedy for this is to use loops that detect the signals before subtracting them to form the loop error signals.

Consider the loop controlling the code NCO. The detected early and late signals are lowpass filtered, i.e., time averaged, over an interval substantially shorter than one data baud. Then they are squared (detected) and the difference of these power values forms the loop's error signal. The hypothetical carrier loop shown here works in the same way. Two carrier stripping mixers are fed quadrature L.O. signals (−45° and +45°). When the loop is locked, these mixers will produce equal powers. The carrier NCO also provides a 0° output, in phase with the original carrier, which feeds mixer M2 which strips the carrier to produce the data stream. The 0° carrier is also used for the code loop.

Since the C/A code repeats every millisecond, rather than every week, the phase of the code generator provides only the LSBs of the time. The MSBs come from data contained in the navigation message. The 50-baud data is divided into 300-bit subframes, so a new subframe begins every six seconds. Every subframe contains a TOW (time of week) word, which is the GPS elapsed time, measured in units of six seconds (6000 msec) from the start of the current week, that corresponds to the transmission of the first bit in the next subframe. A distinctive header word identifies the beginning of each subframe. (Every subframe also contains the PRN code i.d. number that identifies the satellite[5].) The receiver has a millisecond counter synchronized to the code generator, i.e., the counter is clocked at the each time the code cycles through its starting point. The receiver's control block checks to verify that the MSBs of the millisecond counter are correct in relation to the TOW word. If incorrect, the control block enables the counter to synchronously set itself to the TOW × 6000 at the beginning of the next 1-msec C/A code cycle. The complete time value from the receiver is, therefore, the time, rounded to milliseconds, from the counter plus the code generator phase, in fractions of a millisecond with submicrosecond precision.

25.5 Acquisition

From the discussion of tracking, you can see that neither loop can lock unless the other is also locked; they track simultaneously or not at all. Acquisition of

the signal therefore requires that the receiver perform a two-dimensional search over both frequency space and code phase. Enough digital processing power is usually available so that the search can be done in a parallel fashion. Figure 25.6 shows a setup for acquisition processing.

One search process is as follows: Mixers (multipliers) M1, M2 and M2Q are provided for every code phase in increments of half a baud. Successively delayed versions of the replica code are fed to each of the M1 mixers. The M2 and M2Q mixers are all fed from a common L.O. generator. The L.O. frequency is stepped in equal frequency increments. At each frequency, the M2 mixer output signals are averaged (lowpass filtered) over an interval, a "dwell time," and the search ends when the detected power (the square of the sum of the two mixer outputs) exceeds a detection threshold. At that point, the L.O. frequency and carrier phase are close enough for a handover to the tracking mode. Longer dwell times require smaller frequency steps, so it takes more time to search for a weak signal. The changing data bits do not spoil the correlation as long as the dwell times are short compared to the data baud length (unless a dwell happens to straddle a data transition). The circuitry or processing resources for one Doppler/code phase cell is called a correlator. With enough correlators running in parallel, the GPS receiver can simultaneously search multiple frequency shifts, multiple code delays, and multiple satellites. Once the signals have been acquired, relatively little processing power is required for tracking.

The C/A signal is easier to acquire than the P-signal, as it has a higher signal-to-noise ratio and a shorter code (less space to search). Receivers that use the P-code usually acquire the C/A code as a first step in acquiring the P-code. (Hence the designation "C/A:" Civil and Acquisition.)

25.6 Ionospheric delay

GPS signals, at 1.5 GHz and 1.2 GHz, interact only slightly with the Earth's lower atmosphere, but the interaction with the ionosphere contributes the largest term to the measurement error budget. We saw in Chapter 20 that the ionosphere's free-electron gas, produced by ionizing ultraviolet solar radiation, changes the dielectric constant from ϵ_0, its vacuum value, to become

$$\epsilon = \epsilon_0 \left(1 - \frac{Ne^2}{\epsilon_0 m \omega^2} \right) = \epsilon_0 \epsilon_{\mathrm{r}}, \tag{25.2}$$

where N is the electron density, e is the electronic charge, m is the electron mass, and ϵ_{r} is the relative dielectric constant (relative to ϵ_0). The phase velocity of the signal is given by $v_{\mathrm{phase}} = \omega/k = (\mu_0 \epsilon)^{-1/2}$. From Equation (25.2) we see that, in the ionosphere, ϵ is less than ϵ_0. Therefore, v_{phase} is greater than the speed of light and the wavelength, $\lambda = 2\pi/k$, is longer than its vacuum value. Information, however travels at the group velocity,[6] $v_{\mathrm{group}} = \mathrm{d}\omega/\mathrm{d}k$, which, as you can verify, turns out here to be

$$v_{\mathrm{group}} = \frac{c^2}{v_{\mathrm{phase}}} = c\sqrt{1 - Ne^2/(\epsilon_0 m \omega^2)}. \tag{25.3}$$

---

[6] Group velocity: A narrowband signal around $\omega = \omega_0$ can be represented by a Fourier integral as $V(t) = \int F(\omega')\mathrm{e}^{\mathrm{j}(\omega_0+\omega')t}\mathrm{d}\omega'$, where the function $F(\omega')$ is concentrated around zero. When this signal is launched as a wave into a dispersive medium where the wave number, k, can be approximated as $k \approx k_0 + \omega' \mathrm{d}k/\mathrm{d}\omega$, the wave at t, z becomes $V(t,z) = \mathrm{e}^{\mathrm{j}(\omega_0 \mathrm{t} - k_0 z)} \int F(\omega')\mathrm{e}^{\mathrm{j}\omega'(t - z\,\mathrm{d}k/\mathrm{d}\omega)}\mathrm{d}\omega'$. Except for a phase factor (the first term on the right), $V(t,z)$ is identical to $V(t=0, z=0)$ when $z = t\mathrm{d}\omega/\mathrm{d}k = tv_{\mathrm{group}}$.

Thus v_{group} is less than c, and the ionosphere increases the satellite-to-ground propagation delay. The propagation time is just $\int (v_{\mathrm{group}})^{-1}\, \mathrm{d}s$ over the signal path or

$$T_{\mathrm{prop}} = c^{-1} \int \left[1 - \frac{Ne^2}{(\epsilon_0 m\omega^2)}\right]^{-1/2} \mathrm{d}s \approx c^{-1} \int \left[1 + \frac{Ne^2}{2\epsilon_0 m\omega^2}\right] \mathrm{d}s, \tag{25.4}$$

where we have assumed that the second term in the brackets is much less than unity. We see that the additional delay caused by the ionosphere is given by

$$\Delta T_{Iono} = \approx c^{-1} \int \frac{Ne^2 \mathrm{d}s}{2\epsilon_0 m\omega^2} = \frac{cr_{\mathrm{e}}}{2\omega^2} \int N \mathrm{d}s = \frac{cr_e \mathrm{TEC}}{2\omega^2}, \tag{25.5}$$

where $r_{\mathrm{e}} = \mathrm{e}^2/(\epsilon_0\, m\, c^2) = 2.82 \times 10^{-15}$ m (the "classical electron radius"), and TEC = $\int N\, \mathrm{d}s$, the total electron content, i.e., the number of electrons in a one square meter column along the signal path.

Under worst case conditions (the ionosphere enhanced by a solar storm and the satellite near the horizon), the value of TEC might reach 10^{19}, in which case ΔT_{iono} would be 43 nsec, corresponding to a position error of 14 m. Normally the ionospheric error would be less than one-tenth of this.

If the receiver is able to measure the delay on both frequencies, L1 and L2, the delay caused by the ionosphere can be calculated and subtracted from the measured delay. From Equation (25.5), the difference between the measured propagation delays will be $T_{\mathrm{L2}} - T_{\mathrm{L1}} = \frac{1}{2}\, c\, r_{\mathrm{e}}\, \mathrm{TEC}\, (1/\omega_2^{\,2} - 1/\omega_1^{\,2})$. This provides the value of TEC, from which we can calculate the true delay,

$$T = T_{L1} - \frac{\omega_2^2 (T_{\mathrm{L2}} - T_{\mathrm{L1}})}{2(\omega_2^2 - \omega_1^2)}. \tag{25.6}$$

25.7 Differential GPS

Over a limited area, GPS receivers tracking the same satellites will be subject to essentially the same systematic errors – satellite clock errors, ephemeris errors, ionospheric delay, and even intentional systematic errors. ("Selective availability" limited the accuracy for civil users by introducing pseudorandom errors in the satellite clocks which could be corrected only by authorized users. However, this was discontinued in 2000.) Thus, over the limited area, individual determinations of absolute position will be biased by the same amount, and calculated differential positions between them will be accurate. The U.S. Coast Guard maintains differential GPS reference stations at well-surveyed positions near harbors. They continuously broadcast the current correction to their GPS reading so that users, nominally aboard ships, can apply that correction to their own GPS reading. This system requires a means of transmission – dedicated beacon transmitters or piggybacking data on subcarriers of local FM stations. It also requires that the users be able to receive these signals and have GPS receivers equipped to apply the corrections.

In an even more accurate form of differential GPS used for precise surveying, the phase of the carrier itself is used to get extremely fine time resolution. This interferometric technique can produce accuracy better than 1 cm. This carrier phase tracking mode requires dual-frequency receivers for ionospheric correction. The maximum practical distance from the reference station is about 30 km.

25.8 Augmented GPS

The Federal Aviation Administration (FAA) has set up a large-scale “wide area augmentation system” (WAAS) with about 25 ground reference stations spread through the U.S. Each of these stations monitors all the GPS satellites within view, on both frequencies, L1 and L2. The data are consolidated at a central location where correction data are generated. The measured TEC values are used to create a model ionosphere in the form of a set of vertical TEC values, from which the TEC for an arbitrary path can be estimated. Correction data is also produced for the satellite clock and ephemerides errors. These data are sent to two geostationary satellites, which broadcast them back down to GPS users. The down-link is on the GPS L1 frequency, and provides the same signal strength as the GPS signals. The WAAS signals are spread with the same kind of C/A codes used by GPS, but with different PRN sequences. This allows a GPS receiver, equipped with suitable firmware, to receive correction data from a WAAS satellite as if it were just another GPS satellite.[7] The WAAS data is transmitted at a net rate of 250 bits/sec. Convolutional encoding for forward error correction is used at a rate of 1/2, so the data stream is 500 bits/sec. In practice, the use of WAAS data reduces C/A code (“Standard Positioning Service”) GPS position errors to about 2 m.

25.9 Improvements to GPS

Replacement GPS satellites include the new L2C (Civil) signal, whose signal path is shown at the top of Figure 25.3. This signal is actually two time-multiplexed signals, a medium-length code, CM, and a long-length code, CL. The CL code is transmitted without data. It can, therefore, be tracked with the system shown in Figure 25.4, which uses conventional phase lock loops which provide better tracking than the loops used in Figure 25.5, for a signal containing the data stream. The CL2 signal also provides dual-frequency operation so that civil GPS receivers can correct for ionospheric delay. The CM code contains the data, but convolutionally encoded for forward error correction.

[7] The WAAS satellites contain atomic frequency standards and can, in fact, be used as additional GPS navigation satellites.

This slows the net data rate to 25 bits/sec. Both the CM and CL codes have a chip rate of 511.5 kHz. The CM code repeats every 20 msec, while the CL code repeats every 1.5 sec. The L2C multiplexes CL with CM+Data by alternating between them every 1/1.023 microseconds.

25.10 Other satellite navigation systems

The Russian *Glonass s*ystem and the European *Galileo* system (scheduled for operation in 2013) are very similar to GPS. Both are L-band systems, using PRN coding for time resolution. The Glonass system, however, does not use the PRN coding for multiple access. Instead, each satellite transmits on its own assigned frequency, which requires that receivers be tunable. The Chinese *Beidou* system began with two geostationary satellites, but is expected to eventually have five geostationary and 30 medium Earth orbit satellites. All of these systems were preceded by the interesting *Transit* or NAVSAT system, which operated from 1964 until 1991. A ship at sea could locate its position within 200 m by analyzing the curve of Doppler shift vs. time from a single satellite pass. With only five satellites, a given user could get a position fix only once every several hours.

Problems

Problem 25.1. The nominal GPS signal power is −160 dBW (10^{-16} W) at the output of the receiver antenna (at the L1 frequency assuming the antenna gain is 3 dB). Assume an antenna temperature of 290 K, since the low directivity of the antenna causes ground noise to dominate. (a) Assume that the receiver noise figure is 4 dB and calculate the signal-to-noise ratio for a bandwidth of 2.046 MHz (the nominal bandwidth of the C/A signal). (b) Use the Shannon formula, $C = B \log_2 (1+S/N)$, to calculate the channel capacity in bits/sec. Compare this with the 50-Hz data rate of the navigation signal.

Problem 25.2. Estimate the gain of the GPS satellite antenna, assuming the beam angle just encloses the Earth. Then use the information given in Problem 25.1 to estimate the power of the satellite transmitter.

Problem 25.3. "Selective Availability" (SA), a now-discontinued GPS security feature, degraded the navigation accuracy for civil users. Suggest some ways to implement this feature.

Problem 25.4. Describe how you would use off-the-shelf RF components, a deep-memory sampling oscilloscope, and a PC to make an "off-line" detection of a GPS satellite signal.

Problem 25.5. Devise an algorithm and write a computer program to solve the set of equations (25.1) for x, y, z, and Δ.

Problem 25.6. Derive an expression for the Doppler shift of the GPS signal, assuming the orbit passes directly overhead.

CHAPTER

26

Radio and radar astronomy

Radio astronomy was discovered accidentally in 1931 by Karl Jansky, a physicist at Bell Telephone Laboratories. Jansky had been assigned to identify the sources of noise encountered in a newly installed transatlantic short-wave radiotelephone service. Using a directional receiving antenna on 20.5 MHz, he observed that one component of the noise, a wideband hiss, had a diurnal variation that reached a maximum intensity on average four minutes earlier each day. Jansky knew that the stars advance in just this way (in siderial time) and deduced that the source of the hiss must be outside the solar system. His observations showed that this "cosmic noise" came from the galactic plane and was strongest from the direction of the galactic center (in the constellation Sagittarius).

After Jansky, the second pioneer of radio astronomy was a radio engineer, Grote Reber, who in 1937, built a 9-m (30-ft) parabolic reflector beside his house in Wheaton, Illinois. This was maybe the first modern dish antenna. Reber began his observations using a receiver at 3 GHz, which pushed the high-frequency state of the art, because he assumed that cosmic radio noise was the low-frequency tail of the thermally generated radiation spectrum from white-hot stars. The intensity of this radiation would increase as the square of the frequency, so using the highest practical frequency would make detection easier and would also make his antenna more directive. Detecting nothing at 3 GHz, he worked his way down finally to 160 MHz, where he was able to make contour maps of the cosmic noise intensity. The radiation he and Jansky observed is now known to be *synchrotron radiation*, caused by the centripetal acceleration of fast, i.e., non-thermal, electrons spiraling in a magnetic field. By the end of World War II, the Sun (an ordinary thermal source under low sunspot conditions) had been detected at microwave frequencies. After the war, a previously-predicted spectral line at 21 cm (1420 MHz) was quickly detected. This famous neutral hydrogen line corresponds to the energy difference between the parallel and antiparallel orientations of the magnetic moment of the nucleus (the proton) with respect to the magnetic moment of the spinning electron. Many radio telescopes have been built in the decades following the war, the largest being the

305-m (1000-ft) diameter dish built by Cornell University at Arecibo, Puerto Rico. Discoveries in radio astronomy include some one hundred atomic recombination and molecular lines, pulsars, natural masers, and the isotropic 3K blackbody cosmic background radiation, a remnant left from the Big Bang.

26.1 Radiometry

Most of the radio sources found in nature emit wideband noise; their radiation comes from a great number of individual radiators whose contributions add randomly to produce *Gaussian noise*. (A histogram of voltage samples from the antenna terminals forms a Gaussian curve centered on zero.) Since such a signal is itself a random process, we can only measure its average properties. The most important of these is the average of the square of the voltage, i.e., the power. If we take, say, several n-minute averages of the power, these averages will be scattered around the true average. If n is made larger, the averages will be distributed more tightly about the true average. It might not take long to measure the receiver output power to a precision of, say, 10% or even 1%. But that is almost never long enough to measure the power of a radio source to the same precision or, for that matter, even to detect a source. The problem is that the power from the source is masked by other sources of noise including receiver noise, antenna noise, and cosmic background noise. When an astronomer is trying to detect a source in a certain direction, the first step is to average the power received from that direction, the on-source direction. The next step is to measure the power from a nearby, but off-source, direction. Finally, the latter "off" power is subtracted from the former "on" power. For weak sources (most sources), these powers are almost identical and might correspond to a system temperature[1] of, say, 100 K. Yet the astronomer may need to detect a source that raises the system temperature by only 10 mK. This requires that the "on" and the "off" powers both be measured to an accuracy of, say, $3.3/\sqrt{2} = 2.3$ mK for a 3-sigma detection. The fractional accuracy of the "on" and "off" power measurements must therefore be $0.0023/100 = 2.3 \cdot 10^{-5}$ or about one part in 50 000 (see Problem 26.1).

If we average N samples of the squared voltage, the relative standard deviation, $\delta P/P$, will be $\sqrt{2/N}$ if the voltage has a Gaussian distribution and if all the samples are independent (see Problem 26.2). A signal from a channel of bandwidth, B, can furnish $2B$ independent samples every second. Integrating for a time T we can therefore collect $2BT$ independent samples and the relative standard deviation of the power measurement will therefore be

---

[1] A *system temperature* of 100 K, for example, means that the equivalent noise power at the receiver input is the same as the noise power from a resistor at 100 K. This equivalent noise power is the sum of the actual noise power (sky noise from the main lobe, ground noise picked up from back-lobes, some thermal noise if the antenna is lossy, plus a contribution representing the noise generated in the receiver.

$$\delta P/P = (BT)^{-1/2}. \tag{26.1}$$

Usually a radio astronomer expresses power in terms of antenna temperature and would write $\delta T/T_{\text{system}}$ rather than $\delta P/P$. Equation (26.1) is commonly known as the "radiometer equation." Note that sensitivity increases with bandwidth, contrary to many communication situations where increasing the bandwidth just increases the noise and decreases the signal-to-noise ratio. We arrived at Equation (26.1) by considering digital (discrete) signal processing. It is also common to use an analog square-law detector followed by an analog lowpass filter, which does the averaging. When the lowpass filter is just a simple RC integrator, an analog signal analysis shows that the radiometer equation can be written as

$$\delta T/T_{\text{sys}} = (2BRC)^{-1/2}. \tag{26.2}$$

26.2 Spectrometry

Many sources produce "colored" noise rather than white noise, i.e., the flux density from these sources varies with frequency. Often these variations reveal characteristic shapes of atomic or molecular lines. Instead of just measuring the total power, the signal is divided into adjacent frequency "bins" and the power in each bin is measured. When a spectrum of bandwidth B is divided into n frequency bins, each of bandwidth B/n, the radiometer equation shows that the integration time must be increased by n. It is therefore especially important in radio astronomy, where weak sources may require many hours of integration, to measure the n individual spectra simultaneously rather than sequentially. Simultaneous analysis is done with multichannel radiometers ("multiplex" spectrum analyzers). The simplest multiplex spectrometer is just a bank of n filters, each followed by its own square-law detector and averager. Such an instrument is called a filterbank, but might better be called a radiometer bank. Today, most radio spectrometry is done digitally, often using digital *autocorrelators* (see Chapter 27).

26.3 Interferometry

The classic single-dish radio telescope such as Reber's backyard dish or the Arecibo dish has an angular resolution which is diffraction limited; the angular size of the beam (between half-power points) is about λ/D radians where D is the diameter of the dish. Such a telescope can make maps by scanning the vicinity of a source and doing radiometric averages at each point, but the resolution of the map is limited to λ/D. Better resolution requires a larger antenna. Interferometry uses more than one antenna to form a beam whose size corresponds to the *spacing* between the antennas rather than their diameters. The simplest interferometer has just two elements. The beam formed by the two antennas together has a series of narrow lobes in one dimension. If a point source moves across these lobes, the radiometer will trace out the lobes, just as a point source moving across the beam of a single dish antenna traces out the beam pattern. (Of course the interferometer's fine lobe structure is multiplied by the broader beam pattern of the individual antennas.) The multilobed pattern of a two-element interferometer is unsuitable for the intensity mapping described above but it is often used to set an upper limit on the angular size of a source.

26.3.1 Imaging interferometry

By using data from multiple antennas, it is possible to synthesize a beam that is small in both dimensions, i.e., a beam that would correspond to a filled-aperture antenna whose diameter is the size of the interferometer array. The VLA (Very Large Array) at Socorro, New Mexico, is an example of such a system. Signals from 27 antennas are transmitted up to 21 km through optical fibers (originally through low-loss circular waveguides) to the central processing laboratory. The VLBA (Very Long Baseline Array) has 10 antennas with spacings as large as the distance from Hawaii to St. Croix in the Virgin Islands. Its signals, together with timing information, are recorded on magnetic media at each station and sent, physically or electronically, to New Mexico for after-the-fact combining and processing. Imaging interferometers (phased arrays) work essentially as follows. Suppose we have an array of antennas such as shown in Figure 26.1. Assume the antennas are all pointed in the same direction, say up. If the voltages from the antennas are all added together in phase, squared, and averaged, the result is a narrow beam, pointing straight up. This process can be written as follows:

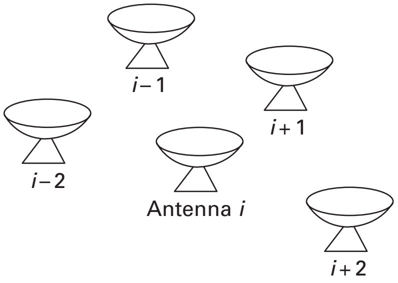

Figure 26.1. An interferometer antenna array.

$$P_0 = \left\langle \sum_n V_n^2 \right\rangle = \sum_{n,m} \langle V_n V_m^* \rangle. \tag{26.3}$$

Now suppose we add the voltages, multiplied by a progressive phase shift, to form a beam tilted slightly off the vertical. If we do this addition, followed by squaring and averaging, we get the *k*-th beam:

$$P_k = \left\langle \sum_{n,m} V_n \mathrm{e}^{\mathrm{j}\phi_{n,k}} V^* \mathrm{e}^{-\mathrm{j}\phi_{m,k}} \right\rangle = \sum_{n,m} \mathrm{e}^{\mathrm{i}(\phi_{n,k}-\phi_{m,k})} \langle V_n V_m^* \rangle. \tag{26.4}$$

This is the general case; for the straight-up beam, $\phi_{n,k}$ and $\phi_{m,k}$ are both zero. The important thing to notice is that we can multiply the signals from every possible antenna pair and average the products first, independent of what beam we wish to form. After averaging these pairs we can *then* form each beam by weighting the averaged products with the appropriate phase factors and performing the double sums. Note also that the averaged products do not have to be measured simultaneously; we could even use one fixed antenna and one mobile antenna and measure the average product for one baseline after another. The VLA has 27 antennas so it can measure (27 × 26)/2 baselines simultaneously. But, as the Earth turns, these baselines become different baselines so, over time, it is possible to collect averaged products from a huge number of baselines. This set of baselines is virtually the same as all the baselines one could form between pairs of points on a dish with a radius of 21 km, and the final synthesized beam can be as sharp and clean as if it had come from a filled dish. An array can thus have the resolution of an enormous antenna even if it does not have the corresponding sensitivity (collecting area). On the other hand, because the individual antenna elements have relatively wide beams, an array has a relatively wide field of view. Radio astronomers hope to have, by the year 2020, a super large array, the SKA (see reference 5) which would have a total collecting area of one square kilometer and provide baselines as long as 3000 km.

26.4 Radar astronomy

Ionized meteor trails produced echoes on WWII radars, but echoes from the Moon were not observed until after the war. In January 1946, a U.S. Army Signal Corps group headed by John H. DeWitt, Jr. observed real-time Moon echos using modified WWII radar equipment delivering 3 kW of power at 110 MHz to a 64-element dipole antenna array. In Hungary, one month later, Zoltán Bay used similar equipment, together with electrolytic cells (“coulombmeters”) to do signal integration. By the end of his experiment, the on-target cell had accumulated significantly more gas than the off-target cell. Many large radars were built in the late 1950s, and radar echo detections from the Sun, Venus, Mercury and Mars were made in the 1960s. Radar was used to measure the rotation rates of Venus and Mercury. Saturn’s rings were detected in the 1970s, as were the large moons of Jupiter, many asteroids and several comets.

26.4.1 The Moon

The Moon’s distance from the Earth, R, is 3.8×10^5 km, and it has a *radar cross-section,* σ, of about $6.6 \times 10^5\ \mathrm{km}^2$. This means that the power density of the echo's SR, in watts per square meter, received back on the radar antenna will be given by $\sigma/(4\pi R^2)$ times the power density incident on the target, S_{inc}. (Note that this defines *radar cross-section* as the collecting area of an equivalent target that isotropically scatters the intercepted incident power.) The incident power density is just $S_{\text{inc}} = P_T G/(4\pi R^2)$, where P_T is the transmitter power and G is the antenna gain. The power into the receiver, P_R, is equal to $S_R A_{\text{eff}}$ where A_{eff} is the effective collecting area of the antenna. We have seen earlier that G is equal to $4\pi A_{\text{eff}}/\lambda^2$. The Moon's radar cross-section is about 7% of its geometric cross-section, i.e., it is 7% as reflective as a metal sphere of the same size. An echo from the Moon will therefore produce a power at the receiver of

$$P_R = P_T \frac{4(\pi A_{\text{eff}}/\lambda^2)}{4\pi R^2}\frac{\sigma}{4\pi R^2}A_{\text{eff}} = \frac{P_T A_{\text{eff}}^2 \sigma}{4\pi R^4 \lambda^2}. \qquad (26.5)$$

Suppose we have a radar with a 1-kW transmitter and a modest 5-m diameter dish antenna with an aperture efficiency of 50%. The effective area of this antenna is therefore half of its geometric cross-section or $A_{\text{eff}} = 0\ .5 \times \pi (5/2)^2 = 9.8\ \text{m}^2$. It is an experimental fact that σ for a planet is approximately independent of wavelength, so we see from Equation (26.5) that the received power is inversely proportional to λ^2 (because of the fundamental antenna relation between gain and effective area). Suppose that the wavelength is 30 cm, i.e., the frequency is 1 GHz. With this radar system, the power received from the Moon would be

$$P_R = \frac{1000\ \text{W}(9.8\ \text{m}^2)^2 6.6 \times 10^{11}\ \text{m}^2}{4\pi(3.8 \times 10^8\ \text{m})^4 (0.30\ \text{m})^2} = 2.7 \times 10^{-18}\ \text{W}. \qquad (26.6)$$

Whether this amount of power is easy to detect or not depends on the noise it competes with. Let us assume that the noise from the antenna (sky noise from background cosmic radio sources plus some "spill-over" noise from the surrounding ground) has an equivalent noise temperature, $T_{\text{ant}} = 50$ K. Let us also assume that our receiver has an equivalent noise temperature, $T_{\text{rcvr}} = 35$ K. The total equivalent input temperature is therefore given by $T_{\text{system}} = 85$ K and the noise power will be $kT_{\text{sys}}B$. If we make the bandwidth, B, very small we decrease the noise power and hence detection becomes easier. But if we make B very small we will need a very accurate prediction of the Doppler shift caused by the relative motion of the Earth and Moon in order to tune the return echo into the passband of the filter. Finally, the rotation of the Moon causes a Doppler *broadening* of the return echo; if we make B less than 25 Hz we will begin to exclude some of the broadened signal. Let us compromise and use a bandwidth of 100 Hz. The signal-to-noise ratio at the receiver output will then be given by

$$S/N = \frac{P_R}{kT_{\text{sys}}B} = \frac{2.7 \times 10^{-18}\text{W}}{1.38 \times 10^{-23}\ \text{W/Hz/K} \times 85\ \text{K} \times 100\ \text{Hz}} = 23.0. \qquad (26.7)$$

This SNR of 23 is large enough that the signal would be visible on an oscilloscope connected at the intermediate frequency (IF) voltage output; no signal averaging would be needed. The modest radar system assumed here could be assembled for a few thousand U.S. dollars.

26.4.2 Venus

Venus is not nearly so easy to detect, being some 280 times more distant than the Moon. Its radar cross-section is about 20 times that of the Moon, so with the radar system described above, the SNR of the return echo would be lower by a factor $280^4/20$ or 307 million! This requires a *much* larger radar. The Arecibo radar, however, has an effective antenna diameter of 200 meters and an average power of 1 MW at 2.38 GHz. It would out-perform our Moon example radar by a factor of $(10^6/10^3)\ (2.38/1)^2\ (200^2/5^2)^2$ or 1.4×10^{10}. Thus, with the same assumed bandwidth and system temperature, the Venus echo from the Arecibo radar would have an SNR of $23\ (1.4 \times 10^{10})/(307 \times 10^6) = 1090$. This is overkill for a simple detection but is needed for high-resolution mapping.

26.4.3 Delay-Doppler mapping

Except for the Moon, planetary targets have angular sizes much smaller than the radar beam. Nevertheless, images of photographic quality can be made by a technique known as delay-Doppler mapping. This method uses short pulses (or pulse compression) to obtain adequate range resolution. The relative motion between the radar and the target provides resolution in the transverse direction via the Doppler effect. This was the method used to get the first surface images of Venus, whose cloud cover kept its features hidden to optical telescopes. The technique is essentially the same as side-looking or synthetic aperture radar by which photographic-like images of ground targets are made from an airborne radar with only a small dish antenna. Figure 26.2 shows how delay-Doppler mapping works. This is a view of the planet as seen from the radar. When a short pulse is transmitted, the first echo to return comes from the front cap or sub-Earth point. At subsequent times the echo signal

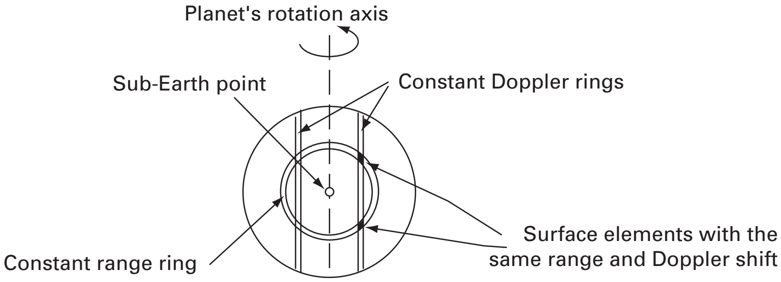

Figure 26.2. Geometry for delay-Doppler radar imaging.

corresponds to loci of equal range that are rings on the planetary surface, centered on the sub-Earth point. Because the planet is rotating, surface points on the right-hand side are moving away from the radar and their echoes are Doppler-shifted to lower frequencies. Likewise, points on the left-hand side are up-shifted. The magnitude of the of Doppler shift is proportional to the cross-range distance, i.e., the distance in the direction perpendicular to both the planet's axis of rotation and the line between the radar and the planet. Loci of constant Doppler shift are rings parallel to the rotation axis of the planet and to the line from the planet to the radar.

The two shaded surface elements have the same range and the same Doppler shift. This fundamental ambiguity can be removed, at least for Venus maps made at Arecibo, by tilting the radar beam slightly to illuminate only the Northern or only the Southern hemisphere of Venus. Obviously this technique requires the narrow beam provided by a very large antenna. Data taking is done as follows: a series of IF voltage samples is read and stored separately as each return pulse arrives. After many pulses have been received, we have a time series for each range ring. Each series is Fourier analyzed to get the Doppler spectrum. The magnitude of a given Doppler component corresponds to the reflectivity of the surface element at the intersection of the range ring and the Doppler ring.

26.4.3.1 Overspreading

The standard delay-Doppler[2] method will not work when the planet is too large and/or spins too fast. This is because the Nyquist sampling theorem requires that the (complex) sampling rate be at least equal to the bandwidth of the signal so that high-frequency Doppler components do not "alias" and appear as lower frequency components (the stroboscope effect). This establishes a minimum pulse repetition frequency (PRF). But if the depth of the planet is too large, even the minimum PRF will result in having more than one pulse on the planet at a time, causing the echoes from different ranges to "fold" together.

The bandwidth of the return echo (twice the highest Doppler shift) is given by $B = 2f_{\text{radar}}\, 2v_{\max}/\text{c} = 4f_{\text{rad}} r_{\text{planer}}\, \Omega\, /c$ where r_{planet} is the radius of the planet, Ω is its apparent angular velocity,[3] f_{radar} is the frequency of the radar, and α is the angle between the radar beam from the Earth and the planet's rotation axis. Therefore, the Nyquist sampling requirement is $f_{\text{sample}} > 4f_{\text{radar}}\, r_{\text{planet}}\, \Omega/c$. The condition to avoid range folding is $1/f_{\text{sample}} > 2\text{r}_{\text{planet}}/\text{c}$. Multiplying these two inequalities gives us $1 \geq 8\, f_{\text{radar}}\, r^2{}_{\text{planet}}\, \Omega/\text{c}^2$, which imposes an upper limit on the frequency of the radar:

---

[2] Note that delay-Doppler mapping of space objects is the same technique as pulse-Doppler radar, discussed in Chapter 21. But while the planet presents a "target" in every range-Doppler cell, a pulse-Doppler surveillance radar is likely to have a target (often an airplane) in only a single range-Doppler cell.

[3] The *apparent* angular velocity of the planet corrects for the planet's tilt and the relative translational (orbital) motion of the Earth and the planet.

$$f_{\mathrm{radar}} < \frac{c^2}{8r^2\Omega}. \tag{26.8}$$

Using Equation (26.8), the radar frequency should be less than about 1.5 GHz for Venus and less than about 1.8 GHz for Mercury. These are practical frequencies for conventional microwave radar technology. For Mars, however, the radar frequency would have to be lower than 14 MHz, because of the high rotation rate. Equation (26.5) shows that such a low frequency would require an extremely large antenna. To make matters worse, sky noise and atmospheric noise at 14 Mz are both much higher than at microwave frequencies.

While standard delay-Doppler does not work for Mars and other overspread targets, Mars images were made in 1988 using the VLA in New Mexico. During the observations, Mars was illuminated with a 10-GHz signal from the JPL NASA Solar System Radar transmitter at Goldstone, California. The resolution of these images was only about 100 km.

A modified delay-Doppler technique, developed around 1986 for radar probing of the ionosphere, was first used at Arecibo in 1990 to solve the overspreading problem for Mars. This "long code" technique is used with the 2.38-GHz transmitter, which puts out a continuous wave (cw) rather than pulsed power, but is biphase-modulated with a long pseudorandom code – for Mars, a sequence of 10-μs bauds. The code elements shift the RF phase by zero or 180°, equivalent to leaving the signal unchanged or changing its polarity. The length of the sequence must be greater than 0.33 seconds (the length of a coherent integration or "look"), though the sequence used at Arecibo repeats only every 3054 hours and can be considered totally random. To see how this technique works, imagine first a simple point target. The echo from such an object would be a delayed version of the code. At the receiver we sample the return echo at the baud rate and multiply successive samples of the echo signal by successive bauds of an identical "replica" code to undo the echo's phase reversals. When the replica code has the correct alignment, it undoes the phase reversals and produces a cw signal. We can separately multiply the echo samples by the replica code for all alignments. Identifying the alignment that produces a cw signal gives us the distance (range) to the point target. If the point target has a velocity component parallel to the radar beam, the recovered cw signal will be Doppler shifted and we can determine the velocity component. Next, imagine that the echo comes from *two* point reflectors, separated in time by at least one baud (1500 m in range). Again multiplying the echo by the replica code, we would find two alignments that produce cw signals and could thereby deduce the range and line-of-sight velocity of each target. Note, however, that the "decoded" signal from either target contains white noise that is the signal from the other target, randomized because the replica code is not aligned with its echo. This "self-noise" has power equal to that of the desired signal, assuming the targets have equal radar cross-sections. We can consider the range rings on a planet to be a set of N such targets, separated in range delay by the

baud length. (Each range ring has a Doppler spectrum.) The self-noise voltage is therefore the sum of N voltages, which add as a random walk. The delay time depth of Mars is 23 ms so, for a baud length of 10 μs, $N=2300$. If we assume that the signals from the rings are approximately equal in strength, the self-noise power will be N times the signal power. Here, this factor can be reduced to 2300 (7.5/100) = 177 by lowpass filtering the data sequences before doing the Doppler analysis, since the self-noise is spread out over a much larger bandwidth (100 kHz) than the Mars echo bandwidth (7.5 kHz). This still appears disastrous, until we remember that the self-noise is in addition to "real" noise, i.e., cosmic noise, antenna noise, and receiver noise. Under the worst weak-signal conditions, the self-noise is insignificant compared to the real noise so, while the system performance will be poor, the self-noise is not to blame. Under the best conditions, the self-noise dominates the real noise and it will determine the integration time needed to pull the signal out of the total noise. When the long-code technique is used with the Arecibo S-band radar system to observe Mars, the effective signal-to-noise ratio is decreased by a factor of 5.2 or 1.7, depending on the polarization of the echo.[4] Figure 26.3 shows a signal processing arrangement that produces the decoded signals for each range, does a Fourier transform on each decoded range signal, and stores the resulting delay-Doppler data points in an array.

---

[4] The radar transmits a signal with circular polarization. Smooth portions of the planetary surface create specular (mirror-like) reflections, which reverse the sense of the circular polarization. Rough portions of the surface create multipath reflections, which cause some of the echo power (usually less than half) to return with the same circular sense as the transmitted signal. The radar is equipped to receive both polarizations.

Problems

Problem 26.1. Use the radiometer equation to find how much time is needed to make a 3-sigma detection of a 10 mK radio source if the radio telescope's system temperature is 100 K. Assume the predetection bandwidth, B, is 10 MHz. A "3-sigma detection" requires that the 0.01 K contribution from the source be $3\sqrt{2}$ times the δT fluctuation predicted by the radiometer equation. (The factor $\sqrt{2}$ takes account of the increased fluctuation when the "off" is subtracted from the "on", assuming an equal time T is spent measuring each.)

Problem 26.2. Verify that if a noise power estimator is defined as the average of N independent samples of the squared noise voltage, the standard deviation of this estimator will be $\sigma^2\sqrt{2/N}$. Assume that the probability distribution of the noise voltage is Gaussian with zero mean and variance σ^2. Hint: for a zero-mean Gaussian distribution, the expected value of V^2 is σ^2 and the expected value of V^4 is $3\sigma^4$.

Problem 26.3. Pulsars (rotating neutron stars) are radio sources that turn on and off with very regular periods ranging from about 2 milliseconds to about 2 seconds. Given a radio telescope at your disposal, how would you go about searching for pulsars, i.e., what kind of data processing scheme would you use to find these periodic sources?

CHAPTER

27

Radio spectrometry

Spectrometry or spectral analysis is the statistical characterization of random (*stochastic*) signals such as the IF voltage in a radio astronomy receiver, as described in Chapter 26. The spectrometers discussed in this chapter are all *multiplex* spectrometers, meaning that they measure N points on the spectrum simultaneously. This is to be distinguished from swept-frequency spectrum analyzers, which measure spectral points sequentially. Multiplex spectrometers are used when long integration times are needed to pull a signal out of the noise, as in radio astronomy. They are also used for low-frequency spectrum analysis, where narrow channel bandwidths require long measurement times to process a sufficient number of independent samples. Most often the signal is Gaussian; if a fine-grained histogram of samples of the signal's amplitude is scaled to make the area below the curve equal to unity, the average curve will be the Gaussian probability density function, $f(V) = (2\pi\sigma^2)^{-1/2}\ \exp(-V^2/2\sigma^2)$. You can verify (Problem 27.1) that σ is the rms value of V, i.e., σ^2 is the power, $\langle V^2 \rangle$. But total power does not completely characterize the signal. A complete description is contained in the *power spectral density function*, $S(\omega)$, the distribution of power vs. frequency. A set of bandpass filters and power meters, i.e., a set of radiometers, serves to measure points on the spectral density function (usually called the PSD or simply the power spectrum). However, the simplest mathematical definition of the power spectrum uses the signal's *autocorrelation function*, $R(\tau)$, a function of time delay. The value of the autocorrelation function for a given time delay, τ, is defined as the average value of the "lagged product"

$$R(\tau) = \langle V(t) \cdot V(t + \tau) \rangle. \tag{27.1}$$

For a signal whose characteristics are unchanging (a *stationary process*), $R(\tau) = R(-\tau)$. We will see that the Fourier transform of the autocorrelation function is the power spectral density so, directly or indirectly, we describe the signal in terms of sine-wave basis functions, i.e., we find the magnitudes (but here not the phases) of a set of sine waves whose superposition has the same power spectrum as the original signal. Why are sine waves preferred to other sets of basis functions? Often the process under study is a spectral line which shows up clearly in a few adjacent Fourier coefficients (frequency bins) or a Doppler shift which just displaces the spectrum. The frequency spectrum is clearly a natural way to represent such signals. Of course we deal with sine waves all the time as the characteristic functions of linear systems; a sinusoidal signal of a given frequency remains a sinusoid with the same frequency after passing through any arbitrary chain or network of linear elements such as amplifiers, filters, and transmission lines. A variety of instruments have been developed for spectrometry. In approximate historical order, these include analog filterbanks, autocorrelators, chirp-z spectrometers, Fourier transform spectrometers, and acousto-optical spectrometers.

27.1 Filters and filterbanks

We have already seen the analog filterbank in Chapter 26, as part of a radiometer bank. Usually the signal is converted down to a convenient intermediate frequency, e.g., tens of MHz, and the filters are the various *LC* bandpass filters discussed earlier or crystal filters or digital filters. A traditional disadvantage of an analog filterbank spectrometer has been that it is not "elastic," i.e., the filters have a fixed width; if narrower or wider filters are needed, another filterbank must be built. With high-speed digital-to-analog conversion and fast memory, this restriction can be lifted by using an interesting spectral expansion technique. Sequences of data are read into the memory at whatever slower rate is needed and then played back at a higher rate into a single wideband filterbank.

27.2 Autocorrelation spectrometry

Autocorrelation spectrometers estimate the power spectrum by taking pairs of samples with a given time separation, multiplying them, and averaging these "lagged products." (In Fourier transform spectral analysis the samples are multiplied by sine waves but the resulting coefficients are squared before averaging. In both cases powers, rather than voltages, are averaged.) When the time separation is zero, the average lagged product is just the total power. But if we measure other lagged products as well (where the time separation is not zero), we can indirectly find the power spectrum because the autocorrelation function (ACF) and the power spectrum form a Fourier transform pair:

$$S(\omega) = \int_{-\infty}^{\infty} R(\tau) \mathrm{e}^{-\mathrm{j}\omega\tau} \mathrm{d}\tau \tag{27.2}$$

$$R(\tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} S(\omega) \mathrm{e}^{\mathrm{j}\omega\tau} \mathrm{d}\omega. \tag{27.3}$$

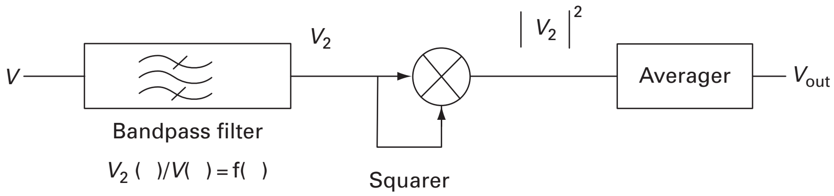

Figure 27.1. Single-channel radiometer.

This relation, the Wiener–Khinchin theorem, is often used to define the power spectrum. To see that S(ω) as defined by Equation (27.2) agrees with our intuitive ideas of the power spectrum, consider the single-channel radiometer shown in Figure 27.1. The (in situ) voltage transfer function of the bandpass filter is defined in the frequency domain by $H(\omega) = V_2(\omega)/V(\omega)$. The power response function or filter shape is therefore given by $|H(\omega)|^2$, so we expect that the time average of $(V_2)^2$ will be given by

$$\left\langle |V_2(t)|^2 \right\rangle = \int_{-\infty}^{\infty} S(\omega)|H(\omega)|^2(2\pi)^{-1}\mathrm{d}\omega \qquad (27.4)$$

where $S(\omega)$ is the spectral power density function. Note that $(2\pi)^{-1}\mathrm{d}\omega = \mathrm{d}f$; the power spectral density has units of watts/Hz.

Let us now show that the output of this radiometer is indeed given by Equation (27.4), and that $S(\omega)$ is given by Equation (27.2). We can express V_2 in the time domain as

$$V_2(t) = \int_{-\infty}^{t} V(t')h(t-t')\mathrm{d}t', \qquad (27.5)$$

where $h(\tau)$, the impulse response function, is the inverse Fourier transform of $H(\omega)$.[1] The output of the squarer is then given by

$$(V_2(t))^2 = \int_{-\infty}^{t}\int_{-\infty}^{t} V(t')V(t'')h(t-t')h(t-t'')\mathrm{d}t'\mathrm{d}t''. \qquad (27.6)$$

Since we assume $V_{\mathrm{in}}(t)$ is a stationary process, the value of t is arbitrary. Let us pick $t = 0$, which gives

$$(V_2(t))^2 = \int_{-\infty}^{0}\int_{-\infty}^{0} V(t')V(t'')h(-t')h(-t'')\mathrm{d}t'\mathrm{d}t''. \qquad (27.7)$$

---

[1] The impulse function, $h(t)$, is the filter output voltage at t, in response to a delta function input at $t = 0$. Note that $h(t)$ is real and that $h(t) = 0$ for $t < 0$.

From causality, $h(t) = 0$ for $|t| < 0$, so the upper limits of integration can be changed from 0 to infinity. Doing this, making a change of variable, $t'' = t' + \tau$, and taking the time average, we find

$$\left\langle (V_2(t))^2 \right\rangle = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \langle V(t')V(t'+\tau)\rangle h(-t')\, h(-t'-\tau) \mathrm{d}t' \mathrm{d}\tau. \tag{27.8}$$

Using the definition of the ACF, $R(\tau) = \langle V(t)V(t+\tau)\rangle$, we find

$$\left\langle (V_2(t))^2 \right\rangle = \int_{-\infty}^{\infty} R(\tau) \left[\int_{-\infty}^{\infty} h(-t')h(-t'-\tau)dt' \right] \mathrm{d}\tau. \tag{27.9}$$

Applying the convolution theorem,[2] the Fourier transform of the term in square brackets is $|H(\omega)|^2$. Therefore, the bracketed term is the inverse Fourier transform of $|H(\omega)|^2$ or

$$\left[\int_{-\infty}^{\infty} h(-t')h(-t'-\tau)\mathrm{d}t' \right] = \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{j}\omega\tau} |H(\omega)|^2 \mathrm{d}\tau. \tag{27.10}$$

Substituting this expression into Equation (27.9) produces

$$\left\langle (V_2(t))^2 \right\rangle = \int_{-\infty}^{\infty} R(\tau) \left[\frac{1}{2\pi} \int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{j}\omega\tau} |H(\omega)|^2 \mathrm{d}\omega \right] \mathrm{d}\tau. \tag{27.11}$$

Finally, interchanging the order of integration gives us

$$\left\langle (V_2(t))^2 \right\rangle = \int_{-\infty}^{\infty} |H(\omega)|^2 \left[\int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{j}\omega\tau} R(\tau)\mathrm{d}\tau \right] (2\pi)^{-1} \mathrm{d}\omega. \tag{27.12}$$

After all this effort, we can now compare Equation (27.12) with Equation (27.4) and confirm that the power spectrum defined by Equation (27.2) agrees with what we would expect to measure with a bandpass filter followed by a squarer and an averager. (Don't worry about the sign discrepancy in the $\mathrm{e}^{\mathrm{j}\omega t}$ term in Equation (27.12); since $V_2(t)$ and $R(\tau)$ are real, we can replace this term by $\mathrm{e}^{-\mathrm{j}\omega t}$.)

27.2.1 Hardware autocorrelators

A hardware autocorrelator is a special-purpose parallel signal processor that calculates an averaged ACF, usually in real time. A single Fourier transform operation in a computer then turns the ACF into the power spectrum with the same number of frequency bins (points on the spectrum) as the number of points

---

[2] If $H(\omega)$ is the Fourier transform of $h(\tau)$, then $|H(\omega)|^2$ is the Fourier transform of $\int h(t)h(t+\tau)\mathrm{d}t$.

on the ACF. Autocorrelators use a simple expandable architecture. Figure 27.2 shows an analog version of the autocorrelator.

Figure 27.3 shows a digital autocorrelator. The analog delay line is replaced with a digital shift register. The analog multipliers and averagers are replaced by digital multipliers and accumulators.

The autocorrelators of Figures 27.2 and 27.3 produce values only for discrete points on the ACF. But, as long as the input signal is band-limited (usually by a bandpass "anti-aliasing" filter), the spectrum can be represented as a Fourier *series*, so sampled ACF points are sufficient to compute the continuous power spectrum. In practice, however, we cannot measure an infinite number of points on the ACF. The spectral estimate obtained by transforming ACF points that extend only to $\tau_{\max}$, i.e., by transforming an ACF "windowed" with a rectangular function that is unity for $\tau_{\max} < \tau < \tau_{\max}$ and zero outside this range, produces a function which is the true spectrum convolved by the function $\sin(\omega \tau_{\max})/(\omega \tau_{\max})$. A sharp line in the spectrum therefore appears as a broadened line, surrounded by sidelobes. It is common to apply a smoother windowing function such as $\cos(½\pi\ \tau/\tau_{\max})$ to reduce the sidelobes even though the main load will be broadened – a trade-off between spectral resolution and leakage between channels.

27.2.2 One-bit autocorrelation

One-bit autocorrelation is a technique that greatly reduces the complexity of the digital circuitry. The input analog voltage is fed to a comparator whose output (one bit) indicates the sign, i.e., the polarity, of the voltage. The continuous range of analog voltages is compressed down to just two values: plus one and minus one. (In the digital hardware, a digital "1" indicates a value of +1 and a digital "0" indicates a value of −1.) The correlator's delay line shift register needs to be only one bit wide and the one-bit × one-bit multipliers can be exclusive NOR gates, since the output of an exclusive NOR gate is + 1 when the inputs are the same and −1 when they are different. The integrators that follow the multipliers are simple counters. Although the output of a one-bit correlator is a distorted version of the actual correlation function, the distortion can be entirely corrected. Because the input signal has Gaussian amplitude statistics, the output of the one-bit correlator turns out to be:

$$\rho_{1-\text{bit}}(\tau) = (2/\pi)\sin^{-1}[\rho(\tau)] \tag{27.13}$$

where ρ is the normalized autocorrelation function: $\rho(\tau) = R(\tau)/R(0) = R(\tau)/\sigma^2$. This functional relation was derived during World War II by J. H. van Vleck while studying the spectrum of clipped noise. (Jammers can have much better power efficiency if jamming with clipped noise works as well as jamming with noise having Gaussian amplitude statistics.)

The averaged values from a one-bit autocorrelator can, therefore, be inverted to get the true correlation function.

$$\rho(\tau) = \sin[(\pi/2)\rho_{1-\text{bit}}(\tau)]. \tag{27.14}$$

A straightforward proof of the van Vleck relation (Problem 27.4) proceeds from the Gaussian bivariate probability density,

$$f(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2(1-\rho^2)^{1/2}} \exp\left(\frac{-1}{2(1-\rho^2)}\left(\frac{x_1{}^2}{\sigma_1{}^2} - 2\rho\frac{x_1 x_2}{\sigma_1\sigma_2} + \frac{x_2{}^2}{\sigma_2{}^2}\right)\right). \tag{27.15}$$

Here x_1 and x_2 are the voltages $V(\mathrm{t})$ and $V(\mathrm{t}+\tau)$, so $\sigma_1 = \sigma_2$. One gives up some radiometric sensitivity for the simplification of one-bit processing; the integration time has to be increased by a factor of $\pi^2/4$ compared to a correlator using multi-bit quantization.

Several generations of digital correlators have been used in radio astronomy. Custom CMOS correlator chips have thousands of lag channels and clock rates above 100 MHZ. A variety of serial and parallel multiplexing techniques are used to combine these chips to increase the number of lag channels and to increase input data rates to several hundred MHZ.

27.3 Fourier transform spectrometry

Fourier transform methods are more efficient than autocorrelation spectrometry simply because the FFT (Fast Fourier Transform algorithm) is an efficient way to compute the DFT (Discrete Fourier Transform). Processing a sequence of N data points requires on the order of N log(N) operations for an FFT vs. N^2 operations for either autocorrelation or a brute force DFT.

27.3.1 DFT spectrometer

The Fourier transform is, by itself, a spectrometer. The DFT of a sequence of voltages, V_n, is given by

$$u_k = \sum_{n=0}^{N-1} V_n \mathrm{e}^{-\mathrm{j}2\pi nk/N}. \tag{27.16}$$

We can write this DFT in terms of time and frequency as

$$u_{\omega_k} = \sum_{n=0}^{N-1} V_{t_n} \mathrm{e}^{-\mathrm{j}\omega_k t_n}, \tag{27.17}$$

where $t_n = n/f_\mathrm{sample}$ and $\omega_k = 2\pi k f_\mathrm{sample}/N$. Note that the transform is equivalent to a bank of N pairs of frequency converters with sine and cosine L.O.s. The k-th pair multiplies the input signal by $\cos(\omega_k t)$ and $\sin(\omega_k t)$, thus shifting the input band to place ω_k at zero frequency. For every converter, N consecutive multiplier output values are summed so one output value is produced every N/f_sample seconds. This summation is equivalent to lowpass filtering and decimation (reducing the sample rate). Successive values of u_k are, therefore, equivalent to (complex) voltages from the signal at and around ω_k, after being shifted to zero frequency and then lowpass filtered. When the input voltage is a random

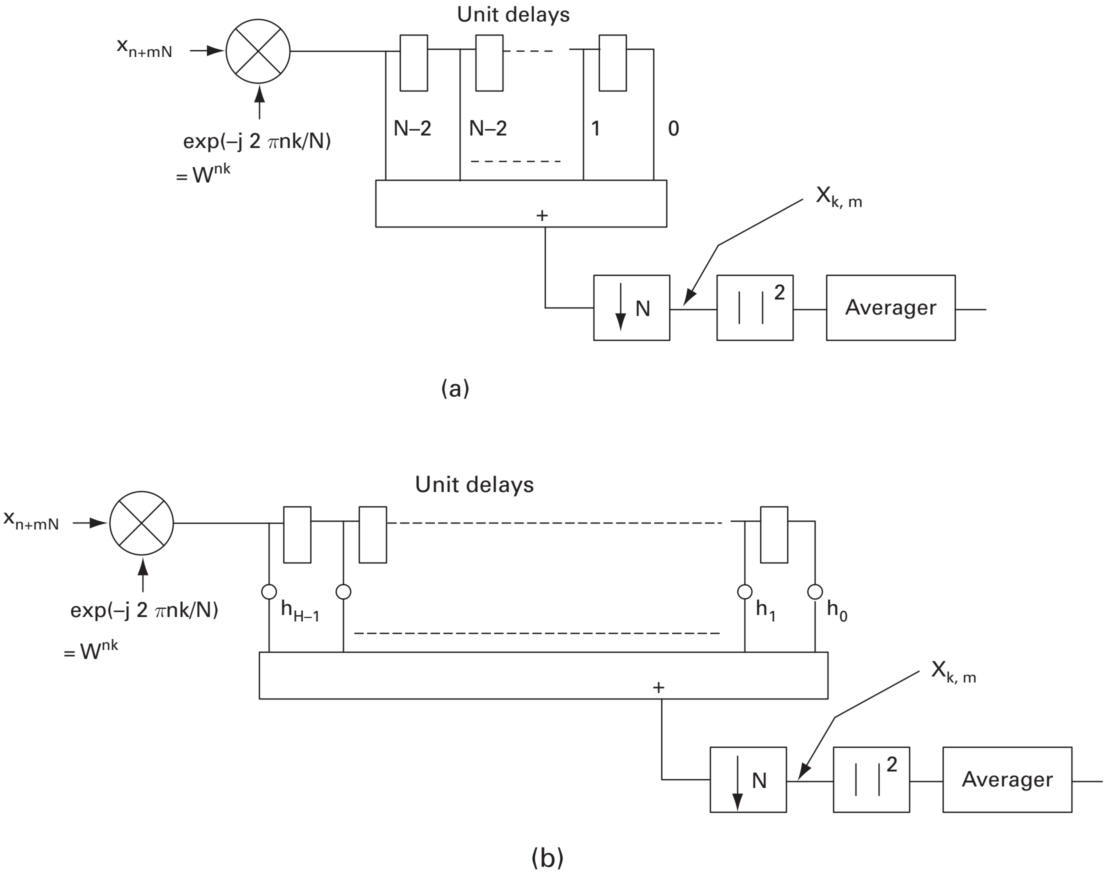

Figure 27.4. (a) One channel of a straight DFT spectrometer (periodogram averager);
(b) filter channel using a longer sum and with arbitrary weights on the inputs to the summer.

process, u_k is also a random process. Its mean is zero. The squared magnitude of u_k represents power, and the set of points, $\{|u_k|^2\}$, is known as a *periodogram*. To estimate the power spectrum of a random process, many periodograms must be averaged together. Figure 27.4(a) shows one channel of a straight periodogram spectrometer.

A shortcoming of the DFT spectrometer (periodogram averager) is that the equivalent filter shape of each channel is not rectangular but, instead, has a $\sin(x)/x$ form, due to the uniform boxcar lowpass filter weights inherent in the DFT. It therefore suffers "leakage" from adjacent and even not-so-adjacent channels. We saw the same problem with the autocorrelation spectrometer. There are obvious remedies for this problem. The application of a weighting function to the input data blocks to give relatively low weight to the data points near the beginning and end of the blocks is equivalent to tapering the weights of the low-pass filter and therefore reduces the amplitude of the filter sidelobes. Such weighting, however, broadens the main lobe and increases the variance of the spectral estimates, since the spectrum is estimated mostly from the data points around the center of the data blocks. This loss of sensitivity can be remedied by computing periodograms from data blocks that overlap each other and including these periodograms in the average. (Even with uniform data weighting, there is a loss of sensitivity when periodograms are computed only from nonoverlapping blocks of data.)

27.3.2 Combined FIR filter/DFT spectrometer

An "FIR/Fourier transform" spectrometer design that fixes the problems of the DFT spectrometer begins with the filter channel shown in Figure 27.4(b). Like the DFT filter, this filter channel will produce one output value for every N input samples. But now, the mixer is followed by a lowpass FIR (finite impulse response) filter which forms a running weighted sum of H successive mixer output values by summing the numbers, weighted by factors, h_i, at the taps of a digital delay line.[3] This would be the same as the DFT filter of the periodogram if all the weights, h_i, were equal to unity and the number of taps, H, were equal to N. Here, however, the number of taps will be an integral multiple of N, $H = RN$. This can be quite a large number, e.g., $H = 4 \times 1024 = 4096$, and the FIR filter can therefore produce a nearly ideal rectangular channel response. As with the straight DFT spectrometer, the bandwidth reduction from lowpass filtering lets us decimate the output of the summer, keeping only one sum per N-point block of input data. Again, the magnitudes of the output of the summer must be squared and averaged to form an estimate of the power spectrum. Note that, because the filter window, H, is longer than the block length, N, the blocks processed by the filter are overlapped; while one output value is produced for every N input samples, the output values are produced from H input samples, where $H > N$. We will designate the input voltage samples as x_n. They enter in blocks of N samples. The output of the summer is $X_{k,m}$, where m is the block number and k, which runs from zero to N, designates the point on the spectrum. Defining W as $W = \exp(-2\pi\,\mathrm{j}\,/N)$, inspection of Figure 27.4 allows us to write

$$X_{k,m} = \sum_{n=0}^{H-1} h_n W^{-k(mN+n)} x_{mN+n}. \tag{27.18}$$

Now, since $W^{-kmM} = 1$, we can rewrite this equation as

$$X_{k,m} = \sum_{n=0}^{H-1} h_n W^{-kn} x_{mN+n}. \tag{27.19}$$

Let us next express n as $rN + \rho$ where the index r goes from 0 to $R-1$, where $R = H/M$, and the index ρ goes from 0 to $M-1$. Using this notation, we have

---

[3] The finite (duration) impulse response is obvious; when an input sample makes its way down the line and falls off at the end, it no longer contributes the output. A FIR filter can be given a desired frequency response function by selecting the tap weights to form the desired impulse function, i.e., the Fourier transform of the desired frequency response.

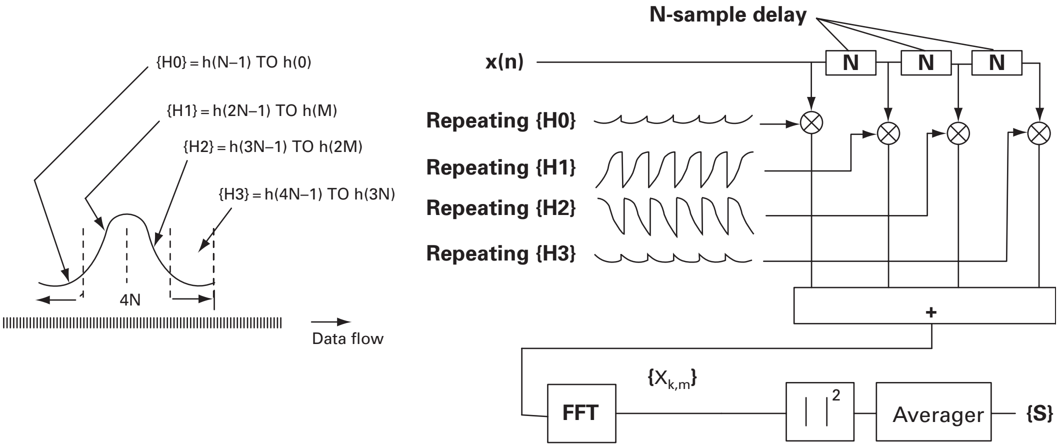

Figure 27.5. Weighted overlap-add filterbank.

$$X_{k,m} = \sum_{\rho=0}^{N-1} \left(\sum_{r=0}^{H/N-1} h_{rN+\rho} x_{mN+n} \right) W^{-k\rho}. \tag{27.20}$$

Note that Equation (27.20) is just an N-point DFT of the term in brackets, and that this term is independent of k, the frequency index. Consider this term for the case where $H = 4N$. The bracketed term is given by

$$(\ ) = h_\rho X_{Nm+\rho} + h_{N+\rho} X_{N(m+1)+\rho} + h_{2N+\rho} X_{N(m+2)+\rho} + h_{3N+\rho} X_{N(m+3)+\rho}. \tag{27.21}$$

In the first term on the right-hand side, successive samples are multiplied by h_0 through h_{N-1}. In the second term, delayed samples are multiplied by h_N through h_{2n-1}, and so on. An architecture that forms this bracketed term is shown in Figure 27.5. Four multipliers are used, together with three delay lines, each of length N. The set of H FIR coefficients is split into four sections, each of which feeds one of the four multipliers in a continuous cycle. An adder sums the products flowing from the multipliers. This preprocessor section feeds a standard FFT block. This architecture is called a *weighted overlap-add* (WOLA) filterbank. Another way of producing the bracketed term yields the *polyphase filter bank* [3].

27.4 *I* and *Q* mixing

In the discussions above, it was implicit that the spectrum of the band-limited signal voltage, $V(t)$, extends from zero to some cutoff frequency, B. This baseband signal can be produced from an IF signal that has been bandpass filtered and then down-converted to put the lower edge of the passband at zero frequency. For digital spectrum analysis, the sampling frequency must be at least $2B$ to avoid aliasing (the stroboscope effect). In the case of the DFT spectrometer and the improved WOLA version, the N channels extend in frequency from

0 to the sampling rate, i.e., from 0 to $2B$. Therefore, only the first $N/2$ output channels can be used, since those channels correspond to the frequency range 0 to B. (The second $N/2$ channels will contain the same information; channel $N-k$ will have the same data as channel k.) This effective waste of half the DFT channels can be avoided with a technique known as *complex sampling*. In this technique, the IF signal of bandwidth B is down-converted into baseband "*I*" and "*Q*" (in-phase and quadrature) channels by using two mixers having L.O. signals $\cos(\omega_c t)$ and $\sin(\omega_c t)$, where ω_c is the center of the IF band. We can express the original IF signal in terms of the mixer outputs, $I(t)$ and $Q(t)$, as

$$V_{\mathrm{IF}}(t) = I(t)\cos(\omega_c t) + Q(t)\sin(\omega_c t). \tag{27.22}$$

To find the spectral value at the point $\omega_c + \Delta$, we must multiply (mix) the IF voltage by $e^{-j(\omega c + \Delta) t}$. Carrying out this multiplication and ignoring terms of frequency $2\omega_c$, we find

$$V_{\mathrm{IF}}(t)e^{-j(\omega_c+\Delta)t} = [I(t) - jQ(t)]e^{-j\Delta t}. \tag{27.23}$$

The term on the right-hand side is equivalent to mixing a complex-valued signal, $I(t)-jQ(t)$, so that the spectral point at $\omega_c + \rho$ is shifted to zero frequency. The beauty of this is that both $I(t)$ and $Q(t)$ have bandwidth $B/2$, since $B/2$ is the greatest separation between ω_c and any point in the IF band. Therefore we can feed $I(t)-jQ(t)$ as a sequence of complex numbers to the straight DFT spectrometer or the improved WOLA version and the N output values will span the entire bandwidth B. The spectrum from $\Delta = 0$ to $B/2$ will appear in the first $N/2$ channels, while the spectrum from $\Delta = -B/2$ to 0 will appear in the second $N/2$ channels. When I and Q mixing is used in autocorrelation spectrometry, both autocorrelation functions and cross-correlation functions are computed from the I and Q signals.

27.5 Acousto-optical spectrometry

The acousto-optical spectrometer (AOS) uses an optical crystal which becomes a diffraction grating by virtue of mechanical waves (sound waves at radio frequencies) propagating through it. These waves produce corrugations in the refractive index along the length of the crystal. The waves are launched into this *Bragg cell* by an electrical-to-acoustic transducer (usually a piezoelectric crystal), driven by the IF signal to be analyzed. Figure 27.6 shows how the crystal is illuminated by a laser and how a multi-element CCD array detects (and averages) the diffraction pattern.

The linear CCD array, like those used in supermarket checkout scanners, accumulates charge along its length at a rate given by the incident light intensity. For read-out, the charge packets are clocked down the length of the CCD in a bucket brigade fashion. The voltage at the end of the array, which is proportional to the charge at that position, is digitized and made available to the data-taking computer.

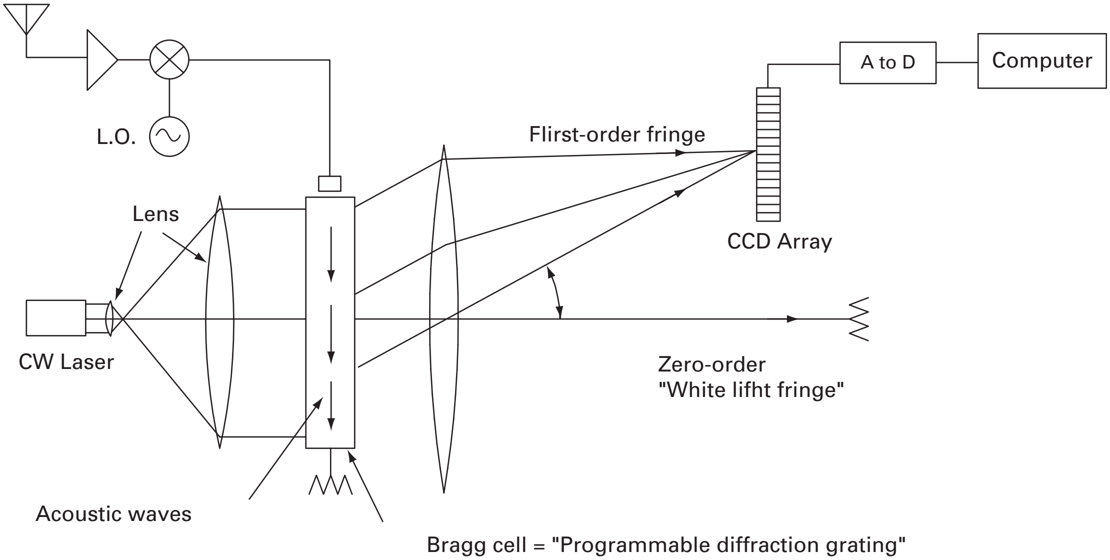

Figure 27.6. Acousto-optical spectrometer (AOS).

A figure of merit for any spectrometer is its number of frequency bins, i.e., its analysis range divided by its resolution. For the AOS, the effective number of channels is given by the time–bandwidth product of the Bragg cell. To see this we note that the angular size (in radians) of the light incident on the CCD is given by $\lambda_{\text{laser}}/L_{\text{cell}}$, the ratio of the laser wavelength to the length of the cell, just as the beam size for an aperture antenna with diameter D is given by λ/D. The first-order diffraction condition (so that all the rays arrive in phase at the CCD) is given by $\lambda_{\text{grating}}\sin\theta = 1 \times \lambda_{\text{laser}}$ where λ_{grating} is the corrugation wavelength in the cell. Now λ_{grating} can be written as v_{cell}/f where v_{cell} is the sound velocity and f is the input RF frequency. Approximating $\sin\theta$ by θ, we find the total angular range over the total frequency range given by $\Delta\theta/\Delta f = \lambda_{\text{laser}}/\text{v}_{\text{cell}}$. The number of channels is then given by the range divided by resolution,

$$N = \frac{\lambda_{\text{laser}}\Delta f L_{\text{cell}}}{v_{\text{cell}}\lambda_{\text{laser}}} = \frac{L_{\text{cell}}}{v_{\text{cell}}}\Delta f = T\Delta f, \tag{27.24}$$

where T is the propagation time through the length of the cell. The quantity $T\,\Delta f$ is known as the *time–bandwidth product* of the cell. Materials used for Bragg cells include quartz, lithium niobate, and glass. A spectrometer for radio astronomy might use cells with a 200-MHz bandwidth and a time–bandwidth product of one thousand.

27.6 Chirp-z spectrometry

The chirp-z spectrometer is shown in Figure 27.7. Also known as the microscan or compressive receiver, it uses a dispersive filter and a swept L.O. While it appears to be a swept spectrum analyzer, it is actually a multiplex analyzer. The

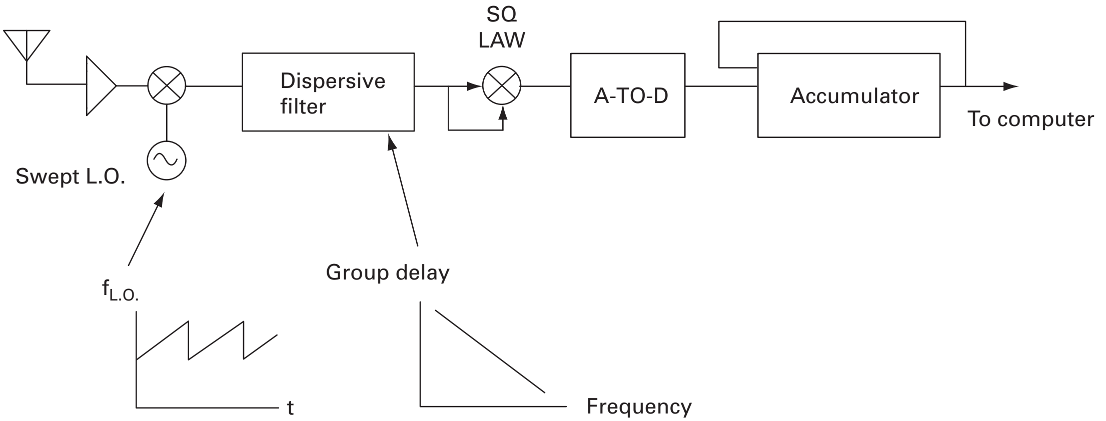

Figure 27.7. Chirp-z spectrometer.

filter has a group delay characteristic that is linear with respect to frequency. In Figure 27.7, the delay is greatest for frequencies at the low end of the filter band. The local oscillator frequency is given a linear sweep or *chirp*, repeated in a sawtooth fashion with period *T*. The ramp rate of the L.O. (MHz/sec) is made to be the reciprocal of the group delay slope (seconds per megahertz) of the filter.

Consider a continuous wave (cw) input signal. Since the L.O. is swept, the mixer output will also sweep in frequency. In the case of a high-side mixer (L.O. frequency above the input signal frequency), the mixer output sweeps up in frequency at the same rate as the L.O. sweep. As the L.O. sweeps upward, the first signals entering the filter are at the filter's low-frequency end. These signals, as they travel through the filter, are delayed the most. Frequencies entering the filter farther up the sweep are delayed less. But all frequencies arrive simultaneously at the filter output, producing a single sharp output pulse. If the input signal consists of two cw tones, there will be two output pulses per sweep. The position of the pulses in time will indicate the frequencies of the cw input signals. Of course this linear system can handle any combination, i.e., spectrum, of input signals. The output data rate from the squarer is equal to the input data rate so additional circuitry (the digital accumulator in Figure 27.7) is required for signal averaging.

The principal application of chirp-z spectrometers has been in electronic warfare – as surveillance receivers to sense radar or communication signals over a wide spectrum and with a high probability of intercept. To find the effective number of channels in this spectrometer we can first consider the output pulse produced by a single cw input signal. This output pulse is produced by a coherent superposition of frequencies over the entire bandwidth, *B*, of the filter. The width of this pulse is therefore given by $1/B$. Dividing the total output time *T* by the pulse width, the effective number of channels is given by *TB*, the time–bandwidth product, just as with the Bragg cell spectrometer.

Dispersive filters used for chirp-z spectrometry are usually surface acoustic wave devices. Piezoelectric transducers convert the input signal into mechanical surface waves and then back again to an electrical output signal. In one design, diffraction gratings on the surface of the crystal are arranged to make the input-to-output path length longer for low-frequency waves than for higher frequency waves. Surface-wave dispersive filters can have bandwidths of hundreds of MHZ and time–bandwidth products of several hundred. Dispersive filters are also made from charge-coupled devices (CCDs). Generically these filters are allpass networks and the first dispersive filters were cascades of many second-order allpass sections. (The number of sections required is equal to the time–bandwidth product.) Note: the filters are not just allpass networks; they are usually given some amplitude "taper," i.e., the amplitude response is made to roll off at the band edges, in order to eliminate the "sidelobes" of the instrumental function that result from uniform amplitude response. The same is done with the AOS; the transmission of the Bragg cell is reduced near the ends.

Problems

Problem 27.1. For the Gaussian probability density, $f(V)=(2\pi\sigma^2)^{-1/2}\exp(-V^2/2\sigma^2)$, verify that

$$\int_{-\infty}^{\infty} f(V)\mathrm{d}V = 1 \quad \text{and} \quad \int_{-\infty}^{\infty} f(V)V^2\mathrm{d}V = \sigma^2.$$

Problem 27.2. (a) The noise-like signals observed in radio astronomy can be modeled as a comb of delta functions in frequency space – a picket fence of sine waves. Use your computer to generate 50 sine waves spanning the angular frequency range 1.00–1.10. Let these frequencies be somewhat random, e.g., $\omega_n = 2\pi(1+0.002n+0.05\ \mathrm{rnd}(1))$ where rnd(1) is a random variable in the range zero to one. Give each sine wave a random starting phase, $\phi_n = 10\ \mathrm{rnd}(1)$. Plot the sum of the sine waves as a function of time for $t=0$ to $t=20$ using a time interval of 0.1. This narrowband spectrum should look quite sinusoidal but with a slowly varying phase and amplitude.

(b) Repeat this exercise but with the angular frequency range extending from 1 to 2, i.e., $\omega_n = 2\pi(1+0.05n+0.05\ \mathrm{rnd}(1))$. This wideband spectrum should look like random noise.

(c) In either case, (a) or (b), the resulting voltage (sum) behaves like a random variable with Gaussian statistics. Plot a histogram of voltage samples to verify this.

Problem 27.3. Suppose a random signal is produced by applying an ideal lowpass filter to white noise. The resulting power spectrum is flat from dc to the filter cutoff frequency ω_c. Show that the normalized autocorrelation function is given by $\rho(\tau)=\sin(\omega_c\tau)/(\omega_c\tau)$.

Problem 27.4. Derive the VanVleck relation, Equation (27.13), that gives the one-bit autocorrelation function in terms of the (normalized) autocorrelation function. Use the bivariate Gaussian probability density function, Equation (27.15), where x_1 and x_2 represent the voltages $V(t)$ and $V(t+\tau)$, and $\sigma_1=\sigma_2$. Since the product $\mathrm{sign}(x_1)\,\mathrm{sign}(x_2)$ is equal to +1 in the first and third quadrants and −1 in the second and fourth quadrants, the expectation of sign(x_1) sign(x_2) is the integral of $f(x_1,x_2)$ over x_1 and x_2, weighted by +1 or −1 according to the quadrant. Hint: change to polar coordinates and keep a table of integrals handy.

Problem 27.5. If the dispersive filter used in the chirp-z spectrometer or pulse compression radar is given an impulse (delta function in time), what sort of output waveform does it produce?

CHAPTER

28

S-parameter circuit analysis

The *S*-parameter (scattering parameter) analysis technique for linear circuits has become the de facto standard in RF engineering, especially for microwave work, where it had its origins in WWII radar development. Physicists-turned-engineers, who were accustomed to analyzing the scattering (collisions) of atomic particles, used that term to describe the reflection and transmission of electromagnetic waves in electrical circuits. The resulting version of circuit theory, in terms of waves rather than currents and voltages, is convenient when working with circuits whose interconnections are transmission lines, especially when those lines are waveguides, where the definitions of voltage and current are somewhat arbitrary. The Smith chart, introduced in 1939, provided a familiar connection to the *S*-parameter method. In the 1960s, Hewlett Packard introduced the first network analyzers for direct *S*-parameter measurements.

28.1 *S*-parameter definitions

Keep in mind that the *S* parameters are just another set of transfer parameters, like the *Y* and *Z* parameters, to describe a linear circuit or circuit element at a given frequency. A two-port network is described equally well by its four complex *Y* parameters, its four complex *Z* parameters, or its four complex *S* parameters. Knowing one set of parameters, we can calculate any other set.

28.1.1 *S* parameter of a one-port network

A resistor, the simplest circuit element, can be described by a single parameter, its resistance, *R*, the ratio of voltage to current. It can be equally well described by its conductance, *G*, the ratio of current to voltage. The conversion between these parameter choices is particularly simple: $G = 1/R$. When a resistor is mounted in a coaxial connector as a dummy load, we regard it as a one-port RF device and often describe it by its reflection coefficient, $\Gamma = (R - Z_0)/(R + Z_0)$, where Z_0, the reference impedance, is often 50 ohms. We saw in Chapter 10 that Γ is the ratio of the reflected wave amplitude to the incident wave amplitude when a wave arrives at the resistor by way of a transmission line of characteristic impedance Z_0. This ratio can be the ratio of either the voltages or currents of the reflected and incident waves, since these ratios are equal. The reflection coefficient is denoted as S_{11}, and is the one and only S parameter for a one-port device. The subscripts refer to a wave leaving port 1 as a result of a wave entering port 1. Using the familiar formula for reflection coefficient, the S parameter of an arbitrary one-port is given by $S_{11} = (Z - Z_0)/(Z + Z_0)$, where Z is the impedance upon which the wave is incident and Z_0 is a reference impedance.

28.1.2 *S* parameters for a general *n*-port network

Let us now define the S parameters of a general n-port device, examples of which include attenuators, filters and amplifiers (two-port devices), two-way power splitters (three-port devices), and directional couplers (four-port devices). For any *properly terminated* n-port device, S_{ij} is the ratio of the (complex) amplitude of the wave exiting port i to the (complex) amplitude of a wave incident on port j. Note that, when $i = j$, the S parameter is a *reflection* coefficient and, when $i \neq j$, the S parameter is a *transmission* coefficient. An n-port device will have n^2 S parameters. Figure 28.1, shows a two-port network reviewing how the input and output currents are written in terms of the amplitudes of forward and reverse waves at each port.

The S parameters for a two-port network are defined as follows:

$$\begin{aligned} S_{11} &= \left.\frac{V_{1\text{rev}}}{V_{1\text{fwd}}}\right|_{V_{2\text{fwd}}=0} & S_{12} &= \left.\frac{V_{1\text{rev}}}{V_{2\text{fwd}}}\right|_{V_{1\text{fwd}}=0} \\ S_{21} &= \left.\frac{V_{2\text{rev}}}{V_{1\text{fwd}}}\right|_{V_{2\text{fwd}}=0} & S_{22} &= \left.\frac{V_{2\text{rev}}}{V_{2\text{fwd}}}\right|_{V_{1\text{fwd}}=0}. \end{aligned} \tag{28.1}$$

$V_2 = V_{2\text{fwd}} + V_{2\text{rev}}$
$I_2 = I_{2\text{fwd}} - I_{2\text{rev}} = \frac{V_{2\text{fwd}}}{Z_0} - \frac{V_{2\text{rev}}}{Z_0}$

Figure 28.1. Forward and reverse waves at the ports of a network.

The condition that the device be properly terminated means that when the *S*-parameters are measured or calculated, each port must be connected to a load impedance equal to the value assigned to that port. Port impedance assignments are usually obvious. If an amplifier is designed to be driven by a 50-ohm source and to feed a 50-ohm load, the input and output ports will both be designated as 50-ohm ports. The one-port dummy load discussed above, if it contains a 50-ohm resistor, would surely be specified by the supplier as having $\Gamma = 0$ (or some very small value). Note, however, that the same 50-ohm device would have a reflection coefficient of (50−100)/(50+100)=−1/3, at a port with an assigned impedance of 100 ohms. When port impedances have been assigned and the corresponding *S* parameters are measured or calculated, the device is totally characterized; if necessary, one can use this set of *S* parameters to calculate a new set of *S* parameters, corresponding to different port impedances.

28.1.3 *S* parameters for an example network

Let us calculate the S parameters for the network shown in Figure 28.2, which contains two passive elements Z_1 and Z_2, which can be resistances or reactances or both, i.e., $Z_1 = R_1 + jX_1$ and $Z_2 = R_2 + jX_2$. Interconnection wires are considered to be infinitesimally short. We will assume 50-ohm port assignments.

To calculate S_{11}, we apply the proper termination, 50 ohms, to port 2 as shown in the figure. S_{11} is then the reflection coefficient at port 1, i.e., $S_{11} = (Z_{in} - Z_0)/(Z_{in} + Z_0)$, where Z_{in} is the impedance looking into port 1. By inspection we see that $Z_{in} = Z_1 + Z_2 \,||\, 50 = Z_1 + (50\, Z_2) /(Z_2 + 50)$. Substituting this expression into the expression for Γ_{in}, we find

$$S_{11} = \frac{Z_1 - 50 + 50Z_2/(Z_2 + 50)}{Z_1 + 50 + 50Z_2/(Z_2 + 50)}. \tag{28.2}$$

V_2
50
Z_2
$S_{21} = V_2 / \left(\frac{V_1 + I_1 Z_0}{2}\right)$
$S_{11} = \Gamma_{in} = (V_1 - I_1 Z_0)/(V_1 + I_1 Z_0)$

Figure 28.2. Example network whose S parameters are calculated.

We calculate S_{22} with the same method, but now terminating port 1 with 50 ohms. Then S_{22} is the reflection coefficient looking into port 2, and we find

$$S_{22} = \frac{Z_2(Z_1 + 50) - 50(Z_1 + Z_2 + 50)}{Z_2(Z_1 + 50) + 50(Z_1 + Z_2 + 50)}. \tag{28.3}$$

To calculate S_{21} (out 2, in 1) we put a 50-ohm load on port 2 and apply an arbitrary voltage V_1 to Port 1. We can then calculate the amplitude of the wave leaving port 2. Because port 2 is properly terminated, there will be no wave reflected back into it. Therefore, the amplitude of the voltage appearing at port 2, V_2, is the amplitude of the wave leaving that port. However, since S_{11} is not zero, V_1 is the sum of an incident wave and a reflected wave. Recalling the transmission line theory of Chapter 10, $V_1 = V_{\text{fwd}} + V_{\text{rev}}$ and $I_1 = I_{\text{fwd}} - I_{\text{rev}} = V_{\text{fwd}}/Z_0 - V_{\text{rev}}/Z_0$. Combining these two equations gives us the amplitude of the forward wave: $V_{\text{fwd}} = ½(V_1 + Z_0 I_1)$. Summing up, a procedure to calculate S_{21} is to apply a voltage V_1 to Port 1, solve for V_2 and I_1, and then calculate $S_{21} = V_2/[½(V_1 + Z_0 I_1)]$. Carrying out this procedure, we find, after a few steps of algebra,

$$S_{21} = \frac{2(50Z_2)}{50Z_2 + (Z_1 + 50)(Z_2 + 50)}. \tag{28.4}$$

If we do the same thing from the other side, to calculate S_{12}, we find that $S_{12} = S_{21}$, which, as we will see later, is not a coincidence.

If, instead of directly calculating S_{11} from the reflection coefficient formula, we had applied a voltage V_1 to port 1, as above, we would have used $S_{11} = (V_1 - I_1 Z_0)/(V_1 + I_1 Z_0)$. Note, then, that we can write general expressions for both S_{21} and S_{11} in terms of conditional ratios of linear combinations of voltage and current, without reference to transmission lines or reflections (or the internals of the two-port), just as we define the *Y* or *Z* parameters:

$$S_{11} = \left.\frac{V_1 - Z_0 I_1}{V_1 + Z_0 I_1}\right|_{V_2 = -Z_0 I_2} \tag{28.5}$$

$$S_{21} = \left.\frac{V_2}{0.5(V_1 + Z_0 I_1)}\right|_{V_2 = -Z_0 I_2}. \tag{28.6}$$

To get the expressions for S_{22} and S_{12}, simply change ones to twos and twos to ones in Equations (28.5) and (28.6).

Before leaving this example, let us look at an alternative way to calculate S_{12} or S_{21}. Rather than connecting an arbitrary voltage generator directly to port 1, we use a 2-V generator and make the connection through a 50-ohm resistor. If the resulting source (the 2-V generator and the 50-ohm series resistor) were connected to a properly terminated 50-ohm cable (or just to another 50 ohm resistor), it would produce a forward wave with an amplitude of 1 V. And if it is connected to a mismatched load, it will still produce a 1-V forward wave. A mismatched load will produce a reflection, but since the source has a 50-ohm

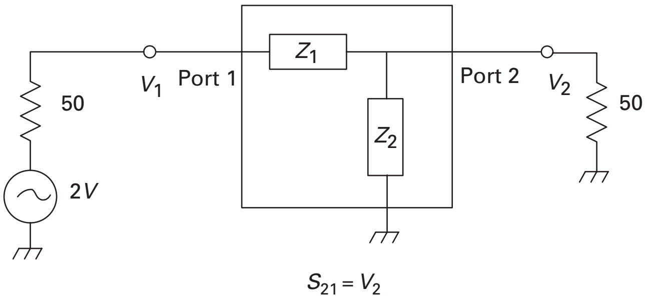

Figure 28.3. Alternate circuit for calculation of S_{21}.

impedance, the reflected wave is totally absorbed and the forward wave maintains its 1-V amplitude. Thus, to calculate S_{21} we simply excite the network with this source and calculate V_2, since $S_{21} \equiv V_{2\text{fwd}}/V_{1\text{fwd}} = V_2/V_{1\text{fwd}} = V_2$. This is shown in Figure 28.3.

28.1.4 Normalization

When the ports of a device are not all assigned the same impedance, it is common to normalize S-parameter magnitudes, i.e., the magnitude of S_{ij} is taken as the square root of the ratio of power emerging from port *i* to power entering port *j* when all other ports are terminated in their assigned impedances.

28.2 Circuit analysis using *S* parameters

Writing the relations between the independent variables (ingoing or "forward" waves) and dependent variables (outgoing or "reverse" waves) for a two-port network in matrix-like form, we have

$$V_{1\text{rev}} = S_{11}V_{1\text{fwd}} + S_{12}V_{2\text{fwd}} \tag{28.7}$$

$$V_{2\text{rev}} = S_{21}V_{1\text{fwd}} + S_{22}V_{2\text{fwd}}. \tag{28.8}$$

Let us use these two equations to solve a basic network problem: finding the reflection coefficient at port 1 of a two-port network when port 2 is connected to an arbitrary load, as shown in Figure 28.4.

As we have noted, the load can be specified by its reflection coefficient, Γ_L. That immediately requires that $V_{2\text{fwd}} = \Gamma_\text{L} V_{2\text{rev}}$, i.e., a fraction Γ_L of the wave leaving port 2 is reflected back into port 2. We will set $V_{1\text{fwd}}$ to unity so that the reflection coefficient at port 1 will be $V_{1\text{rev}}$. Equations (28.7) and (28.8) then become

$$V_{1\text{rev}} = S_{11} \cdot 1 + S_{12}\Gamma_L V_{2\text{rev}} \tag{28.9}$$

$$V_{2\text{rev}} = S_{21} \cdot 1 + S_{22}\Gamma_L V_{2\text{rev}}. \tag{28.10}$$

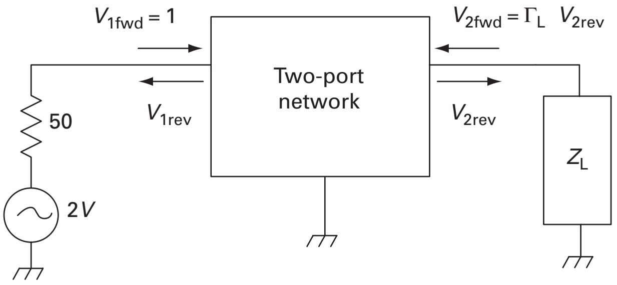

Figure 28.4. A two-port network with an arbitrary load.

Solving Equation (28.10) for V_{2rev} and substituting into Equation (28.9), we find

$$\Gamma_{in} = V_{1rev} = S_{11} + \frac{S_{12}\Gamma_L S_{21}}{1 - S_{22}\Gamma_L}. \tag{28.11}$$

If we simply turn things around, we see that the reflection coefficient seen at port 2 is obtained by interchanging 1's and 2's and *S*'s and *L*'s in this expression, i.e.,

$$\Gamma_{out} = V_{2rev} = S_{22} + \frac{S_{21}\Gamma_S S_{12}}{1 - S_{11}\Gamma_S}. \tag{28.12}$$

28.2.1 Signal flow graphs

A convenient aid to S-parameter circuit analysis is the signal flow graph – a directed graph that represents a set of linear equations. A signal flow graph for the circuit discussed above is shown in Figure 28.5(a).

The nodes (dots) on the graph correspond to the magnitudes of the forward and reverse waves. The branches (lines) are labeled with the transfer coefficients (*S* parameters) that determine the node values. Equations (28.7) and (28.8) are contained in this graph. Consider for example the node at the upper right, V_{2rev}. Only two branches are directed toward this node, one from V_{1fwd} and one from V_{2fwd}. Summing the contributions that arrive through these branches we write $\mathrm{V}_{2rev} = S_{21}\ V_{1fwd} + S_{22}\ V_{2fwd}$, which is just Equation (28.8). On this graph, the load is represented by a branch which indicates that $V_{2fwd} = \Gamma_L\ V_{2rev}$. The source, which could be the 2-V generator and series 50-ohm resistor, produces a forward wave with a magnitude of one, which is represented on the graph by assigning the value unity to the left-most node, V_{1fwd}. Let us now see how we can use the graph to arrive at our previous result for the reflection coefficient, V_{1rev}. Inspecting the graph, we see that if we first find the value of V_{2rev}, we will immediately be able to write

$$V_{1rev} = V_{2rev}\Gamma_L S_{12} + 1 \cdot S_{11} \tag{28.13}$$

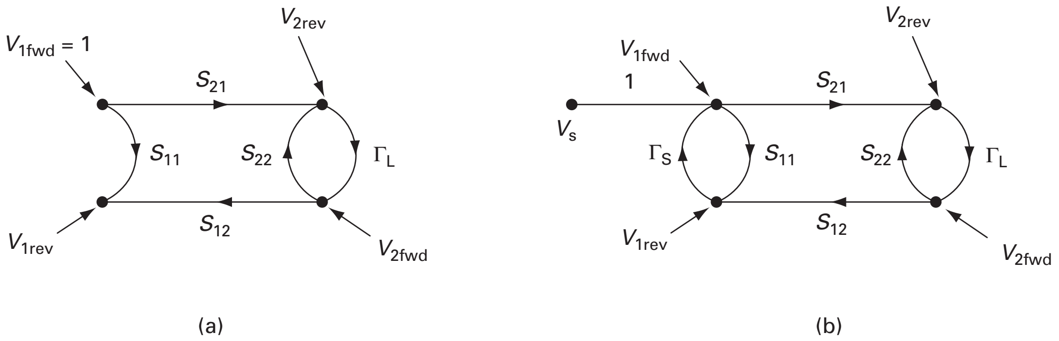

Figure 28.5. (a) Signal flow graph for the circuit of Figure 28.4; (b) same, but for a source whose impedance is not Z_0.

by following the two paths into the node V_{1rev}. Focusing on the node V_{2rev}, see that two branches are directed into it, so we write $V_{2rev} = 1 \cdot S_{21} + V_{2rev}\,\Gamma_L\,S_{22}$, from which $V_{2rev} = 1 \cdot S_{21}/(1-\Gamma_L)$. Substituting this into Equation (28.13) produces $V_{1rev} = S_{11} + \Gamma_L\,S_{12}\,S_{21}/(1-\Gamma_L)$, as before.

28.2.2 Two-port transmission and reflection with arbitrary source and load impedances

Let us now look at the same circuit, but with an imperfect source, i.e., a source having a reflection coefficient $\Gamma_S \neq 0$. The signal flow graph, Figure 28.5(b), acquires two extra branches. One is Γ_S, which steers some of the reflection from the two-port around, contributing to V_{1fwd}. The other branch comes from a node, V_S, which is the forward wave the source would produce at a matched input port. Our goal is to solve for V_{2rev}, the wave transmitted to the load. Examining the graph, we write simultaneous equations for V_{2rev} and V_{1fwd}:

$$V_{2rev} = V_{1fwd}S_{21} + V_{2rev}\Gamma_L S_{22} \tag{28.14}$$

$$V_{1fwd} = V_S + V_{1fwd}S_{11}\Gamma_S + V_{2rev}\Gamma_L S_{12}\Gamma_S. \tag{28.15}$$

Eliminating V_{1fwd}, we have our desired result:

$$V_{2rev} = \frac{V_S S_{21}}{(1-\Gamma_L S_{22})(1-\Gamma_S S_{11}) - S_{12}S_{21}\Gamma_L\Gamma_S}. \tag{28.16}$$

Note: if the identification of the equations for V_{2rev} and V_{1fwd} is too great a reach, the reader can readily identify equations for all four variables:

$$\begin{aligned} V_{2rev} &= V_{1fwd}S_{21} + V_{2fwd}S_{22} \\ V_{2fwd} &= V_{2rev}\Gamma_L \\ V_{1rev} &= V_{2fwd}S_{12} + V_{1fwd}S_{11} \\ V_{1fwd} &= V_S + V_{1rev}\Gamma_S \end{aligned}$$

and then eliminate V_{2fwd} and V_{1rev} to obtain Equations (28.14) and (28.15).

When the two-port is an amplifier, we often want to find the gain. There are several definitions of gain. The *operating power gain* is just the ratio of the net power delivered to the load to the net power delivered by the source. The *transducer gain* is the ratio of the net power delivered to the load to the power available from the source, and the *available power gain* is the ratio of the power available from the amplifier divided by the power available from the source. Let us calculate the operating power gain. The net power delivered to the load is the power of the wave into the load, $|V_{2\text{rev}}|^2$, minus the power of the wave leaving the load, $|\Gamma_L V_{2\text{rev}}|^2$, i.e., $P_{\text{load}} = |V_{2\text{rev}}|^2 (1 - |\Gamma_L|^2)$. The net power delivered by the source is the power of the wave from the source minus the power reflected back into the source, i.e., $P_{\text{source}} = |V_{1\text{rev}}|^2(1 - |\Gamma_{\text{in}}|^2)$, where Γ_{in} is the reflection coefficient already calculated (Equation 28.11). To find $V_{1\text{fwd}}$, we can substitute the expression for $V_{2\text{rev}}$ back into Equation (28.13). Stirring this all together, we find

$$G_{\text{operating}} = \frac{|S_{21}|^2(1 - |\Gamma_L|^2)}{|1 - \Gamma_L S_{22}|^2(1 - |\Gamma_{\text{in}}|^2)}. \tag{28.17}$$

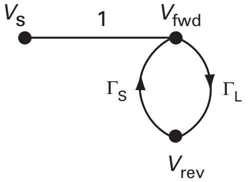

Figure 28.6. Signal flow graph for a source driving a load. The source would supply a forward wave of amplitude V_S to a load for which $\Gamma_L = 0$.

To calculate the other gain expressions, we must find expressions for the available powers. Figure 28.6 shows a load connected to a generator. Again, this is a generator that would supply V_S volts to a resistive load of Z_0 ohms.

From this signal flow graph we see that $V_{\text{fwd}} = V_S + V_{\text{fwd}} \Gamma_L \Gamma_S$ or $V_{\text{fwd}} = V_S/(1-\Gamma_L \Gamma_S)$. The net power to the load is $|V_{\text{fwd}}|^2/Z_0 - |V_{\text{rev}}|^2/Z_0 = |V_{\text{fwd}}|^2 (1-|\Gamma_L|^2)$. We know that maximum power is transferred to the load when $Z_L = Z_S^*$, from which $\Gamma_L = \Gamma_S^*$. Putting this together, the maximum available power from the source becomes $|V_S|^2/[Z_0 (1-|\Gamma_S|^2)]$. In the same way, the maximum available power from the network is $|V_{2\text{rev}}|^2/[Z_0 (1-|\Gamma_{\text{out}}|^2)]$. Finally, we can also find the voltage amplification factor $A_V = V_2/V_1$, since we know that $V_1 = V_{1\text{fwd}} - V_{1\text{rev}}$ and $V_2 = V_{2\text{fwd}} - V_{2\text{rev}}$.

28.3 Stability of an active two-port (amplifier)

If the input impedance measured at any port of a device has a negative real part – a negative resistance – the device can supply power. Obviously this can only occur with active devices, such as amplifiers, which are connected to an external source of power. An impedance with a negative resistance value produces a reflection coefficient, Γ, whose magnitude is greater than unity (Problem 28.2). Thus, if $|S_{ii}| > 1$, the device has the potential for oscillation. It will oscillate unless the port is terminated with an impedance whose real part is larger than the negative resistance of the port. To see if an amplifier is potentially unstable, we check whether there are any values of load impedance that will make $|\Gamma_{\text{in}}| > 1$ and also whether there are any values of source impedance that will make $|\Gamma_{\text{out}}| > 1$. Consider first the load impedances. We use the expression for Γ_{in}

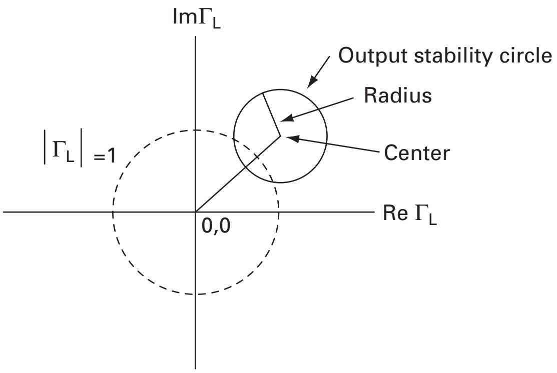

Figure 28.7. Output stability circle in the Γ_L plane.

given in Equation (28.11) and find all the values of Γ_L that will make $|\Gamma_{in}| = 1$. These values of Γ_L will form a closed curve, always a circle,[1] that divides the Γ_L plane into two regions. The values of Γ_L in one region result in $|\Gamma_{in}| < 1$, while the values of Γ_L in the other region result in $|\Gamma_{in}| > 1$ (potential instability). You can use Equation (28.11) to show that the circle in the Γ_L plane, called the *output stability circle*, will be centered at the point

$$\Gamma_L(\text{center point}) = \left| \frac{S_{22}^* - \Delta^* S_{21}}{|S_{22}|^2 - |\Delta|^2} \right|, \tag{28.18}$$

where $\Delta = S_{11}S_{22} - S_{12}S_{21}$, and will have a radius given by

$$\text{rad}_L = \left| \frac{S_{12}S_{21}}{|S_{22}|^2 - |\Delta|^2} \right|. \tag{28.19}$$

Figure 28.7 shows an example of an output stability circle. Suppose we have found that the “good” values of Γ_L are in the region outside the output stability circle (for example, by verifying that $|\Gamma_{in}| < 1$ for $\Gamma_L = 0$). For this example, the output stability circle partially overlaps the $|\Gamma_L| = 1$ circle. Values of Γ_L in the overlap region are “bad” values; they will give the amplifier a negative input resistance, even though these Γ_L values correspond to passive loads. The “bad” values outside the overlap region all have $|\Gamma_L| > 1$ so they represent loads with negative resistance. These values could be important if the load is not passive, for example, the input of an amplifier which might have $|\Gamma_{in}| > 1$.

---

[1] The locus of points $|\Gamma_{in}| = 1$ is a circle in the Γ_{in} plane. The expression for Γ_{in} (Equation 28.11) can be written in the form $\Gamma_{in}(z) = (a + b\,\Gamma_L)/(c + d\,\Gamma_L)$, where a, b, c, and d are constants. This form, a *bilinear transformation*, maps circles to circles. Thus the values of Γ_L that map to a circle in the Γ_{in} plane must form a circle in the Γ_L plane. In the same way, the constant resistance and constant reactance circles on the Smith chart (Γ plane) are mapped from the Z-plane, where they are segments of infinite-radius circles (lines).

As you can imagine, *input stability circles* are found in the same way. Interchange twos and ones in Equations (28.18) and (28.19) to get the radius and center point for the input stability circle. If both the output and input stability circles lie totally outside the $\Gamma < 1$ circle, an amplifier is unconditionally stable, i.e., no combination of passive terminations will cause it to oscillate.

28.4 Cascaded two-ports

Two-port devices are often connected in series, as in cascades of amplifiers and filters or in amplifiers, as cascades of components. Obviously a cascade of two two-port devices must be equivalent to a single two-port device, and the *S* parameters of the equivalent device must be functions of the *S* parameters of the individual devices. In Figure 28.8, a cascade is fed by a reflectionless source providing a wave of amplitude unity. We place a reflectionless load at the far end. Therefore, the wave reflected back into the source will be S_{11}, while the wave incident on the load will be S_{21}.

Because of the matched load and matched source, this circuit is quite simple to analyze. Let *x* represent the value of the signal at the top center, the forward wave into device B. By inspection of the graph we can immediately write an equation for *x*: $x = S^A{}_{21} + x\, S^B{}_{11} S^A{}_{22}$ or $x = S^A{}_{21}/(1\text{-}S^B{}_{11} S^A{}_{22})$. Therefore $S_{11} = S^A{}_{11} + x S^B{}_{11} S^A{}_{12}$ or

$$S_{11} = S^A_{11} + S^A_{21} S^B_{11} S^A_{12}/(1 - S^B_{11} S^A_{22}). \qquad (28.20)$$

Note that we had earlier found the reflection coefficient of a two-port terminated by an arbitrary load. In this case the arbitrary load is just $S^B{}_{11}$. Again by inspection, S_{21} is just $x S^B{}_{21}$ or

$$S_{21} = S^B_{21} S^A_{21}/(1 - S^B_{11} S^A_{22}). \qquad (28.21)$$

Interchanging S^A's with S^B's and ones with twos gives us the remaining two S parameters:

$$S_{22} = S^B_{22} + S^B_{12} S^A_{22} S^B_{21}/(1 - S^A_{22} S^B_{11}) \qquad (28.22)$$

$$S_{12} = S^A_{12} S^B_{12}/(1 - S^A_{22} S^B_{11}). \qquad (28.23)$$

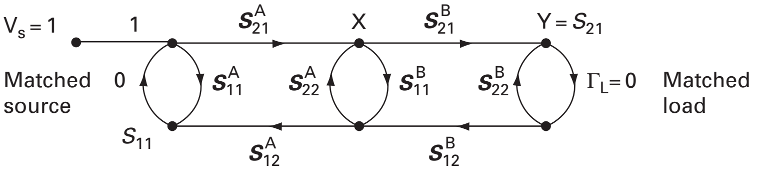

Figure 28.8. Circuit for calculation of overall *S* parameters for a cascade of two two-port devices having *S*-parameter sets $\{S^A\}$ and $\{S^B\}$.

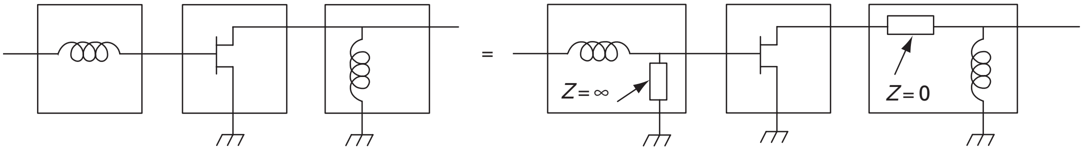

Figure 28.9. An amplifier drawn as a cascade of two-port networks.

In an amplifier, transistors are obvious two-port devices. Shunt and series impedances can also be treated as two ports, as shown in Figure 28.9, which shows that they are just special cases of the network of Figure 28.2.

28.5 Reciprocity

In circuit theory, a common statement of the reciprocity theorem is that if a voltage source V is inserted into any branch of a circuit, branch n, say, and it causes a current of I amps to flow in branch m, then the same current, I, would flow in branch n if the voltage source had been inserted in branch m. This is a conditional theorem; the circuit must contain only passive linear elements (no tubes or transistors or other dependent sources). Moreover, the circuit must not contain nonreciprocal elements, i.e., *circulators* or *isolators* which are microwave components that contain ferrites – magnetic materials in which the permeability is a tensor ($\boldsymbol{H}$ and $\boldsymbol{B}$ are not in the same direction). We used this theorem in Chapter 20 to find the relation between an antenna's receiving performance (effective capture area) and its transmitting performance (directional gain). In the context of S-parameter analysis, the theorem requires that $S_{ij} = S_{ji}$, i.e., the S matrix must be symmetric, even when the circuit itself is not symmetric, as in Figure 28.2. (Reciprocity takes the same form with the Z and Y parameters; $Z_{ij} = Z_{ji}$ and $Y_{ij} = Y_{ji}$.)

28.6 Lossless networks

A lossless network contains no resistive elements. For such networks, conservation of energy requires that the average total power going into the network be equal to the average total power leaving the network. (In S-parameter analysis we are dealing with ac, so the averaging time, strictly speaking, should be an integral number of cycles.) Let us see how the constraint of energy conservation puts constraints on the S parameters.

Suppose we connect a generator of output impedance Z_0 to port i of an N-port network while all the other ports are properly terminated. Let this generator supply a forward wave whose amplitude is unity. No power will flow into the network from the other ports, since they all have nonreflective terminations. Assuming normalized impedances, the total power flowing into the network is therefore 1. The total power flowing out will be the sum of $|S_{ii}|^2$, the power reflected back into the generator plus $\sum|S_{ji}|^2$, summed over the other ports. Putting this into a single sum and equating the powers, we have

$$\sum_{j=1}^{N}\left|S_{ji}\right|^2 = 1. \tag{28.24}$$

This says that the sum of the squared magnitudes of any column of the S matrix must be unity, if the network is lossless. And, since $S_{ij}=S_{ji}$, the same is true for any row. Next, consider the situation where power is fed simultaneously into *two* ports. Let us apply a forward wave of amplitude V_i to port i and a forward wave of amplitude V_k to port k. Again, we use reflectionless generators ($Z_{\text{out}}=Z_0$) and terminate the other $N-2$ ports in Z_0. The total input power will be $|V_i|^2+|V_k|^2$. This must equal the total output power, which is the sum of the squares of the magnitudes of the waves leaving the ports, i.e.,

$$|V_i|^2+|V_k|^2=\sum_{j=1}^{N}\left|(V_iS_{ji}+V_kS_{jk})\right|^2. \tag{28.25}$$

Expanding the right-hand side we find

$$|V_i|^2+|V_k|^2=|V_i|^2\sum_{j=1}^{N}\left|S_{ji}\right|^2+|V_k|^2\sum_{j=1}^{N}\left|S_{jk}\right|^2+2\mathrm{Re}\left(V_iV_k^*\sum_{j=1}^{N}S_{ji}S_{jk}^*\right). \tag{28.26}$$

From Equation (28.24), we see that the first two terms on the right are equal to the first two terms on the left, leaving us with

$$0=2\mathrm{Re}\left(V_iV_k^*\sum_{j=1}^{N}S_{ji}S_{jk}^*\right). \tag{28.27}$$

Since V_i and V_k are arbitrary, their product could be entirely real or entirely imaginary which requires that, for $i\neq k$,

$$\sum_{j=1}^{N}S_{ji}S_{jk}^*=0. \tag{28.28}$$

Thus, for a lossless network, the "dot product" of one column of the S matrix times the complex conjugate of any different column, must be zero. The same is true for rows since $S_{ij}=S_{ji}$.

Let us apply Equations (28.24) and (28.28) to a lossless two-port network. A general two-port is described by four complex S parameters, i.e., eight real numbers. If the network is reciprocal, $S_{ij}=S_{ji}$, reducing the eight real numbers to six. If the network is lossless, Equation (28.24) gives us $|S_{21}|^2+|S_{11}|^2=1^2$. Thus the magnitude of the transmitted wave is determined completely by the magnitude of the reflected wave, $|S_{21}|^2=1-|S_{11}|^2$, i.e., we could determine the bandpass shape of a lossless filter by just measuring its input reflection coefficient (with the output correctly terminated). Equation (28.24) also gives us $|S_{12}|^2 + |S_{22}|^2 = 1$. With these two equations, the number of real parameters drops to four. Note that, from these two equations, it also follows that $|S_{22}|^2 = |S_{11}|^2$. Next we apply Equation (28.28), giving us

$$S_{11}S_{12}^* + S_{21}S_{22}^* = 0. \tag{28.29}$$

This appears to be two equations (real and imaginary parts), but actually amounts to only one equation [1]. To see this we express the S parameters in polar form as $S_{11} = |S_{11}|e^{j\theta_1}$, $S_{22} = |S_{11}|e^{j\theta_2}$, and $S_{21} = (1 - |S_{11}|^2)^{½} e^{j\phi}$. Putting these expressions, which contain four parameters, into Equation (28.28) will give us $[e^{j(\theta_1-\phi)} + e^{j(\phi-\theta_2)}] = 0$, from which $\theta_2 = 2\phi - \theta_1 + (2n+1)\pi$ where n is an integer. Any odd multiple of π will be equivalent, so we can set $\theta_2 = 2\phi - \theta_1 + \pi$. Thus we see that a lossless two-port network can be completely specified by only *three* real numbers, $|S_{11}|$, θ_1 and ϕ.

If we have a vector reflectometer (a one-port network analyzer) and measure S_{11} and S_{22} for a lossless two-port, we will have values for $|S_{11}|$, θ_1, $|S_{22}|$ and θ_2. Writing ϕ in terms of θ_1 and θ_2 gives $\phi = [\theta_2 + \theta_1 - (2n+1)\pi]/2$. If n is increased by one, ϕ changes by π. Therefore, while measurements of either S_{11} or S_{22} let us calculate the magnitude of S_{12}, measurements of both S_{11} and S_{22} allow us also to calculate the phase of S_{12}, but with a 180° ambiguity. (To see that this must be the case, suppose we attach a half-wave cable to one side of a two-port network. Then S_{11} and S_{22} will remain unchanged, but S_{12} will change by 180°.)

Since it can be described by three real numbers, a lossless two-port can also be modeled (for one frequency) as a network containing three parameters. As an example of such a network, suppose we start with the capacitor, which, if paralleled with a 50-ohm resistor, would produce an impedance Z, such that $|(1-Z)/(1+Z)| = |S_{11}|$. Let this capacitor be a shunt element to ground. To its left, install a 50-ohm cable with the length needed to get the correct phase for S_{11}. To its right, install a 50-ohm cable whose length produces the specified phase for S_{22}. One capacitor value and two lengths make up the three parameters.

Finally, since a lossless two-port must contain only reactors (no resistors), Z or Y-parameter analysis will show that the Z or Y parameters must be completely imaginary. Add in reciprocity, and four imaginary numbers become three imaginary numbers, showing us again that a lossless two-port can be specified by three parameters.

Three-port lossless networks

We saw in Chapter 15 that hybrids are four-port networks that are completely matched, that is, the impedance looking into any port will be equal to Z_0 if the other three ports are terminated in Z_0. Let us show by contradiction that a lossless reciprocal three-port network cannot have this property. Suppose, then, that we have a matched three-port, i.e.,

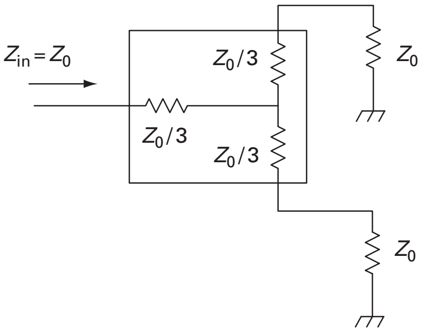

Figure 28.10. 6-dB matched power divider.

$$S = \begin{bmatrix} 0 & S_{12} & S_{13} \\ S_{12} & 0 & S_{23} \\ S_{13} & S_{23} & 0 \end{bmatrix}, \qquad (28.30)$$

where we have also assumed reciprocity, i.e., $S_{21}=S_{12}$, $S_{23}=S_{32}$, and $S_{13}=S_{31}$. Applying Equation (28.28) to rows one and two, we find $S_{13}\,S_{23}=0$. One of these parameters must be zero, say, S_{13}. The S matrix then becomes

$$S = \begin{bmatrix} 0 & S_{12} & 0 \\ S_{12} & 0 & S_{23} \\ 0 & S_{23} & 0 \end{bmatrix}. \qquad (28.31)$$

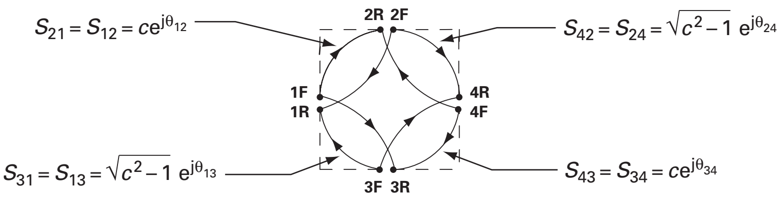
Finally, applying Equation (28.24) to row one yields $S_{12}=0$ and applying it to row three yields $S_{23}=0$.

Thus, if a lossless reciprocal three-port network is matched, all of its elements are zero. Power going in any port is totally absorbed – the opposite of lossless. Three resistors, each of value $Z_0/3$ in “T” connection, as shown in Figure 28.10, form a matched but lossy three-port network that is often used as a power divider.

A circulator is a matched nonreciprocal device; it contains ferrite material. You can show (Problem 28.4) that any lossless matched three-port must be a circulator. Power entering port 1 exits from port 2; power entering port 2 exits from port 3; and power entering port 3 exits from port 1.

Directional couplers

In Chapter 15 we looked at hybrids, which are 3-dB directional couplers. From Equations (28.24) and (28.28) it can be shown that any lossless matched ($S_{ii}=0$ for all i) reciprocal four-port network must be a directional coupler and that, conversely, and directional coupler will be matched. Figure 28.11 is a signal flow graph of the general directional coupler. Opposite ports are isolated from each other, i.e., $S_{14}=0$ and $S_{23}=0$. The real number c is the coupling coefficient. If $c=0.1$ for example, the power coupling is $c^2=0.01$ and the device is a 20-dB directional coupler. For hybrids, $c^2=1/2$.



$S_{21} = S_{12} = ce^{j\theta_{12}}$
2R 2F
$S_{42} = S_{24} = \sqrt{c^2 - 1}\, e^{j\theta_{24}}$
1F
1R
4R
4F
$S_{31} = S_{13} = \sqrt{c^2 - 1}\, e^{j\theta_{13}}$
3F 3R
$S_{43} = S_{34} = ce^{j\theta_{34}}$

Figure 28.11. Directional coupler signal flow graph.

From Equation (28.28) you can show that

$$e^{j(\theta_{12}-\theta_{24})} + e^{j(\theta_{13}-\theta_{34})} = 0, \tag{28.32}$$

which imposes the condition

$$\theta_{12} - \theta_{24} = \theta_{13} - \theta_{34} \pm \pi. \tag{28.33}$$

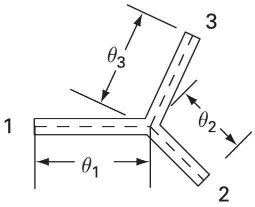
Problems

Problem 28.1. The net power absorbed by a load is $P = (|V_{\text{fwd}}|^2/Z_0) - 1/2\,(|V_{\text{rev}}|^2/Z_0)$, i.e., the net power delivered to the load. Show that this is equal to the power expressed by the current voltage product at the load, $P = \text{Re}(VI^*)$.

Problem 28.2. Show that if the real part of Z is negative, the reflection coefficient, $(Z-Z_0)/(Z+Z_0)$, will have a magnitude greater than unity.

Problem 28.3. Derive an expression for S_{11} of a two-port in terms of its Y parameters. Hint: use Equation (28.5), together with the definition of the Y parameters: $I_1 = V_1Y_{11} + V_2\,Y_{12}$ and $I_2 = V_1Y_{21} + V_2Y_{22}$. Remember that port 2 is terminated in Z_0.

Problem 28.4. Three 50-ohm transmission lines are connected as shown in the figure to form a three-port network. The electrical lengths of these lines are θ_1, θ_2, and θ_3. Find the S parameters of this network. Hint: first find the S parameters when lengths are zero and then determine the appropriate phase factors.



Problem 28.5. Draw a circuit for a three-port network whose S parameters are all zero.

Problem 28.6. Show that a matched three-port device must be a circulator. Hint: write down the S matrix with zeros on the diagonal (the matching condition) but do not assume $S_{ij} = S_{ji}$ for the off-diagonal elements. Use Equations (28.24) and (28.28).

Problem 28.7. A linear three-port network has ports 2 and 3 terminated with Γ_2 and Γ_3, respectively. Find the reflection coefficient, Γ, looking into port 1. Hint: the signal flow graph is shown below. A forward wave of magnitude 1 is assigned to port 1. Select the two intermediate points, y and z, and find their values by first writing an equation for each one by inspection of the graph. Then, by inspection of the graph, $\Gamma = S_{11} + y\,\Gamma_3\,S_{13} + z\,\Gamma_2\,S_{12}$.

CHAPTER

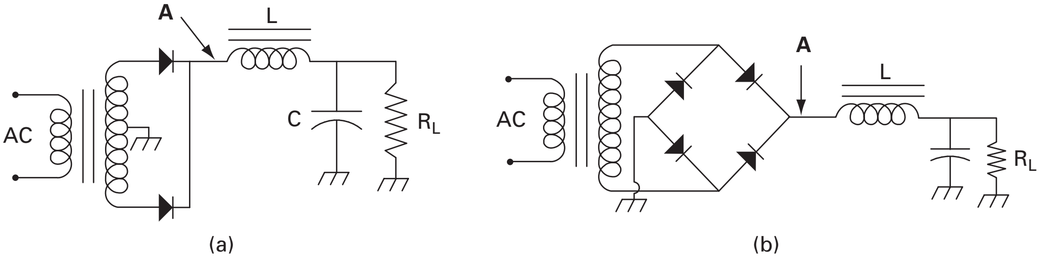
29 Power supplies

Power supplies provide the constant dc voltage(s) used to power amplifiers, oscillators, and logic circuitry. As switching frequencies increase, RF engineers need to understand switching power supply techniques, which are often incorporated in the designs of high-efficiency RF amplifiers, and power supply designers need to learn RF techniques. Conventional power supplies, originally known as "battery eliminators," operate from the ac power line and are usually transformer/rectifier/filter combinations. Dc-to-dc converters are called switching power supplies. Both conventional and switching power supplies are discussed in this chapter.

29.1 Full-wave rectifier

Probably the most straightforward circuit combines a full-wave rectifier with a choke-input filter. A "choke" is an inductor which ideally has infinite inductance and no dc resistance. Two such power supplies are shown in Figure 29.1.

Figure 29.1. Choke-input power supplies: (a) full-wave; (b) full-wave bridge.



The full-wave rectifier delivers power on both the positive and negative halves of the input ac waveform. The bridge version does not require a center-tapped transformer and needs only half as much copper in the secondary winding, since it uses the entire secondary winding on both halves of the cycle. The two-rectifier circuit, on the other hand, has only half as much rectifier voltage drop and, for that reason, is usually chosen for low-voltage supplies (five volts

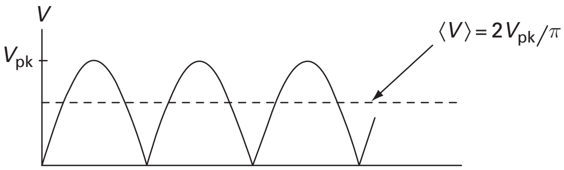


Figure 29.2. Voltage waveform at the filter input. The average value of this waveform is the dc voltage at the output of the filter.

or less) in order to maintain high efficiency. For either circuit, the voltage at point "A" should be as shown in Figure 29.2.

29.1.1 Inherent regulation of the choke-input power supply

Here regulation means voltage stability with respect to changes in the load, R_L. (A separate consideration is regulation with respect to variations in the input ac voltage.) It is important to see that a choke-input power supply provides constant output voltage as long as the current through the choke is never zero. Here is why: If the current through the choke is not zero, then either one rectifier (or rectifier pair) or the other is forward biased and has nearly zero voltage drop. The left side of the choke is therefore always connected to the transformer secondary and the voltage will be as shown in Figure 29.2, complete half-cycle cusps from zero to V_{pk}, the peak secondary voltage. This waveform, in as much as it derives from an almost ideal voltage source (the power line), is practically independent of load current. Its average value is $V_{pk}(2/\pi)$. Since there can be no dc voltage across an (ideal) inductor, the dc component on R_L is the same, V_{pk} $(2/\pi)$, and the regulation is perfect except for the small ohmic losses in the rectifiers, transformer windings and choke, and any leakage inductance in the transformer.

Let us see what is necessary to maintain a nonzero current in the choke. The L-section *LC* filter suppresses ripple, so the ac voltage at the right-hand side of the inductor is negligible compared to the ac voltage at the left-hand side. At the left-hand side, most of the ac voltage is the 120-Hz component of the rectifier output. Since the peak rectifier voltage is V_{pk}, the peak voltage of the 120-Hz Fourier component is $4V_{pk}/3\pi = 0.42V_{pk}$. The peak ac current through the choke will be $4V_{pk}/(3\pi\omega L)$. To keep the current from turning off the rectifiers and bottoming out, the dc current must be greater than this peak ac current. Therefore we have $2V_{pk}/(\pi R_L) > 4V_{pk}/(3\pi\omega L)$ or $L > 2R_L/3\omega$. This minimum inductance is known as the critical inductance,

$$L_{\text{critical}} = 2R_L/3\omega. \tag{29.1}$$

In some applications the load may vary such that the current drops to very low values, even zero. A minimum current can be guaranteed by paralleling a "bleeder" resistor across the load. Unfortunately, the resistor will consume

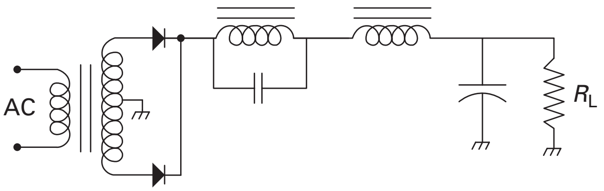

Figure 29.3. Power supply with a resonant filter.

some power. High-voltage power supplies often include a bleeder for safety; it discharges the filter capacitor when the supply is turned off. Another method to maintain constant current is to use a "swinging" choke which has high inductance when needed (i.e., at low current) but presents lower, though still sufficient, inductance at high current, where the core goes into partial saturation.

Ripple

The L and C form a simple L-section lowpass filter. In a full-wave power supply the peak value of the "ripple," the 120-Hz sine wave at the input of the filter (left-hand side of the choke) is $0.42V_{\text{pk}}$. The capacitor will normally have a reactance much smaller than the load resistance, R_L, so we can find the output ripple voltage by considering just the L and C as a voltage divider:

$$V_{\text{ripple(peak)}} = \frac{0.42V_{\text{pk}}X_C}{X_L - X_C}. \tag{29.2}$$

Sometimes a resonant LC circuit is used, as in Figure 29.3, as a bandpass filter to suppress the primary ripple frequency even more.

29.2 Half-wave rectifier

The simplest rectifier circuit, shown in Figure 29.4, uses a single diode. With just a load resistor (no filtering), the output waveform is zero during the negative half-cycles of the 60-Hz line voltage.

Obviously this arrangement does not make good use of the transformer secondary. Moreover, if we add the series L, shunt C filter to get a smooth dc output, the voltage waveform at a point "A" will float upward by an amount depending on the load and there will be no inherent voltage regulation. The solution is to add a "freewheeling" diode, as shown in Figure 29.5.

When the voltage at the top of the secondary becomes negative and "disconnects" the top diode, the freewheeling diode conducts and continues to supply current (from ground) to the inductor. The voltage at the left-hand side of the choke is therefore always the positive secondary voltage or zero volts, just as in Figure 29.4(b), and the circuit can have the inherent regulation of the full-wave choke-input power supply.

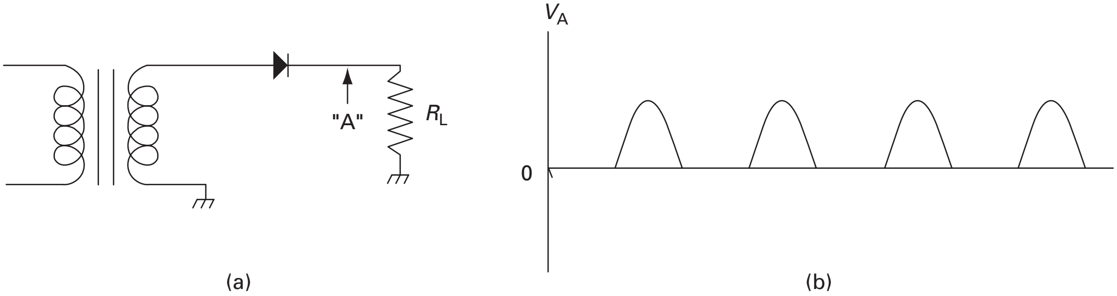

Figure 29.4. Simple half-wave rectifier circuit.

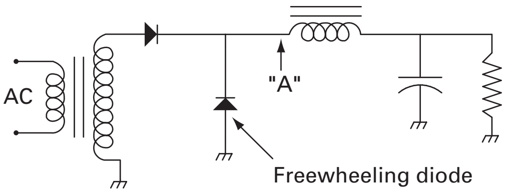
Figure 29.5. A half-wave circuit can also have choke-input regulation if a freewheeling diode is included.



The simplest power supplies use an *RC* filter, substituting a resistor for the inductor. Power is wasted in the resistor and regulation is poor; the average voltage at the rectifier output depends on the load. Of course, for many low-power devices that draw constant current or can tolerate voltage variations, these disadvantages are slight, and this is the kind of circuit you will find in "wall wart" dc power adapters.

29.3 Electronically regulated power supplies

If a basic power supply, such as any of those described above, is followed by a series "pass transistor," a feedback circuit can control the pass transistor's resistance to maintain an extremely constant output voltage. A typical circuit is shown in Figure 29.6.

Note that the pass transistor is used as a series "dropping resistor." An alternate regulator circuit uses a series resistor followed by a parallel transistor as an active bleeder resistor to make a shunt-regulated power supply. These regulator circuits, really just class-A dc amplifiers with negative feedback, operate by dissipating power. Laboratory power supplies use this kind of circuitry to achieve precise regulation and to allow the user to set the desired voltage, as well as a protective current limit. If the load tries to exceed the current limit, the circuitry switches from a voltage regulation mode to a current regulation mode.

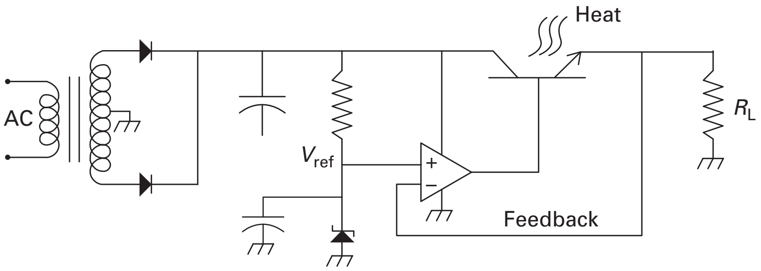


Figure 29.6. Electronically regulated power supply.

29.4 Three-phase rectifiers

Big power supplies, like big motors, benefit from three-phase power which allows more efficient power transmission and lighter transformers. Let us examine a few common circuits. Figure 29.7 shows a three-phase half-wave supply.

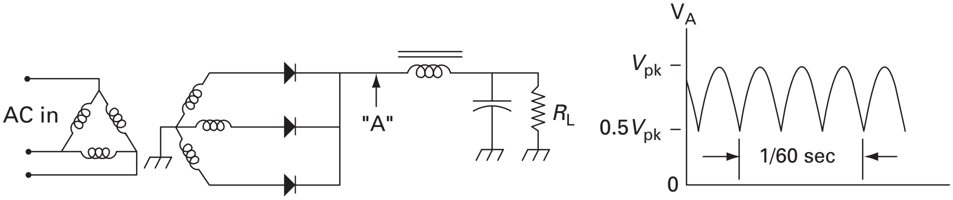

Figure 29.7. Three-phase half-wave power supply.

This is already an improvement over the full-wave single phase supply. The voltage at the input to the choke has a higher ripple frequency (180 rather than 120 Hz) and much less ripple, since the voltage at point “A” is always greater than $V_{pk}/2$. Choke-input filters can be used without the need for freewheeling diode(s). A three-phase full-wave rectifier is shown in Figure 29.8.

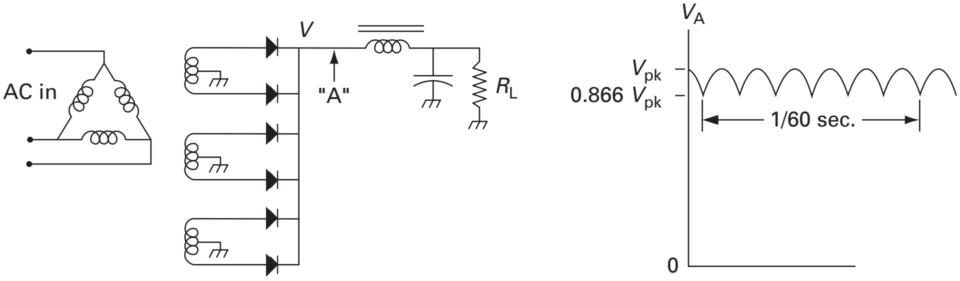

Figure 29.8. Three-phase full-wave power supply.

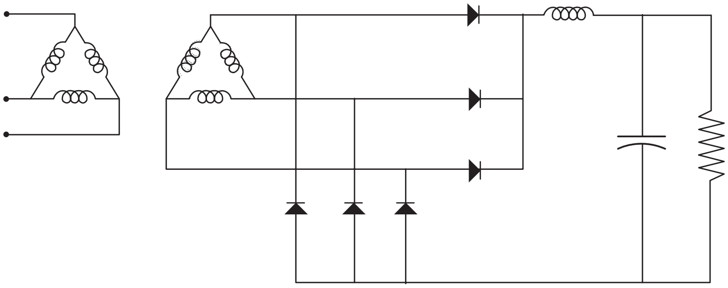

Figure 29.9. Three-phase full-wave bridge power supply.

This circuit uses center-tapped secondary windings. The voltage at the input to the choke now has very low ripple and the fundamental ripple frequency is 360 Hz (which allows even smaller values of L and C). Note that this is really a six-phase circuit; each rectifier connects to one of the six phases. Note again that the voltage from a three-phase or six-phase rectifier set never goes to zero. There is power available from a multiphase ac line at every instant. By comparison, an ordinary single-phase ac line suffers 120 power interruptions every second. A dc power supply operating off a single-phase line must include at least one energy storage element (C or L) to ride through these "power failures." On the other hand, an electronic regulator circuit like the one shown in Figure 29.6 could be powered by the three-phase rectifier of Figure 29.8 to make a dc supply having no energy storage elements. Such a supply would dissipate some of its input power in removing the ripples. When delivering maximum voltage, 0.866 V_{pk}, the efficiency would be 91%. A three-phase full-wave bridge circuit is shown in Figure 29.9.

This bridge rectifier has the same relation to the previous circuit as the four-diode full-wave bridge has to the two-diode ordinary full-wave circuit. Again there are six equivalent phases. You may recognize this circuit as the one used in automobile alternators.

29.5 Switching converters

Switching converters are dc-to-dc power converter circuits based on switching elements, often one transistor and one diode, and an inductor (sometimes the magnetizing inductance of a transformer). They are often used as local "board-level" power converters in systems with a single power bus. For example, a bus voltage of 20 volts dc can be converted wherever needed to power 5-volt logic circuitry, to furnish various positive and negative voltages for analog circuitry, and to drive high-voltage display systems. A switching converter can be preceded by a rectifier and filter capacitor to derive its input power directly from the ac power line. This combination, a *switching power supply*, is found, for example, in every line-powered computer. By varying the duty cycle of the

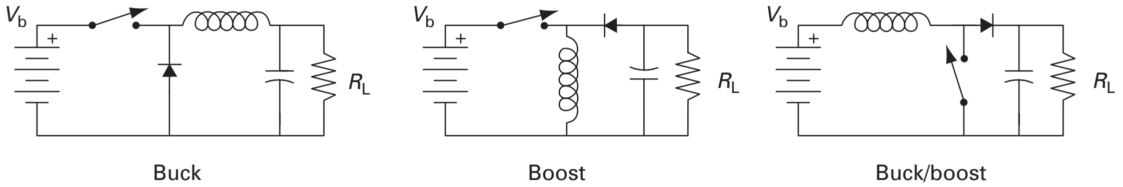

Figure 29.10. Three common dc-to-dc converters.

switching element, the dc output can be precisely regulated. If the duty cycle is deliberately modulated, the switching converter becomes a high-efficiency "class-D" power amplifier used, for example, as an AM modulator for a class-C RF amplifier or as a high-efficiency audio amplifier in a battery-operated MP3 player or hearing aid. The virtues of switching converters are their high efficiency and light weight. Three common converter circuits are shown in Figure 29.10. All include a switch, an inductor, a diode, and a filter capacitor. (The dc input supply is shown as a battery.)

In all these circuits an inductor provides the means by which energy is transferred from the supply side to the load side.

29.5.1 Buck circuit – continuous mode

The buck circuit is the same as a choke-input power supply fed by a half-wave rectifier with a freewheeling diode, except that here the filter sees rectangular voltage pulses rather than the positive halves of a sine wave. When the switch is open, the diode provides the left side of the inductor with a current path from ground. If the choke inductance is large enough to maintain nonzero positive current in the inductor, the average voltage at the input of the choke will be the supply voltage, V_b, times the duty factor of the switch (the fraction of the time the switch is on). The output voltage is equal to this average voltage, so it will remain constant with respect to load changes. (Perfect inherent regulation with respect to load changes requires ideal components, e.g., no dc resistance in the choke.) The duty factor may, of course, be changed to control the output voltage. Feedback control of the duty factor can be used to obtain regulation with respect variations of the input voltage. Feedback control will also provide very precise regulatizon with respect to load changes but, due to the inherent regulation, it will not have to make more than slight adjustments.

The current through the choke ramps up while the switch is closed and ramps down when it is open. Since $V = L\mathrm{d}I/\mathrm{d}t$, the slope of the current up-ramp is a constant, equal to the supply voltage minus the output voltage divided by the inductance. The slope of the down-ramp is also constant, equal to the output voltage divided by the inductance. This operation is shown in Figure 29.11.

When $V_{out} < V_b/2$ (i.e., the duty factor is $< 1/2$) the charging slope is steeper than the discharging slope and vice versa.

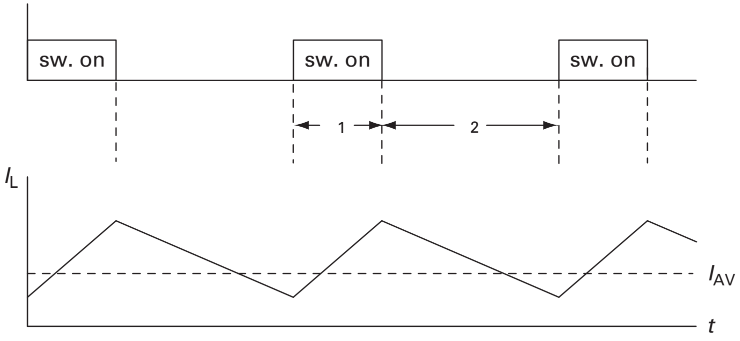

Figure 29.11. Buck supply operation cycle (continuous mode).

Buck circuit – discontinuous mode

If the inductor value is too low, the down-ramp will drain the inductor dry (zero current). The freewheeling diode will stop conducting and the left-hand side of the choke will float. The inherent regulation will be lost and output voltage will now be a function of the load. Figure 29.12 shows the operation cycle in this discontinuous mode. We will assume the capacitor is large enough to allow us to treat the output voltage as a constant.

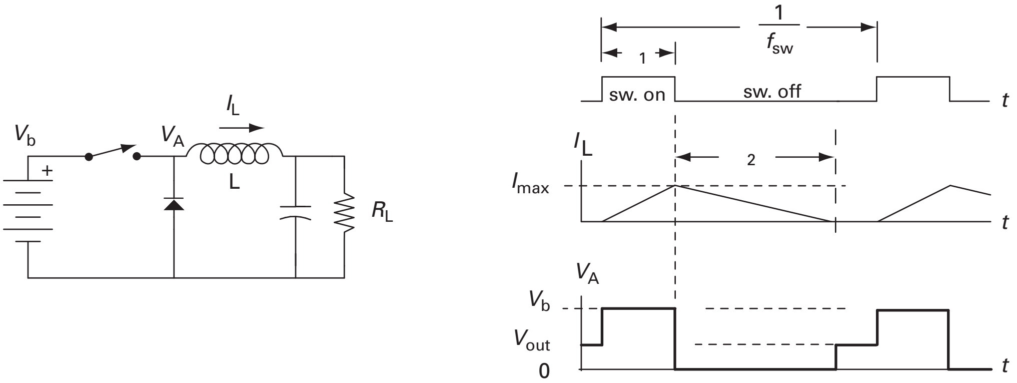

Figure 29.12. Buck supply operation cycle (discontinuous mode).

The length of the up-ramp is τ_1, the *on* time of the switch. In the discontinuous mode, the length of the down-ramp is the time needed for the inductor current to reach zero. To find the output voltage, we first note that the average current through the choke must be equal to the current in the load, V_{out}/R. From Figure 29.12, the average current through the choke is the area under the triangle divided by the length of the cycle, $1/f_{sw}$ where f_{sw} is the switching frequency. The duration of the down-ramp, τ_2, is given by $L\,I_{max}/V_{out}$. Finally, the up-ramp shows that I_{max} is equal to $(V_b-V_{out})\tau_1/L$. Putting all this together yields a quadratic equation for the output voltage, V_{out}.

$$\left(\frac{V_{\text{out}}}{V_{\text{b}}}\right)^2 + \frac{f_{\text{sw}}\tau_1^2 R}{2L}\left(\frac{V_{\text{out}}}{V_{\text{b}}}\right) - \frac{f_{\text{sw}}\tau_1^2 R}{2L} = 0. \tag{29.3}$$

But while this lets us find V_{out} in the discontinuous mode, we would prefer to avoid this mode altogether. To find the necessary critical inductance, we note that the discontinuous mode becomes continuous when there is no space between the triangular current pulses in Figure 12.12. The average current is then just half the height of the triangle, $I_{\text{max}}/2$ or $\frac{1}{2}\tau_1(V_{\text{b}} - V_{\text{out}})/L$. Since this average current has to be equal to V_{out}/R, we have

$$L_{\text{critical}} = \frac{\tau_1 R}{2}\left(\frac{V_{\text{b}}}{V_{\text{out}}} - 1\right). \tag{29.4}$$

29.5.2 Buck/boost circuit – continuous mode

The buck/boost circuit provides negative voltage, whose magnitude can be greater than the supply voltage. In this circuit, energy is pumped into the inductor while the switch is closed and is then transferred to the load when the switch is open. The inductor current vs. time, shown in Figure 29.11, also applies for the buck/boost circuit in the continuous mode. While the switch is closed, the inductor current ramps up linearly. The diode is back-biased during this time so the load side is disconnected. When the switch opens, the inductor current remains continuous, supplied now by the load via the diode. Since current is drawn from the load, the output voltage is negative. For the up-ramp we have $\Delta I = V_{\text{b}}\tau_1/L$. For the down-ramp we have $\Delta I = -V_{\text{out}}\tau_1/L$. The up and down ramps have equal current excursions, ΔI, so we have

$$V_{\text{out}} = -V_{\text{b}}\frac{\tau_1}{\tau_2}. \tag{29.5}$$

Note that, in the continuous mode, the output voltage is also inherently regulated, i.e., independent of the load.

Buck/boost circuit – discontinuous mode

Figure 29.13 shows the voltage and current waveforms for this circuit in the discontinuous mode. The analysis is not much different from that of the buck circuit. The maximum inductor current is given by $I_{\text{max}} = \tau_1 V_{\text{b}}/L$ and also by $I_{\text{max}} = -\tau_2 V_{\text{out}}/L$ so $\tau_2 = \tau_1 V_{\text{b}}/|V_{\text{out}}|$. Again, the load current is given by $|V_{\text{out}}|/R$ and must equal the average current furnished by the inductor. The latter is the area under the τ_2 triangle divided by the cycle length, $1/f_{\text{sw}}$, so we have

$$\frac{|V_{\text{out}}|}{R} = \frac{1}{2}\tau_2 \mathrm{I}_{\text{max}} f_{\text{sw}} = \frac{1}{2}\frac{V_{\text{b}}\tau_1}{|V_{\text{out}}|}\frac{V_{\text{b}}\tau_1}{L} f_{\text{sw}}. \tag{29.6}$$

Solving for V_{out} gives

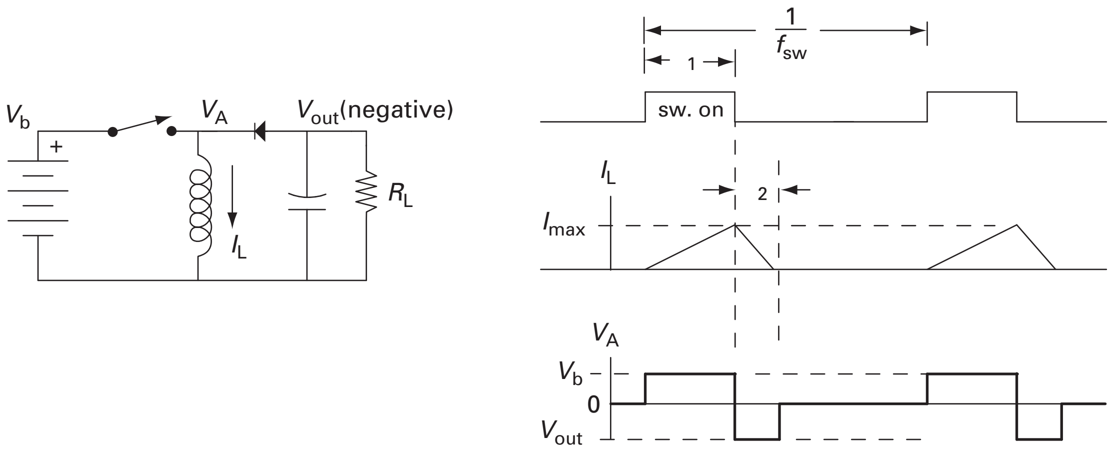

Figure 29.13. Buck/boost operation (discontinuous mode).

$$V_{out} = V_b \tau_1 \sqrt{\frac{f_{sw} R}{2L}}. \tag{29.7}$$

As before, the output voltage in this mode is a function of the load, so inherent regulation is lost. The critical inductance needed to stay out of this discontinuous mode is the subject of Problem 29.6(a).

29.5.3 Boost circuit – continuous mode

The boost circuit, like the buck/boost circuit, uses the inductor for energy storage. For the boost circuit, Figure 20.11 again represents the current in the inductor for the continuous mode. The inductor's charge and discharge become $\Delta I/\tau_1 = V_b/L$ and $\Delta I/\tau_1 = (V_{out} - V_b)/L$. The boosted voltage is therefore

$$V_{out} = V_b \left(1 + \frac{\tau_1}{\tau_2}\right). \tag{29.8}$$

Once again the continuous mode provides inherent regulation.

Boost circuit – discontinuous mode

Finally, we have the case of the discontinuous mode for the boost circuit. Figure 29.14 shows I_L and V_A vs. time. Again the current ramps up from zero when the switch is closed and ramps back down to zero when it is opened. As before, we assume the filter capacitor, C, is large so that V_{out} is constant. In this case the maximum inductor current is given by $I_{max} = \tau_1 V_b/L$ and also by $I_{max} = \tau_2 (V_{out} - V_b)/L$ so $\tau_2 = \tau_1 V_b/(V_{out} - V_b)$. Again, the current into the load is given by V_{out}/R and must equal the average current furnished by the inductor. The latter is the area under the τ_2 triangle divided by the cycle length, $1/f_{sw}$, so we have

$$\frac{V_{out}}{R} = \frac{1}{2}\tau_2 I_{max} f_{sw} = \frac{1}{2}\frac{V_b \tau_1}{V_{out} - V_b}\frac{V_b \tau_1}{L} f_{sw}. \tag{29.9}$$

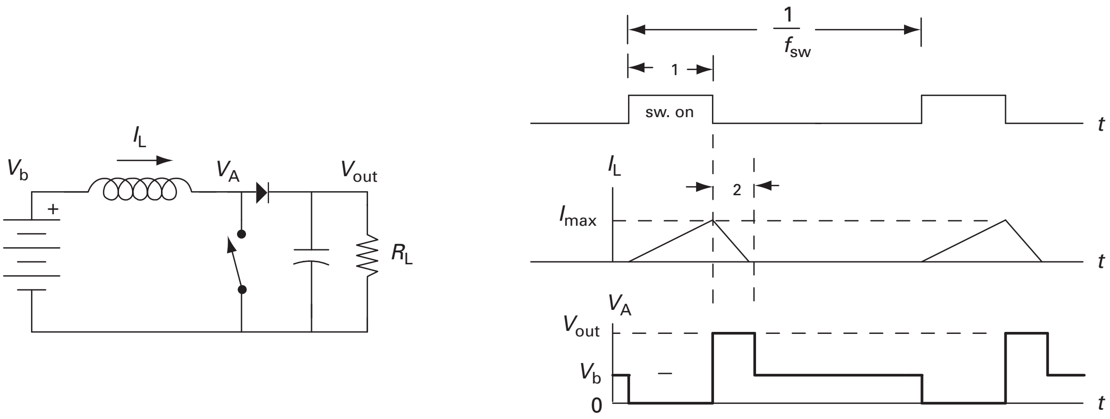

Figure 29.14. Boost supply operation cycle (discontinuous mode).

Rearranging gives us a quadratic equation for V_{out},

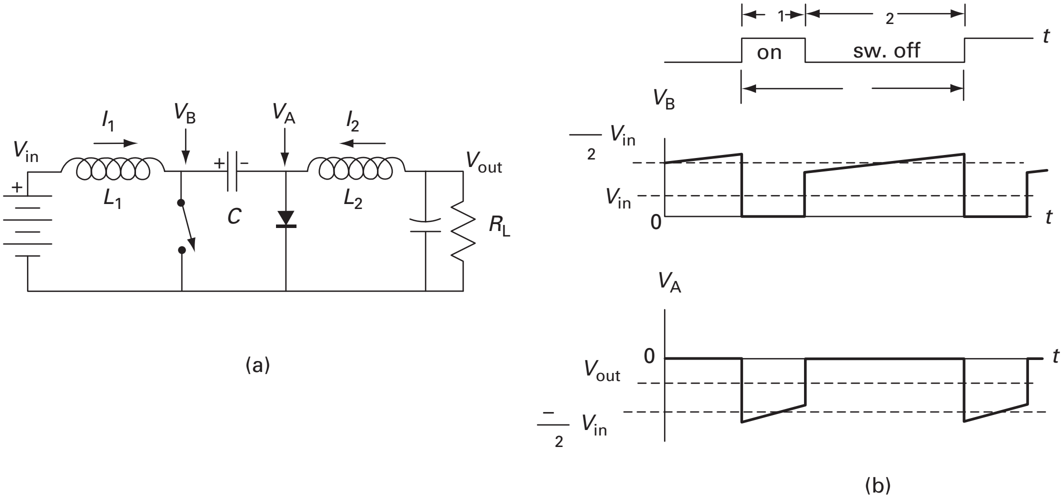
$$V_{out}(V_{out} - V_b) = V_b^2 \tau_1^2 \frac{f_{sw} R}{2L}. \tag{29.10}$$

29.5.4 Ćuk converter

In all three converter designs discussed above, an inductor is used as an energy storage element, to pass power from the input side to the output side. The Ćuk converter circuit, shown in Figure 29.15, uses a capacitor for this purpose.

The input and output inductors filter out ac currents (ripple). Their inductances can be large and, hence, they will store little pulsating energy. Unlike the previous converters, this converter will have negligible ripple currents at both input and output sides. Note also that the capacitor provides dc isolation between the input and output circuits, a useful feature for some applications. Like the buck/boost converter, the output voltage is negative and, for the continuous mode, is given by $V_{out} = -V_{in}\ \tau_1/\tau_2$. This can be seen as follows: Assume that the current in each inductor is essentially just a dc current, i.e., that the inductances are large enough to make any ripple currents very small. When the switch is off (open), current I_1 (from L_1) and current I_2 (from L_2) converge and flow through the diode to ground. During this time, V_A will, therefore, be zero, except for a small voltage drop across the diode. During this *off* period, of duration τ_2, the capacitor will receive an amount of charge $Q_{charge} = (I_1 + I_2)\tau_2$. When the switch is closed, V_A will go negative. The diode therefore stops conducting and I_2 flows into the capacitor. During this *on* period, of duration τ_1, the capacitor will therefore be (dis)charged by an amount $Q_{discharge} = I_2\tau_1$. In steady state, the capacitor must have same charge at the end of every cycle, so we can equate $Q_{discharge}$ and Q_{charge} to find

$$(I_1 + I_2)\tau_2 = I_2\tau_1. \tag{29.11}$$



(a)

(b)

Figure 29.15. Ćuk converter uses a capacitor to transfer energy from input to output.

Next, consider that the input power from the dc supply must equal the power delivered to the load, since there are nominally no lossy components in the circuit. Setting $I_{in}V_{in}=I_{out}\,V_{out}$, we have

$$I_1 V_{in} = -I_2 V_{out}. \tag{29.12}$$

Combining these two equations and using the fact that $I_2=-V_{out}/R$, we confirm that

$$V_{out} = -V_{in}(\tau_2/\tau_1). \tag{29.13}$$

The waveforms are shown in Figure 29.15(b), for the continuous mode, which will be the operating mode unless the inductor values are too small. To verify these waveforms, remember that during the *on* period, $V_A=-V_{CAP}$ and during the *off* period, $V_B=V_{CAP}$. Moreover, there can be no average dc across the inductors, so $\langle V_A\rangle\tau_1/\tau= V_{out}$ and $\langle V_B\rangle\tau_2/\tau=V_{in}$, where $\tau= \tau_{1+}\tau_2$.

29.5.5 Transformer-coupled converters

When the dc input is derived from a rectifier connected directly to the ac power line, the three basic converters are modified by incorporating an isolation transformer. The transformer provides isolation from the power line, required for safety whenever external connections will be made to the circuitry powered by the converter. Operating at a high frequency, this transformer can be much smaller and lighter than a 60-Hz transformer of equivalent power. Transformer versions of the buck/boost and boost converters are known as *flyback* converters and can provide voltage of either polarity. Flyback converters require no inductor apart from the transformer. The inductance needed for energy storage is provided by the magnetizing inductance of the transformer. Positive and negative output flyback circuits are shown in Figure 29.16.

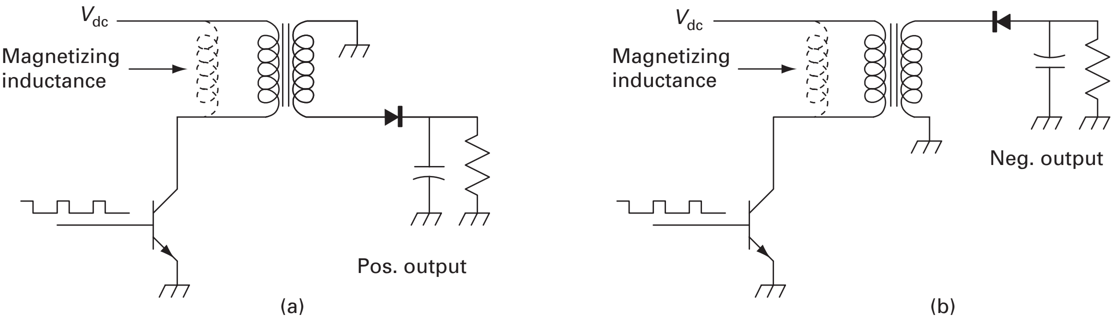


Figure 29.16. Flyback converters.

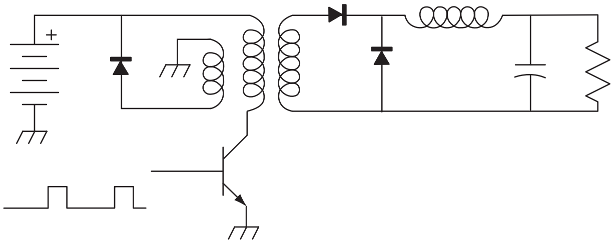
Figure 29.17 Forward converter.



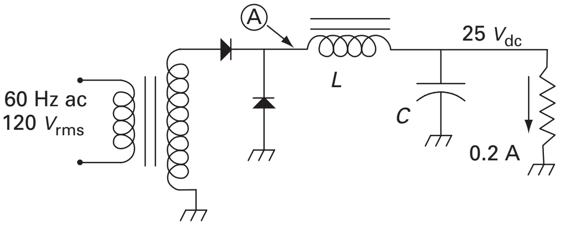
When the switch is closed, the diode disconnects the secondary and a ramp current flows in the primary, storing magnetic energy. When the switch is opened the transformer discharges, just as in the simple buck/boost circuit, except that now the discharge is through the secondary winding. (The magnetic energy does not care which winding carries the discharge current.)

The transformer version of the buck converter is the *forward converter* shown in Figure 29.17. Here the original choke remains; the transformer is an additional component.

While the switch is pulsed on, the transformer secondary supplies power to the load. Here the transformer is used as a real transformer rather than as an energy storage device. The turns ratio of the transformer, as well as the duty factor of the switch and the primary supply voltage, determine the output voltage. There is a problem, however, with opening the switch since there will be current flowing in the magnetizing inductance. (Remember that the magnetizing inductance is an equivalent shunt inductance on the primary side equal to the inductance of the primary winding or, just as well, a shunt inductance on the secondary side equal to the inductance of the secondary winding.) Even if the transformer has a high magnetizing inductance, there will be some stored energy when the switch is opened. A third winding can be provided, as shown above, to discharge this energy back into the primary supply, so that it is not wasted. This winding is sometimes called a *reset winding* since it resets the transformer to zero energy, readying it for the next pulse. In the forward converter, the transformer secondary delivers a stiff voltage pulse, i.e., a pulse from an equivalent low-impedance voltage generator. This circuit therefore needs a choke and a freewheeling diode to provide inherent voltage regulation.

Problems

Problem 29.1. The half-wave power supply shown below supplies 25 volts dc at 0.2 amps to the load (shown as a resistor). Assume the components are ideal and that the capacitor is large enough so that the ac voltage at the output (ripple) is very small.



(a) Assuming the inductance of the choke is large enough to maintain positive current, sketch the voltage waveform at point "A."

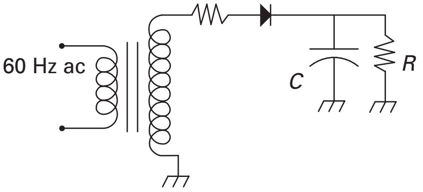
(b) The value of the average voltage at "A" must be 25 volts since there is no dc drop across the choke. Find the rms voltage, $V_0/\sqrt{2}$, across the transformer secondary. Answer: 55.5 V rms.

(c) Calculate the peak value of the dominant ac component (the 60-Hz component) of the voltage at "A," i.e., find its Fourier amplitude. If you have trouble with this, estimate the magnitude of this component from your sketch. Answer: 39.3 V peak.

(d) Use the result from (c) to find the critical inductance of the choke, i.e., the inductance just large enough to keep the current in the choke always positive. Answer: 0.52 H.

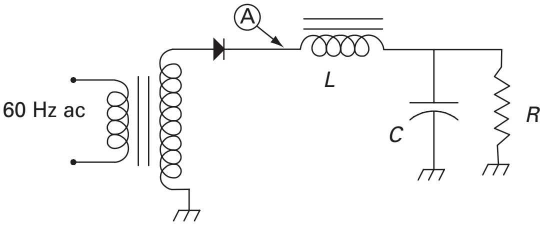
(e) What value should the capacitor have to make the 60-Hz ripple at the output be less than 100 mV rms? Answer: 3700 μF.

Problem 29.2. Consider the common half-wave capacitor-input power supply shown below.



The resistors r and R represent, respectively, the ohmic resistance of the diode and the load resistance. Assume that the transformer is perfect and that C is large enough to make any ac voltage at the output negligible. Suppose that the peak voltage on the transformer secondary is 10 volts, and that the values of r and R are 1 ohm and 20 ohms. Calculate the output voltage, V_{dc}. Hint: the average current through the diode is equal to the current in the load, $V_{dc}/20$. Current flows in the diode only when the voltage at the top of the transformer secondary is greater than V_{dc}; the instantaneous value of the current is $(10 \cos \theta - V_{dc})/1$. Integrate this current over one cycle to find its average and set this expression equal to $V_{dc}/20$. You willl need a calculator to solve for the angle at which the current stops flowing. Answer: 7.51 V.

Problem 29.3. A not-so-common choke-input half-wave power supply is shown below. This circuit, without the free-wheeling diode, will not provide the inherent regulation of the circuit of Problem 19.1. If the load is constant, however, regulation is not important and with this circuit the voltage can be lowered (with no power loss) by increasing the inductance of the choke. Assume as before that the value of the capacitor is large enough to make any ac voltage at the output negligible.



(a) Draw a sketch showing the voltage at point "A" and the current in the inductor. Hint: remember that $V = L\mathrm{d}I/\mathrm{d}t$. It may help you to consider the cases where R is very large and where R is very small.

(b) If the 60-Hz voltage at the transformer secondary is $10 \sin(\omega t)$ and the output voltage is 5 volts, find duty cycle of the diode, i.e., the angle at which the diode goes into conduction (where the diode becomes forward biased) and the angle at which it goes out of conduction (where the choke goes dry, i.e., choke current goes to zero).

(c) If the output current is 1 ampere, find the value of L.

Problem 29.4. Show that when an uncharged capacitor is brought to potential V by connecting it through a resistor to a battery of voltage V, the energy supplied by battery is twice the energy deposited in the capacitor (CV^2 versus $CV^2/2$), i.e., the transfer is only 50% efficient even if the value of the resistor is made very small.

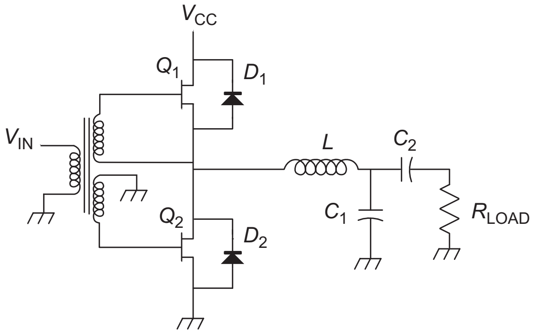
Problem 29.5. Draw the voltage waveform at point "A" for continuous mode operation of the buck, buck/boost, and boost converters (see Figures 29.12, 29.13, and 29.14).

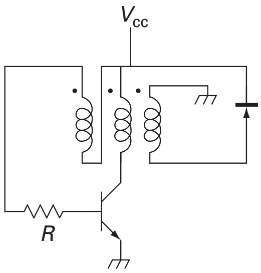
Problem 29.6. Find the critical inductance needed to stay out of the discontinuous mode (a) for the buck/boost converter of Figure 29.13, and (b) for the boost converter of Figure 29.14.

Problem 29.7. The diagram below shows a circuit for a class-S amplifier (switching amplifier). This could be an audio amplifier, in which case the load resistor represents a loudspeaker. The transistors operate as switches, i.e., fully on or fully off. The voltage on the left-hand side of the inductor is always either zero or V_{cc}. The average value of this voltage appears at the right-hand side of the inductor and also on the load (except that C_2 blocks dc).

(a) When the signal is zero, the duty cycle must be 50%. For this case, draw the waveforms of the currents in the inductor, Q_1, D_1, Q_2, and D_2.

(b) For this zero signal case, explain why there is no net energy flow from the power supply.





Problem 29.8. The circuit shown below, a blocking oscillator, is essentially a self-excited switching converter. The transformer has three windings. Assume they are perfectly coupled and have equal inductance, L. The current from the dc supply is a positive ramp during the first half of the cycle while the transistor is on. If the magnetic core does not saturate, this ramp ends when the transistor goes out of saturation, i.e., when $I_c = \beta I_b$. The transistor quickly turns off and the stored energy in the transformer is returned to the power supply via the diode.

(a) Show that the frequency is given by $f = R/(4\beta L)$. (Assume the base-to-emitter junction is a short circuit.) Sketch the waveforms of the collector voltage and of the collector and diode currents.

(b) Show that, if the magnetic core saturates before the transistor goes out of saturation, this circuit is a VCO or voltage-to-frequency converter.

CHAPTER

30

RF test equipment

In RF work, as in low-frequency work, test instruments generally are designed either to analyze signals, or to determine parameters of components and systems. Signal analysis ranges from simple voltage, current, and power measurements to measurements of frequency, relative phase, frequency stability, modulation characteristics, RF field strength, and spectrum analysis. Parameter measurements range from simple resistance and reactance measurements through measurements of transfer characteristics of linear multiport devices (filter shapes, amplifier frequency response, etc.), and distortion (dynamic range, intermodulation). Parameter measurements require a signal generator to provide the stimulus whose response is measured. It is now common for measurement instruments to include built-in signal generators, but free-standing signal generators are widely used in specialized test setups.

30.1 Power measurements

Power measurements, as pointed out in Chapter 18, are best made with a square-law detector. If the waveform is unknown or noisy (i.e., has a random component), a square-law detector *must* be used, as power, by definition, is proportional to the average square of voltage. If the signal waveform is known, e.g., a sine wave, the power can also be calculated, for example, from a measurement of $\langle |V(t)| \rangle$. Commercial RF power meters normally present a 50-ohm impedance to source being measured, allowing a reflectionless connection to a 50-ohm cable.

Thermistor (temperature-dependent resistor) power meters are true square-law instruments and have a dynamic range typically from 1 μW (−30 dBm) to 100 mW (20 dBm). The power to be measured heats a thermistor which is one leg of a Wheatstone bridge circuit.[1] A feedback circuit supplies dc or low-frequency ac power to heat the a second *reference* thermistor in an adjacent leg in the bridge. When the heater power is equal to the input RF power, the two thermistors come to equal resistance values and the bridge is balanced. A feedback control circuit keeps the bridge balanced. The voltage × current product of the reference thermistor is calculated and this power is displayed. These instruments use small "bead"-type thermistors with very small heat capacities, so that when the power changes, the reading will come to equilibrium within less than one second. More refined circuits provide better compensation for changes in ambient temperature. Similar instruments use thermocouples instead of thermistors.

---

[1] With one end of the thermistor at ground, the RF signal is coupled to the other end through a dc blocking capacitor. A series RF choke isolates the input signal from the rest of the bridge circuit.

Powers down to about 10^{-3} μW (−60 dBm) can be measured with carefully calibrated *diode-based power meters*. An upper limit results from the need to keep the signal low enough that the fourth and higher even power terms in the diode I vs. V curve will be negligible (see Chapter 18). A typical upper limit is 100 mW (20 dBm). Thus, the nominal dynamic range of a diode-based power meter is three orders of magnitude greater than that of the thermistor-based power meter. However, when used to measure signals with high crest factors (signals such as noise or multiple carriers, whose peak powers greatly exceed their average power), the upper limit of the diode meters must be derated in order to preserve measurement accuracy.

Power meters measure the power a source would deliver to a standard impedance, usually 50+j0. Directional power meters measure the power traveling in each direction along a transmission line. This is best done with two power meters connected to a directional coupler with a low coupling factor. Negligible power is diverted from the main line and, in principle, the device introduces no reflections. Directional power meters are often installed permanently in the transmission line connecting an antenna to a transmitter as they show both that the transmitter is putting out its rated power and that the antenna is operating properly. Many times the reflected power detector is used to turn the transmitter off automatically or reduce power when a disturbance to the antenna has caused abnormal reflected power.

Flow calorimeters are used for high-power measurements and sometimes for low-power mm-wave signals. These contain a liquid-cooled load resistor ("dummy load"). The fluid temperature is measured on both sides of the load to get the temperature difference (a thermocouple pair can be used). The flow rate must also be measured. Note that all the power measurements discussed above are "true rms" measurements; they do not require that the unknown voltage be sinusoidal.

30.2 Voltage measurements

Probing any circuit with a voltmeter always inevitably "loads down" the circuit to some degree, so it is necessary that the impedance of the voltmeter be much

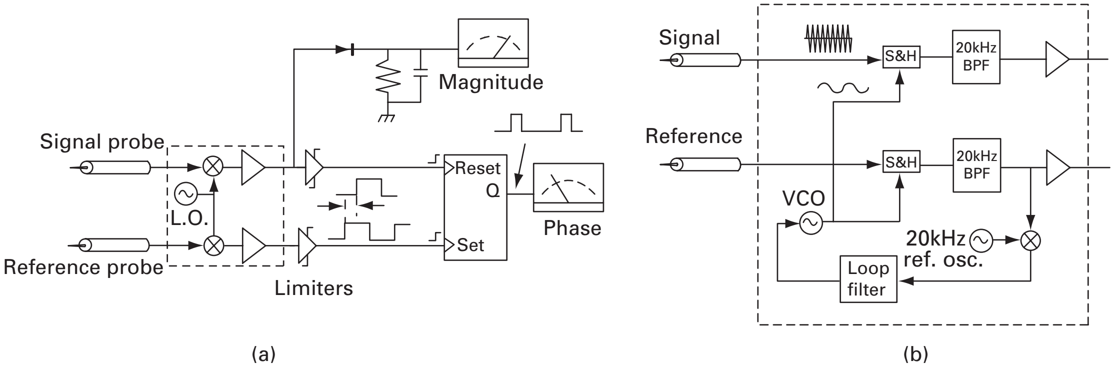

Figure 30.1. (a) Superheterodyne vector voltmeter; (b) phase-locked low-frequency oscillator drives sampling mixers.

greater than the equivalent Thévenin source impedance of the node being probed. For low-frequency work, it is sufficient that the meter probe present high shunt resistance. For RF work, the meter must present high shunt reactance as well.

An early innovative instrument was the *vector voltmeter* that displayed phase as well as amplitude. Since phase is relative, the instrument had an auxiliary "reference" input. A simplified circuit is shown in Figure 30.1(a). The signal and reference signal are both converted down to a low IF frequency, 20 kHz, and amplified. By mixing with identical L.O. signals, the relative phases are left unchanged. One channel is fed to a diode peak detector, to measure the amplitude. Both channels are fed to limiting amplifiers. The outputs of the limiters are used to produce a pulse whose duty factor is proportional to the phase difference or to operate a start/stop counter.

Figure 30.1(b) shows how the IF frequency was kept constant over the 1 MHz to 1 GHz range of the instrument. Sample and hold (S&H) circuits were used as mixers: an integral multiple of the sampling frequency differed by 20 kHz from the input frequency, causing the outputs of the S&H units to form a staircase version of a 20 kHz sine wave.[2] A phase lock loop controlled the sampling to keep the IF signal at 20 kHz. This scheme was also used in the receiver sections of vector network analyzers (VNAs), discussed below, instruments which have superseded the vector voltmeter.

30.3 Spectrum analysis

Spectrum analyzers, once called "panoramic receivers", are superheterodyne receivers with swept local oscillators. A nonlinear IF amplifier provides a logarithmic output voltage, i.e., the detector output is proportional to the log of the input signal power. This output is displayed on the *Y*-axis of a display

---

[2] With the sampling frequency low compared to the input frequency, the output of the sampler is an "aliased" version of the input, like the stroboscopic effect in movies or television that makes fast turning wheels slow down or appear to rotate backward.

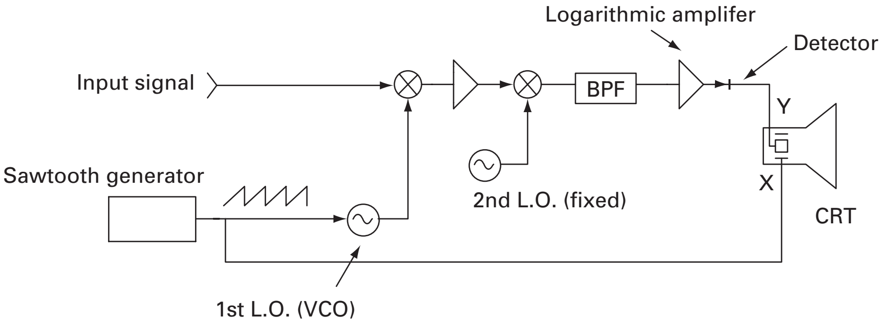

Figure 30.2. Spectrum analyzer.

while the *X*-axis is swept in sync with the local oscillator. The display is therefore a graph of signal strength vs. frequency. RF spectrum analyzers usually have a wide range such as 10 MHz to 20 GHz. A block diagram for such an instrument is shown in Figure 30.2.

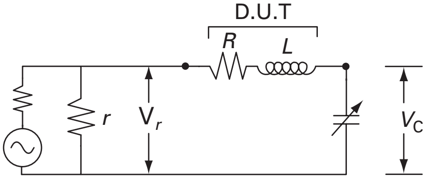
A swept-frequency spectrum analyzer using a CRT has objectionable flicker in situations where the sweep time must be greater than about 1/20 second. The sweeping filter must spend a time at least equal to the reciprocal of its bandwidth on each frequency to get the desired resolution. The total sweep time must therefore be greater than the effective number of points divided by the resolution bandwidth which is the same as the frequency span divided by the square of the resolution bandwidth. For example, if it is necessary to analyze a span of 20 kHz with 200 effective points, the resolution bandwidth would be 20 000/200 = 100 Hz and the sweep time would have to be two seconds. Digital storage is a solution to the flicker problem when the unknown spectrum is stable (not noise-like) and when the total sweep time (time to acquire the spectrum) is not objectionable.

Multiplex spectrum analyzers, as opposed to swept-frequency spectrum analyzers, evaluate all the spectral points simultaneously. The probability of intercept is 100%, i.e., a signal that pops up momentarily will not be lost because the instrument is off scanning a different part of the band. Moreover, at low frequencies, parallel processors vastly increase the measurement speed. DSP chips calculate fast Fourier transforms in low-frequency spectrum analyzers and can be built into swept spectrum analyzers to extend the low-frequency range. FFT processors are even included as a feature in many oscilloscopes.

30.4 Impedance measurements

The simplest instrument for impedance measurement was the so-called *Q meter*, shown in Figure 30.3, an instrument for testing inductors. It provided the values of both the reactive part and the resistive part of the impedance. The circuit, shown in Figure 30.3, is very simple, and can be set up quickly in the lab in lieu

Figure 30.3. Q meter.



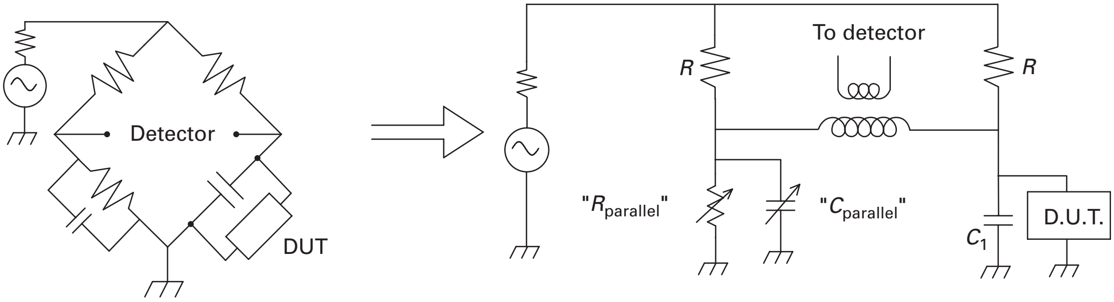
of a suitable instrument. A signal generator provides a fairly constant sine wave voltage V_r across r, a low-value resistor. The variable capacitor is tuned to maximize V_C, the voltage across the capacitor. This maximum occurs when $X_C = X_L$ (series resonance). The operator can read the capacitance dial and, knowing the generator frequency, calculate the unknown inductance. At series resonance, the current through the device-under-test (D.U.T.) is just V_r/r so $V_c = X_C I = (X_C/r)V_r = Q_{\mathrm{DUT}}V_r$ and, therefore, $Q = V_C/V_r$.

The operation of the Q meter assumes that the Q of the variable capacitor is very much higher than the Q of the inductor to be tested. This is almost always true in RF work, and for this reason, there was no similar instrument to measure capacitors.

30.4.1 Impedance bridges

At low frequencies (where lumped components are practical) impedance can be measured directly with a straightforward bridge such as shown in Figure 30.4.

Figure 30.4. Impedance bridge.



If the device under test (D.U.T.) is purely resistive, the variable capacitor, C, will be set to the same value as the fixed capacitor C_1. It is convenient to use a variable capacitor with a midpoint capacitance equal to C_1. The front panel “$\mathrm{C}_{\text{PARALLEL}}$” dial is offset so that this point is marked zero. If the load has an inductive component, the bridge can be balanced by setting C to less than C_1. The dial then indicates a negative capacitance which the operator interprets as a parallel inductance. The value of the variable resistor is indicated on its dial as “R_{PARALLEL}.” This kind of bridge was made famous by the Boonton Electronics Corporation’s “RX meter.” The RX meter used an amplified detector, actually a superheterodyne circuit.

Amateur radio operators use a version of this bridge, the “noise bridge,” in which the signal generator is replaced with a wideband noise generator, usually a Zener diode followed by a wideband amplifier, and the null detector is replaced with a tuned receiver, e.g., a communications receiver.

30.4.2 Reflectometers

A directional coupler, e.g., a hybrid, allows the measurement of the reflection coefficient magnitude for one-port devices and of gain, as well as input and output reflections of two-port devices. In Figure 30.5, any power reflected by the D.U.T. is divided between the generator port, where it is absorbed by the matched generator and the cross-port, where it can be measured.

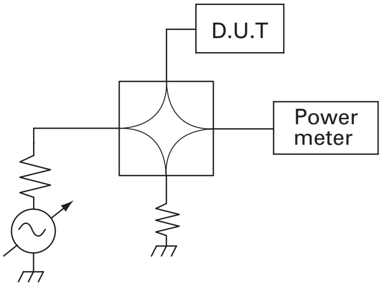


Figure 30.5. Reflectometer.

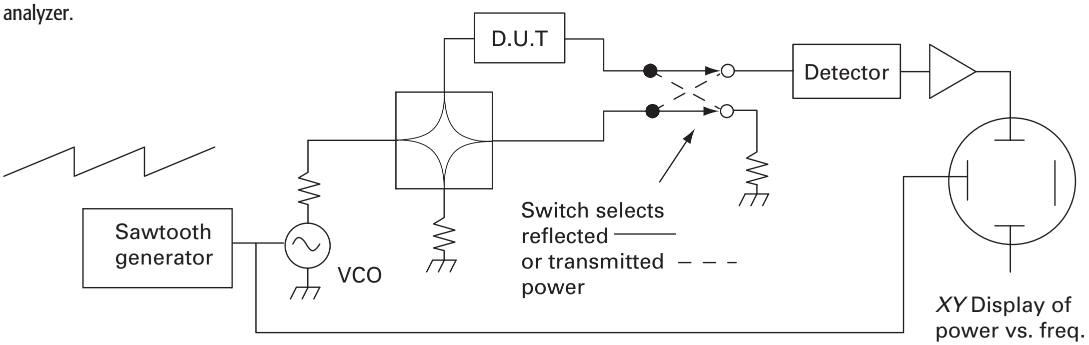
To calibrate the instrument, the D.U.T. is temporarily replaced by a perfect reflector (usually a short) and the power meter gain is adjusted for a reading of unity (0 dB). This kind of circuit, when used with a swept-frequency RF source (sweep generator) and power display, makes a *scalar network analyzer*, as shown in Figure 30.6, where a switch is provided for two-port devices, such as amplifiers, to measure either reflected power or transmitted power.

Figure 30.6. Scalar network analyzer.



A *vector reflectometer* measures the phase of the reflection coefficient as well as its magnitude. This can be done by combining a vector voltmeter with the above circuit. But it is easy to build a circuit that produces a polar display, i.e., a Smith chart on a CRT screen. Such a circuit is shown in Figure 30.7.

Figure 30.8. Vector network analyzer with a three-channel tracking receiver.

A swept-frequency vector reflectometer is called a *vector network analyzer* (VNA) and is the ultimate RF test instrument. It uses a superheterodyne receiver section. Figure 30.8 shows how one commercial network analyzer uses two RF conversions before the final conversion to baseband. This design uses sample-and-hold mixers with the same phase lock L.O. circuit used in the vector voltmeter (Figure 30.1b). Other VNAs use straightforward fundamental mixing. Only one complete signal channel is shown, but usually two are provided, together with a dual-trace display. Often a reversing switch is included to interchange ports “A” and “B” so that all four *S* parameters of a two-port device can be measured without having to turn the device around. All newer vector network analyzers digitize the signals after the final conversion and apply calibration corrections before presenting the data on the display, sending it to a computer, or storing it for subsequent retrieval.

30.4.3 VNA calibration

When using a VNA, coaxial cables are normally used to connect the device under test to the analyzer. Reflection and transmission coefficients will therefore be rotated on the display screen, the Γ plane, by an amount proportional to the length of the connecting cables. Moreover, these coefficients will appear too small if the cables have nonnegligible loss. Unless told otherwise, the analyzer knows nothing of these cables, and will assume the D.U.T. is right up against its front panel. Knowing the propagation constant, loss factor, and length of the cables, the operator could calculate the necessary corrections. But modern analyzers have built-in data processors to make these corrections automatically, once the operator has gone through a calibration procedure. At its simplest, this procedure simply lets the analyzer determine electrical length and loss of the cables.

30.4.3.1 One-port calibration procedures

If only reflection coefficients are to be measured, the analyzer could prompt the operator with a message such as “Substitute a short circuit for the device under test. Then press the CAL button and wait for the CALIBRATION COMPLETED prompt.” When the operator presses the CAL button, the analyzer steps through the selected set of frequencies and reads the phase and amplitude of the reflected or transmitted signal at each frequency. It stores these numbers and uses them to correct each data point when the operator replaces the short with the D.U.T. Most network analyzers provide this calibration as an option. However, this simple procedure is often not adequate. Consider the situation in which the D.U.T. does not have a 50-ohm port. An adapter must be used to make the transition from the end of the 50-ohm cable to the device port. Examples of adapters are coax-to-waveguide transitions and microprobes, used to probe RF integrated circuit chips. Adapters are seldom perfect; they nearly always introduce a reflection of their own. In addition, an adapter will introduce a phase shift, since its length is not zero. The 50-ohm test cable may not be perfect; it might have worn or otherwise imperfect connectors or it may have been kinked, leaving it with an internal point where some power is reflected. The instrument can correct errors caused by all these defects, as well as by the line loss and delay, if it has first been calibrated with a procedure that uses a sequence of *three* calibration standards rather than just one. Often the three standards are chosen to be a short, an open, and a load. In Figure 30.9, the D.U.T. is a microwave horn antenna and

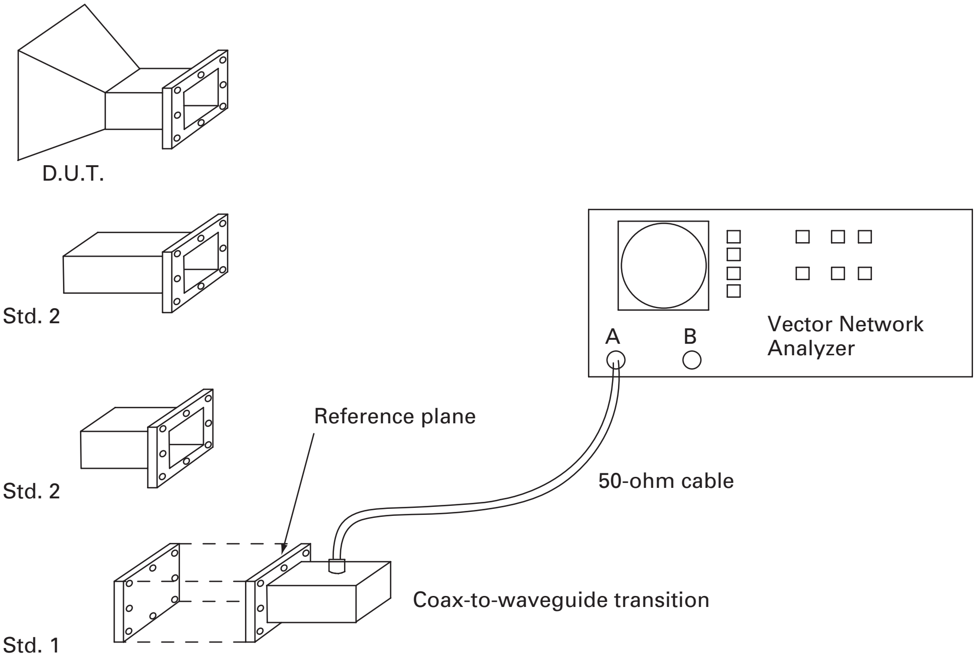

Figure 30.9. VNA setup to measure reflection coefficient vs. frequency of a microwave horn antenna.

the test setup includes a coax-to-waveguide transition. In this example, the three standards comprising the calibration kit are three waveguide shorts of different lengths. Let us look in detail to see why an accurate calibration requires three standards.

Network analyzer calibration for S_{11} *measurements using three standards*

In Figure 30.10, a signal flow diagram, the two-port network represents everything between the analyzer and the device to be tested, usually a cable plus an adapter. Either a standard or the D.U.T. is put at the right-hand side of this hypothetical two-port network. The S parameters of this network will be designated A_{11} , A_{12}, A_{22}, and A_{21} to distinguish them from the S parameters of the D.U.T., which are S_{11}, S_{12}, S_{22}, and S_{21} or just S_{11}, if the D.U.T. is a one-port device.

For the setup of Figure 30.9, for example, the two-port network is the combination of the cable and the coax-to-waveguide transition. Again, neither the cable nor the transition needs to be perfect, nor do they need to be previously characterized. The analyzer outputs a wave of unit amplitude. The wave Γ_{OBS} is the signal reflected back into the analyzer. The external device, either one of the three standards or the device under test, has reflection coefficient Γ_{EXT}. If the external device is the D.U.T., then Γ_{EXT} will be equal to S_{11} if the D.U.T. is a one-port device or if it is a multiport device with the other ports terminated in matched loads. Let us first find Γ_{OBS} as a function of Γ_{EXT}.

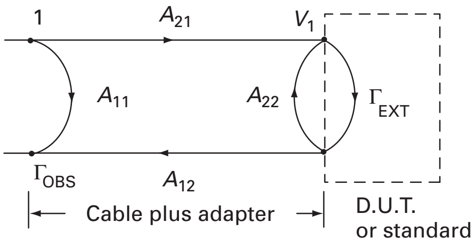

Figure 30.10. Signal flow diagram for reflection measurement setup.

By inspection of the diagram, we see that the forward wave into the external device, V_1, can be expressed as

$$V_1 = A_{21} + V_1\Gamma_{\mathrm{EXT}}A_{22} \quad \text{or} \quad V_1 = \frac{A_{21}}{1 - \Gamma_{\mathrm{EXT}}A_{22}}. \tag{30.1}$$

It follows that

$$\Gamma_{\mathrm{OBS}} = A_{11} + \frac{\Gamma_{\mathrm{EXT}}A_{21}A_{12}}{1 - \Gamma_{\mathrm{EXT}}A_{22}}. \tag{30.2}$$

Solving for Γ_{EXT}, we find

$$\Gamma_{\mathrm{EXT}} = \frac{\Gamma_{\mathrm{OBS}} - A_{11}}{A_{21}A_{12} - A_{22}A_{11} + \Gamma_{\mathrm{OBS}}A_{22}} \quad \text{or} \quad \Gamma_{\mathrm{EXT}} = \frac{\Gamma_{\mathrm{OBS}} - A}{B + \Gamma_{\mathrm{OBS}}C} \tag{30.3}$$

where A, B and C are three constants ($A = A_{11}$, $B = A_{21}A_{12} - A_{22}A_{11}$, and $C = A_{22}$). Measuring Γ_{OBS} for each of the three known values of Γ_{EXT} provided in the CAL kit provides three simultaneous linear equations that can be solved for the values of A, B, and C. This is done automatically by the analyzer when one performs a full S_{11} calibration. Moreover, it is done at each discrete frequency contained between the start and stop frequencies. Once the calibration procedure has been run, the device under test is attached and $\Gamma_{\mathrm{EXT}} = \Gamma_{\mathrm{DUT}}$ is calculated from Γ_{OBS} using Equation (30.3).

In the discussion above, we assumed the two-port network of Figure 30.9 included just the test cable and any adapter. But this network can represent everything between a hypothetically perfect network analyzer and the D.U.T; the three-standard calibration procedure corrects not only for the cable and adapter, but also for deficiencies of the analyzer itself: imperfect directivity and port reflection. You can see that none of these corrections are possible with the scalar network analyzer of Figure 30.6.

Full calibration for two-port measurements requires that we consider the second cable and any adapter as another two-port network. Both networks must be characterized using three standards. In addition, a “through” standard is required. In a coaxial cable set-up, the “through” might be a coaxial male-to-male “bullet.” In the waveguide setup, no actual “through” device is needed; the coax-to-waveguide adapters connected by cables to the analyzer’s “A” and “B” ports are simply placed face to face.

30.5 Noise figure meter

The automatic noise figure meter, Figure 30.11, consists of a tuneable receiver, power meter, and calibrated noise source.

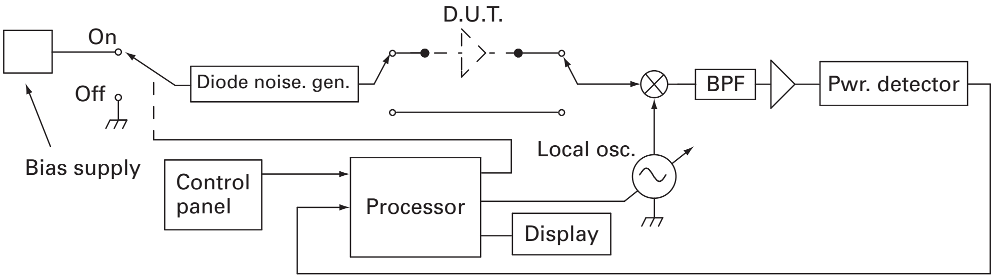

Figure 30.11. Automatic noise figure meter.

In principle, the noise figure of a D.U.T., often an amplifier, can be determined without the use of an external noise source. The noise spectral density at the D.U.T. output can be measured using a power meter, a filter whose bandpass shape is known, and, usually, an auxiliary high-gain amplifier whose gain and noise figure are known. The D.U.T. gain can be measured if a calibrated sine wave source is also available. But when a calibrated noise source is used, the shape of the filter and the gain and noise figure of the auxiliary amplifier need not be known. We define T_{sys} as the equivalent system noise temperature at the input of the D.U.T. when the noise source is turned off and equivalent to a 50-ohm resistor at the ambient temperature, T_0. When turned on, the calibrated noise generator has an equivalent noise temperature T_{hot}. The instrument turns the noise generator on and off and calculates the power ratio $Y = P_{\text{on}}/P_{\text{off}}$. As explained in Chapter 17, the system temperature is given by $T_{\text{sys}} = (T_{\text{hot}} - YT_0)/(Y-1)$. If the D.U.T. has high gain, its equivalent noise temperature, T_{DUT}, is essentially equal to T_{sys}. But if the D.U.T. has low gain, correction must be made for the noise in the rest of the system, i.e., the rest of the noise meter. Note that, by operating the switch that bypasses the D.U.T, the noise meter can measure its own noise temperature and then calculate the noise figure of the D.U.T.

Problems

Problem 30.1. In testing a high-power transmitter with a water-cooled dummy load it is found that the water leaving the dummy load is hotter by 10 degrees Celsius than the water entering the load. If the flow rate is 10 liters/second, what is the output power of the transmitter? (1 calorie = 4.18 joules.)

Problem 30.2. Sketch a digital circuit to provide a numerical phase readout for the vector voltmeter of Figure 30.1. Hint: use a start/stop counter in place of the S/R flipflop. Include provision to count multiple turns, i.e., give the readout a range of 360 degrees × *n*.

Problem 30.3. Design a three-short vector network analyzer calibration kit for WR430 waveguide (width = 4.30 inches). Assume that the midband frequency is 2.38 GHz. Determine the lengths of the three shorts so that, at midband, their reflection coefficients are as different as they can be, in order to reduce systematic errors.

Problem 30.4. After building the calibration kit of Problem 30.3, how would you measure the reflection coefficient of the waveguide-to-coax transition?

"Free energy from the air?, Yea, right!" Sardonic skepticism was my first reaction to this unusual concept, as well.

Though, its not so far out there, in fact. Light can be converted to DC current with solar panels, electricity can be converted to magnetism as I did in my last article (https://www.instructables.com/id/DIY-Electro-Magnetic-Levitation/), in a microphone sound waves are converted to an electrical signal (by vibrating a magnet near a coil (http://hyperphysics.phy-astr.gsu.edu/hbase/audio/mic.html)), solar rays can even be focused and converted to heat in awesome devices like this! (http://www.gosunstove.com/) When we think about it, energy is all around us and can be harvested in an enumerable many of ways.

Today, we are going to take a rather novel approach. We are going to build a device specifically designed to sense and capture a particular band of energy which is all around us.

The earth is magnetic and anyone who has ever used a compass knows this. Magnetic bodies in motion produce electricity, we can see this in any alternator, like the one in your car. So, therefore the earth is electric as well as magnetic, by definition.

Can we detect this energy? Yes, we sure can! Ever turn on a radio in the middle of nowhere and heard static? That is your radio picking up naturally occurring energy in the RF spectrum!

Can we use this energy to do work? Absolutely! This has been known for a long time. Crystal radios (https://en.wikipedia.org/wiki/Crystal_radio) have been around since before the 1930's and can run with no input energy other than the radio signal. Even when completely isolated, but from the atmosphere, a crystal radio will produce a voltage in the earpiece resulting in a sound (albeit and undesirable one).

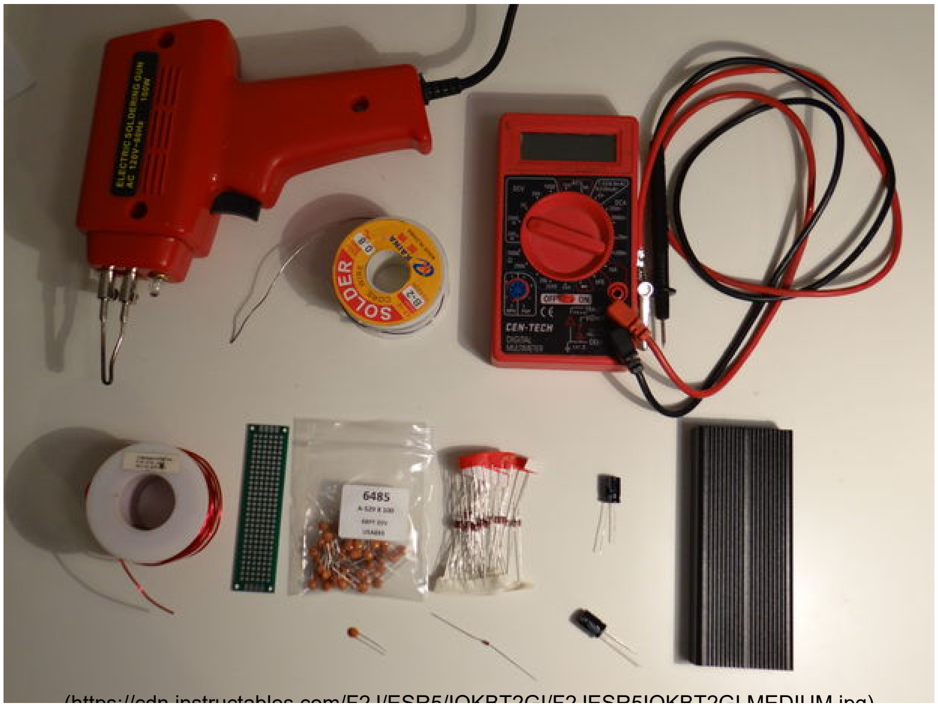
Well, this is where it gets interesting...

Can we replicate this effect? Yea, and with modern components like the high quality crystals found in germanium diodes, we can even increase efficiency. By applying this concept as a Crystal Energy Receiver we can take advantage of a wide range of energetic frequencies rather than tuning in to just one.

Can we scale it up? Definitely. Things like micro germanium diodes, high efficiency antennas and compact contemporary capacitors make the components that are required to build a crystal receiver fit in the palm of your hand. While there may or may not be a more efficient way, this renewable energy solution is simple to employ and can be scaled up, or down, indefinitely.

It sounds like we can build a Crystal Energy Receiver. Let's give it a shot...

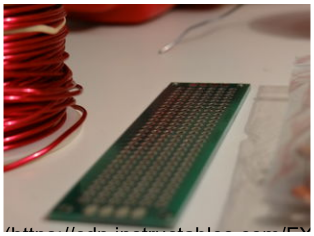
Step 1: What You'll Need



(https://cdn.instructables.com/F2J/ESP5/IOKBT2GI/F2JESP5IOKBT2GI.MEDIUM.jpg)

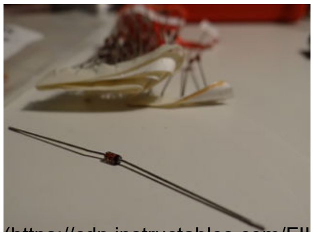
(https://cdn.instructables.com/F53/EHON/IOKBT2

(https://cdn.instructables.com/FP2/G266/IOKBT2

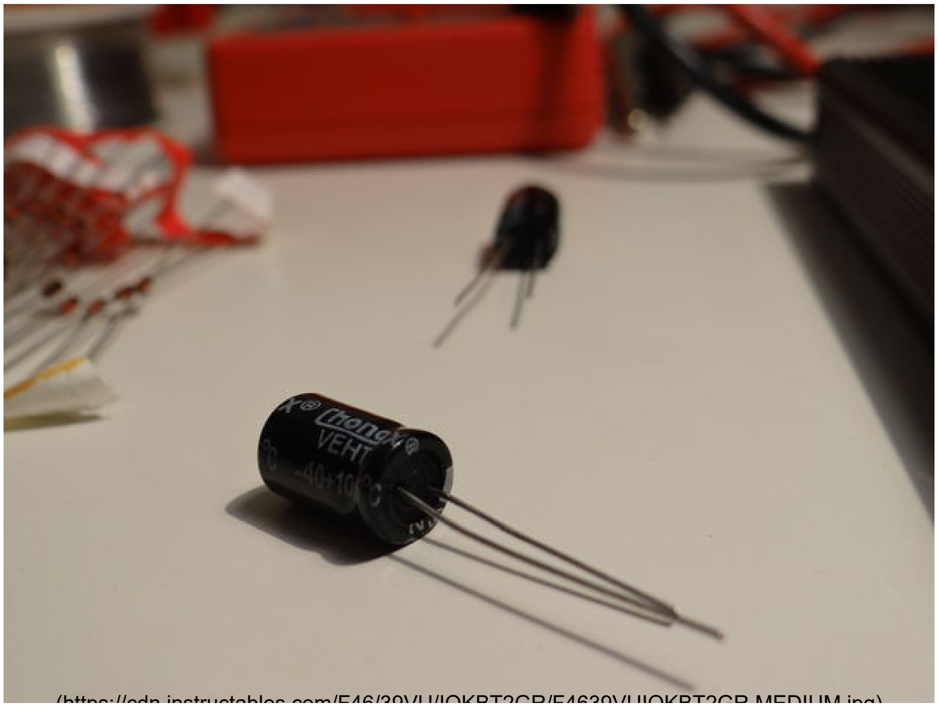


(https://cdn.instructables.com/FX

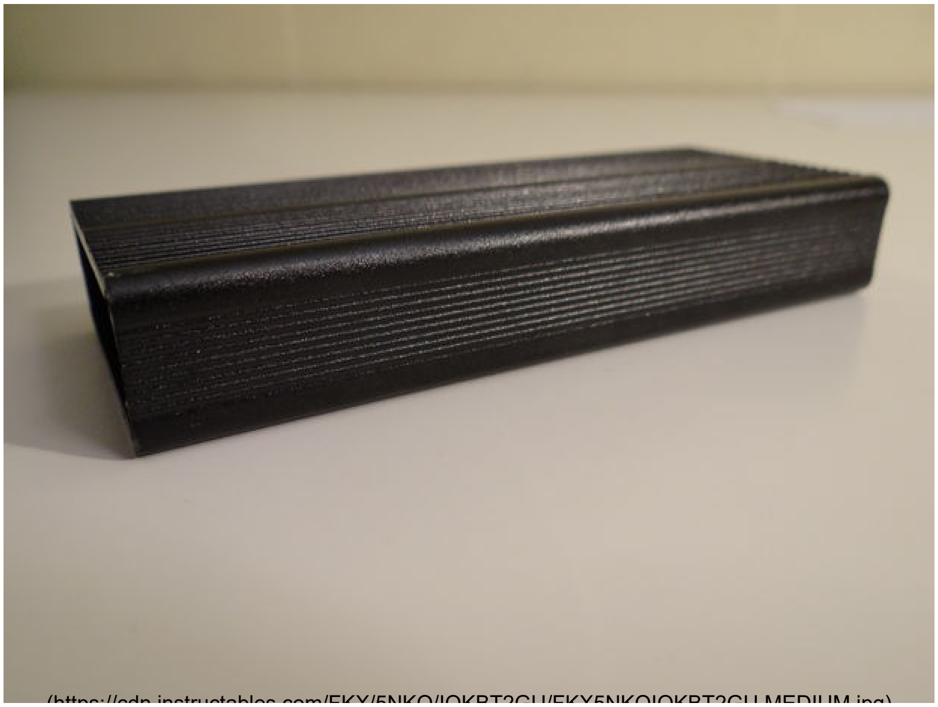
(https://cdn.instructables.com/FX



(https://cdn.instructables.com/FII



(https://cdn.instructables.com/F46/39VU/IQKBT2GP/F4639VUIQKBT2GP.MEDIUM.jpg)



(https://cdn.instructables.com/FKY/5NKO/IQKBT2GU/FKY5NKOIQKBT2GU.MEDIUM.jpg)

One of the reasons this particular renewable energy harvesting method is so viable is the relatively few and easy to obtain materials required.

The simplest crystal receiver design needs no power and can be built with only three parts: a coil, a crystal and a resistor. We're going to optimize that design in order to produce a cleaner and more reliable output signal by first polarizing the input amplitude, then rectifying and filtering the signal. Then we'll add an antenna, case and connections.

Get the circuit diagram here (http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html)
Get the kit here (http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html)

The parts for the circuit include:
(1) Circuit Board (http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html)
(1) 10-18 gauge Copper Wire
(2-12+) Ceramic Capacitors (matched)
(2-6+) Electrolytic Capacitors (matched)
*note various types of capacitors can be used
(4) Germanium Crystal Diodes (1A+)

Total Unit Cost: +/- **$0.40** (USD, scaled for volume of 1,000+ units)

In addition, you'll probably want to get:
(1) Project box (optional)
(1) Antenna (a loop antenna or elevated antenna is recommended and can be made with copper wire)

The tools you'll need are:
Soldering Iron/ Solder (optional)
Multimeter
Oscilloscope (http://www.seeedstudio.com/depot/DSO-Nano-v3-p-1358.html?cPath=63_65) (optional)

That's it. Yup, that's all. Once we've got it all, let's begin.

Step 2: Build the Circuit

We're going to build the simplest version of this circuit variation in order to understand how each component interacts and as a proof of concept.

There are three simple systems at work in the circuit that are composed of capacitors, which store energy, and diodes that direct it.

Energy in the band of radio waves, among others, will vibrate a wire antenna on an atomic level, sending a discernible signal to its lead. This signal will then meet the junction between two ceramic capacitors wired in series. This junction will force positive charge from the wave to travel in one direction and negative charge in the other direction which, when collected again, makes the signal uniform and polar. Connecting the two capacitors in series creates leads on each end; the now positively charged side of one and the now negatively charged side of the other creates a two cell battery.

This next stage of the circuit takes a signal with a net value of zero, adds the absolute values of the positive and negative amplitudes with respect to the origin and produces a positive integer. This concept can be thought of as taking:

(+1) + (-1) + (+1) + (-1) = **0**

and converting it to:

| [(+1) + (+1)] | = **2**
+
| [(-1) + (-1)] | = **2**
= 4

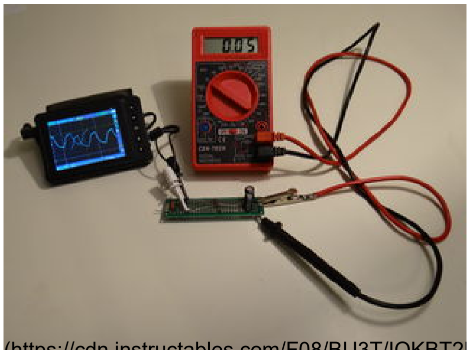
Isn't math fun?

To each of these leads from our two capacitors in series, we will connect two crystal diodes, one facing each direction, to form what is called a bridge rectifier. A bridge rectifier is a configuration which will convert an alternating current to a direct one by cleverly rerouting the signal.

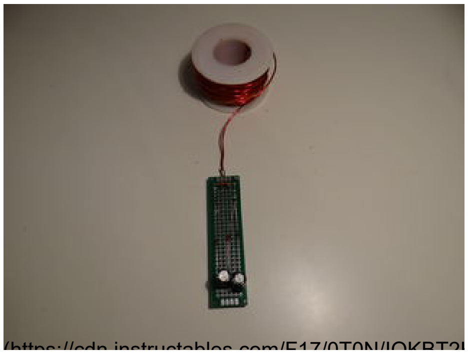
By connecting the bridge rectifier as shown in the circuit diagram, this direct current from the diodes then charges the electrolytic capacitors. This stage normalizes the amplitude, making the current constant and usable.

Components can easily be twisted together for testing and then soldered to a circuit board to secure.

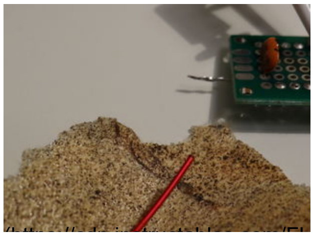
Step 3: Test and Optimize Your Circuit



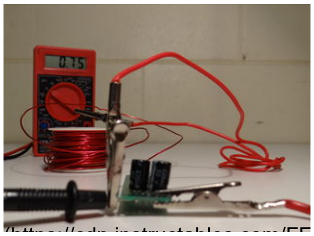
(https://cdn.instructables.com/F08/BU3T/IQKBT2



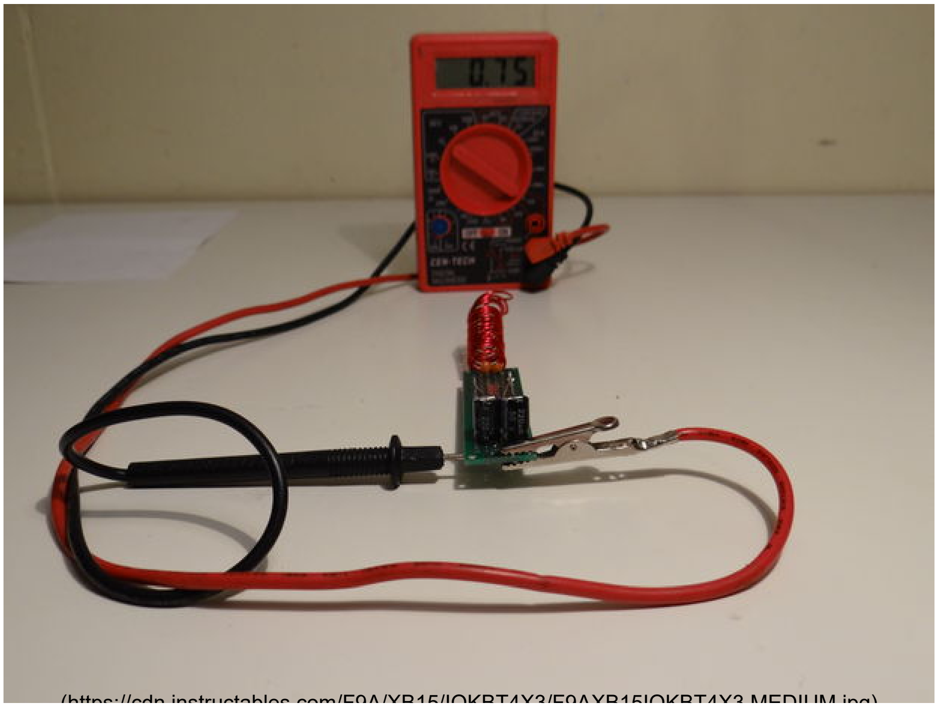
(https://cdn.instructables.com/F17/0T0N/IQKBT2



(https://cdn.instructables.com/FK



(https://cdn.instructables.com/FF



(https://cdn.instructables.com/F9A/YB15/IQKBT4X3/F9AYB15IQKBT4X3.MEDIUM.jpg)

(https://cdn.instructables.com/FOD/30OB/IQKBT

(https://cdn.instructables.com/F6T/0GE2/IQKBT4

To test and analyze our circuit, we'll be using a digital voltmeter and oscilloscope.

By connecting a voltmeter to the output, we'll immediately begin to see a small voltage climbing in the 10-100mV range. If not, we'll want to check our connections and make sure the circuit is not isolated from the environment by taking it outside to a clear area.

Then, by connecting an oscilloscope to the outside leads of our two ceramic capacitor bank, we will see the the polarized signal being captured from the air around us. We can then connect after the diodes to see our varying direct current and then to after the electrolytic capacitors to see a normalized, usable direct current at our output.

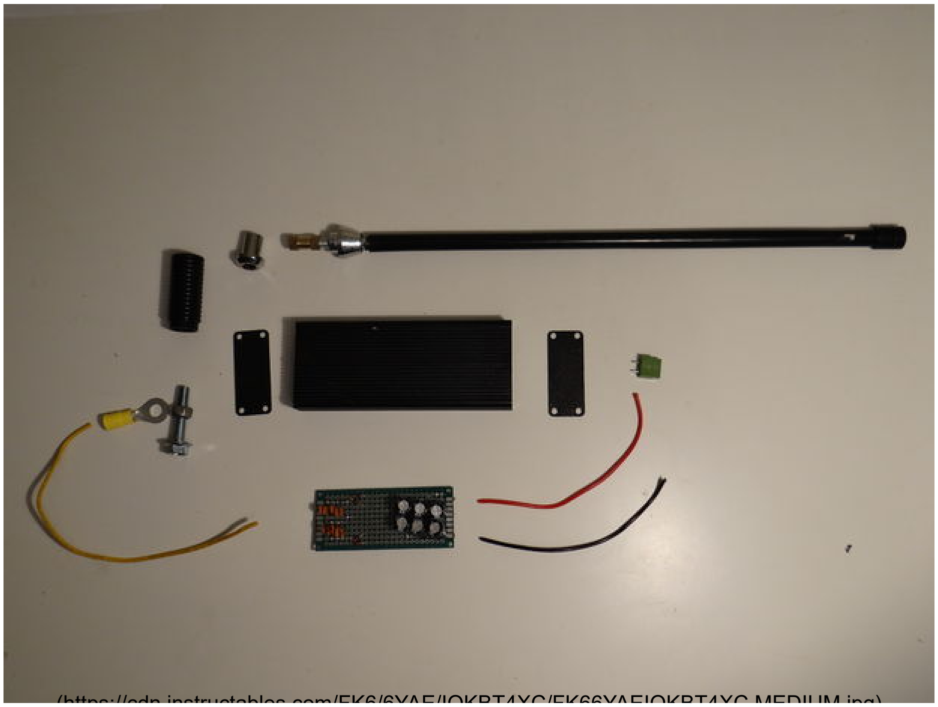
We can then optimize the input resistance in two ways. Firstly, we can add additional ceramic capacitors in parallel to our original two and make sure our soldered connections are consistent and thick in this area.

We can optimize the circuit's capacity by adding electrolytic capacitors in parallel to our original two which will allow this circuit to charge slightly when not in use. For this purpose, a charging circuit can also be added here in order to incorporate an optional battery bank.

We can optimize the antenna by attaching loops and coils of copper wire in various positions, store-bought antennas or by stringing some wire up to the highest point you can reach.

We don't have to stop there, either. We can now connect multiple circuits in series to increase voltage or in parallel to increase current. This can be done indefinitely.

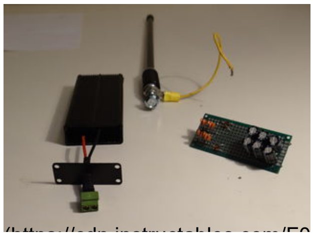
Step 4: Add a Case and Antenna



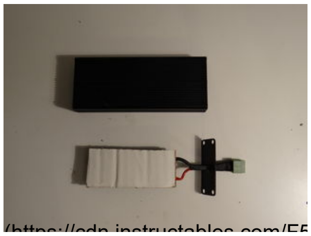
(https://cdn.instructables.com/FK6/6YAF/IOKRT4XC/FK66YAFIOKRT4XC.MEDIUM.jpg)

(https://cdn.instructables.com/F62/QRPB/IOKRT4

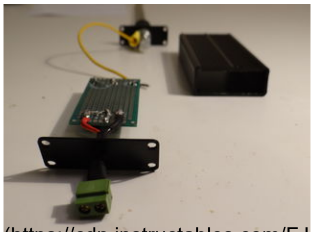
(https://cdn.instructables.com/F9JW9R4/IOKRT4



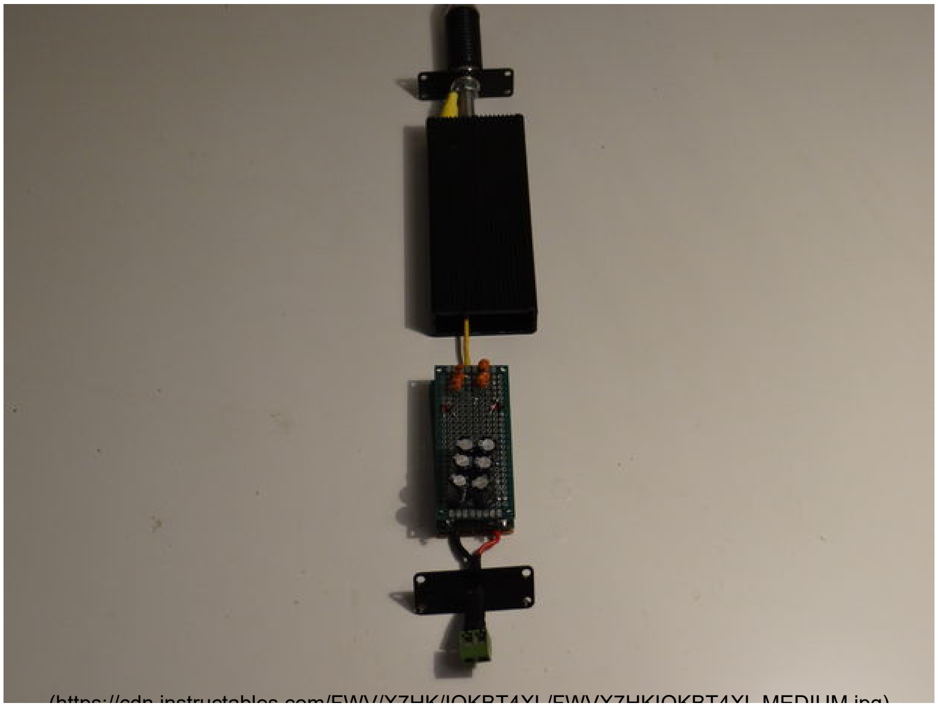
(https://cdn.instructables.com/F9



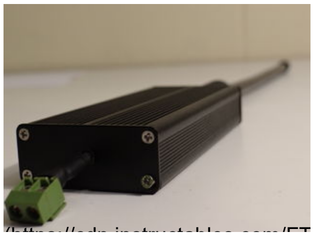
(https://cdn.instructables.com/F5



(https://cdn.instructables.com/F



(https://cdn.instructables.com/FWV/XZHK/IOKRT4XL/FWVXZHKIOKRT4XL.MEDIUM.jpg)



(https://cdn.instructables.com/FT

(https://cdn.instructables.com/FN

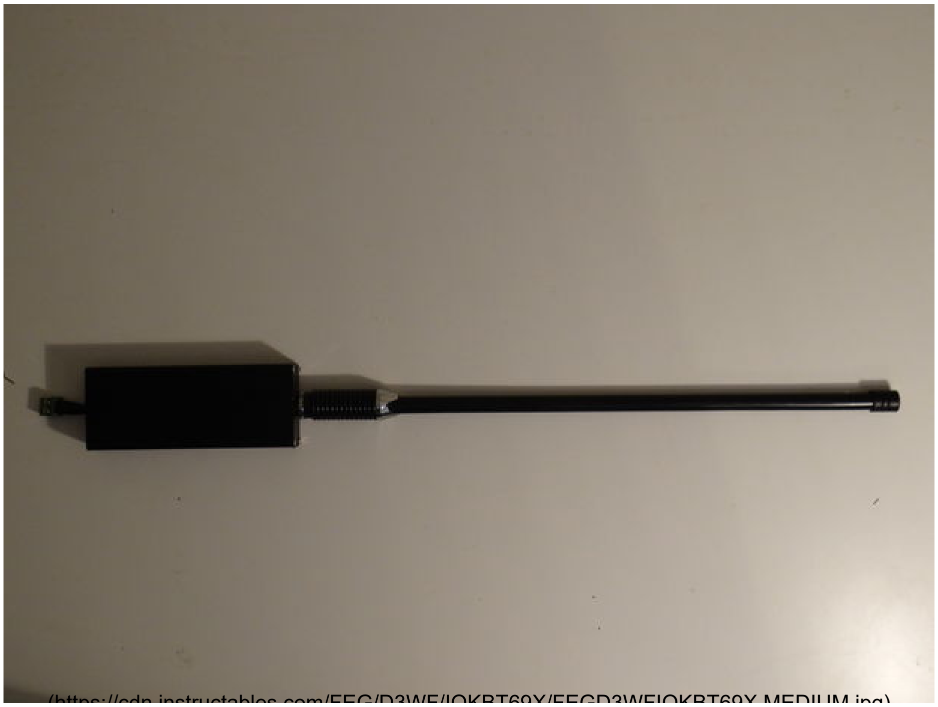
(https://cdn.instructables.com/FR

After choosing an antenna in the last step we'll now want to permanently wire it. Whether you choose a compact antenna for portability or a tall fixed antenna for power and range, we will wire it in the same manner according to the diagram in the previous step. Note that the input on the configuration here is grounded to the metallic case, and thus the users hand, and incorporation of longer antennas will require proportionally more substantial grounding.

We will then attach a terminal to the output to allow us to connect this circuit to an electrical device or charging circuit and battery bank.

Next, we will add a case, making sure to isolate exposed leads with non-conductive material especially if mounting in a conductive case. A piece of cardboard secured with glue is sufficient for the circuit's bottom and shrink wrap or electrical tape can be used in the case of any additional exposed leads. Drill two holes in your enclosure, one for the antenna or antenna lead and another for your output terminals. You can then insert your components, fasten the enclosure and your device is ready to use!

Step 5: Your Crystal Energy Receiver Is Complete!



(https://cdn.instructables.com/FEG/D3WE/IOKBT69X/FEGD3WEIOKBT69X.MEDIUM.jpg)

(https://cdn.instructables.com/FY4/8V5I/IOKBT4X

(https://cdn.instructables.com/FLD/DTVI/IOKBT4X

(https://cdn.instructables.com/F1J/6B39/IOKBUZ

(https://cdn.instructables.com/FXB/6LU4/IOKBTC

Your Crystal Energy Receiver is now complete and ready to use!

I built a portable version, for proof of concept and demonstration purposes. However, you can go as big as you want- to passively charge batteries or run equipment remotely; or go as small as you want- to power sensors, RFID devices, small electronics and more.

I used this harvested energy to easily power a low-consumption quartz clock, a digital chronograph with integrated circuits and LCD and was even able to momentarily rotate a small dc motor.

Because of its simplicity this device is a durable, efficient and reasonably effective method of harvesting radiant energy in a simple, replicable and sustainable way. I humbly hope that the contributions made here, and by those reading, can be one day used by people worldwide to conveniently capture free energy.

Thanks for checking out my project and I look forward to seeing everyone's variations, suggestions and improvements!

1: what rating capacitors (ceramic)?

2: what rating capacitor (electrolytic)?

3. why both types of capacitors and not one type?

4. You've mentioned grounding to earth, but where is the grounding line?

5. Looking to make this a kids' project to charge a phone so expanding these size isn't a problem at all.

DrewPaulDesigns

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ Dornier (/member/Dornier/)

2017-07-29 Reply

Thanks for checking out my project. A lot of these questions are covered in the Instructable but I will answer them briefly for you.
The ceramic capacitors used are 104s and their purpose is to polarize the charge. Electrolytic caps are 50v rated and are used to hold the charge in order to provide a usable current. In this example the ground is connected to the case, and thus grounded through the users hand. Scaling this up for that purpose will require a more significant antennae, ground and wiring up multiple circuits in series which is covered in more detail in the article.
Let me know if you have any other questions and be sure to post your project pictures here when you're done for everyone to see!

Loveforcats (/member/Loveforcats/) 2017-07-17 Reply

Hey,how much maximum voltage can be obtained at the output by adiing capacitors in parallel....????

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ Loveforcats (/member/Loveforcats/) 2017-07-17 Reply

Thanks for checking out the project. Great question. Adding capacitors will only increase the capacity (mAh). If you want to increase voltage you can build multiple circuits in parallel and make sure your antennae is as tall as possible.

Loveforcats (/member/Loveforcats/) ▸ DrewPaulDesigns (/member/DrewPaulDesigns/) 2017-07-26 Reply

I dont want to place my antenna on roof top.I want a min of 5 volt and max of 20 volts and a portable circuit.So what shud i add to the circuit for getting it.??? and what kind of antenna shud i make..??

sir, why the first kit show value 0.75v and the second kit show value 3.50v,

what is different make? (coil turn, coil component, total component, etc..)

Raghdado (/member/Raghdado/) 2017-07-04 Reply

What a nice instructable! But I have few questions though, if you don't mind.
How long did it take you to complete the project?
How much did it cost you?
Would it be realizable for the duration of one month only (for a beginner)?
And most of all, Could you tell me about the output (after testing)?

Thank you :)

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ Raghdado (/member/Raghdado/)

2017-07-04 Reply

Thank for checking out my instructable! This project can be done in an afternoon and the kit can be found here: http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html

Before getting started you will also want to get a soldering iron and take some time to practice with it.

Just follow the instructable carefully and you will have no problem.

You can get everything you need here: http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html

frisbrob (/member/frisbrob/) 2017-03-30 Reply

I am always looking for ways to generate power, mostly because it's fun but most of our renewable energies have their down sides. Solar only works while it's day time, wind only works while there is wind. I don't know about where you live but here in Sandy Utah there is no sun at night and at night during winter or summer there is no wind at night, so that takes care of generating power at night. I have looked at several of these pulling power out of the air things, I have even looked at finding Tesla's plans and there is nothing usable. I don't know how to do the math to figure out what parts are needed to build these diy collectors and generators. To me it sounds like you would need an entire back yard to hold anything big enough to do any good, most of the things people build might charge a cell phone but that's about it. If I was to build this unit but big enough to constantly run an 800 watt unit, how big would the antenna need to be and what parts would I need? Just curious.

PhillipH50 (/member/PhillipH50/) 2017-03-12 Reply

I think what you should look into is tuning this simular curcuit to recieve in the frequency range of 7.83hz to 8.4hz. Because this is the earths magnetical resonance frequency. Tesla's paper state that 1 meter = 100v on a horizontal wire. So at 3 feet tuned into this frequency can produce 100v and at 6 feet produce 200v, ect..
About 10 years ago there was a video that was taken down of a Russian man who was demostrating his setup with a hand full of scientists. I don't remember all the details but one thing I do remember was that his antenna was 68 feet of 14 gauge copper wire hanging 6 feet above the ground horizontally. The ground stake was 1/2" rebar 6' into the ground.

You can look into these frequencies by searching "Schumann resonances are global electromagnetic resonances in the cavity formed between the earth’s surface and the ionosphere. "

Just some of my thoughts..

---

tatebullrider (/member/tatebullrider/) 2017-02-09 Reply

Great instructable!! Just a quick question though. So the higher the antenna is in the atmosphere the better? And if so, you could (in theory) use a long thin wire attached to a kite or a weather balloon to temporarily generate more power, correct?

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ tatebullrider (/member/tatebullrider/) 2017-02-09 Reply

You got it. You could use a kite or even a drone or quadcopter to take measurements at different altitudes. Post your data for us to see!

16me121lucifer (/member/16me121lucifer/) 2017-01-07 Reply

Sir i am getting 0.06v but negligible current. I am unable to light a LED. I wanted to know how can we connect similar circuits in series or parallel. I would be grateful if you upload a schematic diagram for the same.
Thank you.

16me121lucifer (/member/16me121lucifer/) 2017-01-02 Reply

Dear sir,
Can i use antenna of my old radio set to complete the given project?

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ 16me121lucifer (/member/16me121lucifer/) 2017-01-02 Reply

Yes, you may. In fact, that is what it was designed for; you'll just using that energy for a different purpose. From there, the taller the antennae you use, the better the results.

Alijo0nn (/member/Alijo0nn/) 2016-12-30 Reply

Dear Paul

Is it possible that this circuit generates 1 ampera current with highest place of Antenna and suitable Earth?

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ Alijo0nn (/member/Alijo0nn/) 2016-12-30 Reply

A single circuit, no. However, by running these circuits in parallel current can be increased to suit your output needs. Thanks for checking out my Instructable and if you have any other questions feel free to let me know.

I not trying to be rude but how do you get free energy from nothing? Unless you do this under a high voltage power line (very dangerous) i am not sure if this would work?

In state matter is neither created or destroyed so were is this energy coming from??

2016-11-07 Reply

Not at all and this is a very good question.

As Faraday and others have demonstrated, magnetic bodies in motion produce an electric charge. If you've ever used a magnetic compass, you know that the earth, along with orbiting bodies, are magnetic with a north and south pole. These moving bodies induce a charge in our atmosphere. This charge, with our new Crystal Energy Receiver, can be captured and harvested as usable energy.

Thanks for reading. Give it a try and be sure to follow and visit www.DrewPaulDesigns.com for more projects.

Brandonoutdoors (/member/Brandonoutdoors/) 2016-11-04 Reply

i like this "ible". I'm seeing a lot of negative comments though so I want lend my support to the author.
In no way is converting radio waves into electricity stealing. I mean think about it. When you turn on a radio to listen to music nobody bills you for the radio waves. They are paid for by ads.
With a homesteader in mind who may not live anywhere near transmission lines could use somthing like this at a larger scale (our planet is saturated in rf). when radio waves cross your property line they become yours to do with what you will (in my opinion). I say build (or buy) a large antenna and start experimenting with a larger scale.

good project

rah187 (/member/rah187/) 2016-07-22 Reply

Cool project! I have favorited this instructable and it is possible that I will eventually construct it. This circuit is actually very simaller to a few others I have seen on the internet, all of which produce around three volts. I have even seen people use crystal radio sets to generate electricity for LEDs. Of course, there are limitations to this setup, including the very low current and the fact that making this unit much larger than it already is may be considered illegal. The truth is, nobody would probably care about one device running off of the RF, seeing as seemingly innoccuous grounded objects such as flagpoles can also "steal" radio waves. However, I am glad I read through the comments before making a gigantic fractal antennae and getting myself in trouble.

Lolz its ??? Nano amperes and 0.06 v

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ İlhamiA1 (/member/%C4%B0lhamiA1/) 2016-07-18 Reply

Eureka! You got it working! You now have proof of concept. Now it's time to increase your current.

First, try extending the antennae all the way to the highest point you can find (try your roof). Then connect a ground lead to the junction between your output terminals (between the two electrolytic caps in series) and run that to a piece of steel rod pressed into the dirt.

Once that is complete, you can optimize it even further! Now, with your antennae and ground set up start wiring in more circuits. Wire them in series, parallel or both according to your needs. Put all of the components on the same circuit board for a supersized version.

Thanks for checking out my 'ible! I hope this helps!

unbottled19208306 (/member/unbottled19208306/) 2016-07-10 Reply

When you say the 2 12 and 6 matched caps, do you mean 12 and 6 volt caps?

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ unbottled19208306 (/member/unbottled19208306/) 2016-07-11 Reply

The voltage capacity is variable, however it is important to use matching pairs of both ceramic and electrolytic capacitors. Thanks for checking out my project and let us know how yours comes out!

Arghus (/member/Arghus/) 2016-06-23 Reply

can u get it to 5v? for a usb port?

RowanS1 (/member/RowanS1/) ▸ Arghus (/member/Arghus/) 2016-07-01 Reply

yes its possible but current would be too low to be usable

RobertH7 (/member/RobertH7/) 2016-06-13 Reply

Congratulations! You built a full-wave rectifier! You passed the first chapter of basic electronics.

Unfortunately, this particular rectifier is an extraordinary waste of time. It produces a negligible amount of power. Your oscilloscope voltage reading is meaningless. Power is voltage TIMES current, and something like this will produce current in the range of nano-Amperes.

Just get some solar cells and call it a day. They absorb energy from the peak of the sun's blackbody radiation spectrum (which happens to be visible light), not in the negligible radio frequency range. The cheapest, least efficient solar cells out there will produce orders of magnitude more power.

NASA's Constellation Program for Exploration of the Moon and Mars places human crews in extreme isolation in resource scarce environments. Near Earth, the discontinuation of Space Shuttle flights after 2010 will alter the up- and down-mass capacity for the International Space Station (ISS). NASA is considering new options for logistics support strategies for future missions. Aerospace systems are often composed of replaceable modular blocks that minimize the need for complex service operations in the field. Such a strategy however, implies a robust and responsive logistics infrastructure with relatively low transportation costs. The modular Orbital Replacement Units (ORU) used for ISS requires relatively large blocks of replacement hardware even though the actual failed component may really be three orders of magnitude smaller.

The ability to perform in-situ repair of electronics circuits at the component level can dramatically reduce the scale of spares and related logistics cost. This ability also reduces mission risk, increases crew independence and improves the overall "supportability" of the program. The Component-Level Electronics Assembly Repair (CLEAR) task under the NASA Supportability program was established to demonstrate the practicality of repair by first investigating widely used soldering "materials and processes" (M&P) performed by modest manual means. The work will result in program guidelines for performing manual repairs along with design guidance for circuit reparability.

The next phase of CLEAR recognizes that manual repair has its limitations and some highly integrated devices are extremely difficult to handle and demand semi-automated equipment. Further, electronics repairs require a broad range of diagnostic capability to isolate the faulty components. Finally repairs must pass functional tests to determine that the repairs are successful and the circuit can be returned to service. To prevent equipment demands from exceeding spacecraft volume capacity and skill demands from exceeding crew time and training limits, the CLEAR project is examining options provided by non-real time tele-operations, robotics, and a new generation of diagnostic equipment. This paper outlines a strategy to create an effective repair environment where, with the support of ground based engineers, crewmembers can diagnose, repair and test flight electronics in-situ. This paper also discusses the implications of successful tele-robotic repairs when expanded to rework and reconfiguration of used flight assets for building Constellation infrastructure elements.

I. Introduction

NASA's plans for long duration missions to the Moon and, especially, to Mars require a much greater degree of self sufficiency on the part of the crew than ever before. Such missions will have greatly reduced logistic support from Earth, compared to International Space Station (ISS) operations. Returning to Earth in the event of an emergency may not be an option either, as a lunar return flight could require two to three days, and a Martian return flight will require much longer.

One area of mission support that NASA must plan for is electronic repairs. Despite the rigorous testing required by NASA, electronics faults have already occurred in both Space Shuttle and ISS operations, leading to the use of backup systems or loss of capability to some degree[1,2]. While the electronics and other systems used in a long duration space mission will undergo rigorous testing, the crew of such missions will most likely encounter an electronics failure at some point in the mission. With the design of the Crew Exploration Vehicle (CEV) already beginning and likely influencing the design of future spacecraft and hardware, it is not too early for NASA to begin exploring and designing techniques and tools for crew members conducting electronics repair during long duration space mission. These considerations include system design (for accessibility, parts type and sizes, and board complexity), repair infrastructure (including diagnostic capabilities, tools, and other needed equipment), and logistics constraints. The decisions on how to approach each of these considerations depends on the overall repair strategy chosen.

---

[1] Aerospace Engineer, 21000 Brookpark Rd., MS 110-3, AIAA Member
[2] Electrical Engineer, 21000 Brookpark Rd, MS 86-5

The historical approach to electronics repair on manned spaceflight missions (particularly those aboard the International Space Station, or ISS) has been to replace modular subassemblies called Orbital Replacement Units (ORU's). The astronaut simply replaces the malfunctioning ORU with a spare, and then returns the faulty ORU to Earth, where it is diagnosed and repaired, then returned to a pool of spares awaiting re-use in space. This approach allows for simplicity in the diagnosis of the problem, as the fault only has to be isolated to a given ORU, rather than determining the fault down to the component level. Crew training and experience in performing repairs are minimized. Also there is a high degree of confidence in the repair, as the ORU can be tested extensively on the ground prior to being re-launched to the ISS.

Conversely, this approach carries with it a severe penalty in terms of the logistics support required (and overall cost to the program). Conceptually, it is easy to imagine the penalty in mass and volume that is levied when an entire ORU (which may weigh ~25 lbs or more on Earth) is launched to remedy a failure of a single, small component such as a resistor, transistor, or other electrical component. While this approach is expensive, it may be acceptable for low Earth orbit (LEO) missions if they are re-supplied regularly since large quantities of spares would not need to be stored on orbit.

Alternatives to the ORU are lower-level repairs which can include shop-replaceable units (SRU) such as circuit board-level swap-outs and / or a component-level repair strategy. This could serve to greatly reduce the planned-spare ORU requirements, while providing a capability to handle unforeseen repair contingencies. The need to handle such unexpected events has been illustrated by several events in NASA flight history. The successful conclusion of the Apollo 13 mission, after an explosion severely damaged the service module, highlights the benefits of having the capability to implement on-the-spot repairs. The consequence of failing to allow for off-nominal repairs was demonstrated in the tragic loss of the shuttle Columbia; even if the crew had been aware of the problems with the leading edge tiles, they were not equipped to make repairs in-flight. Since that incident, NASA has made considerable efforts to allow for contingency repairs of problems of that nature[3].

The Component-Level Electronics-Assembly Repair (CLEAR) project under the NASA Supportability program was established to develop and demonstrate the technology necessary to allow crew-member to effectively perform electronic repair down to the component level. CLEAR involves collaborative efforts between NASA's Glenn Research Center, Langley Research Center, Johnson Space Center, the National Center for Space Exploration Research, and the U.S. Navy. The overall processes involved with repair which are the objectives of the CLEAR task are composed of four primary elements:

1. Capability to diagnose an electronics assembly and identify the faulty component(s) with equipment that fits within the mass-volume and power constraints of spacecraft.
2. Capability to repair electronics down to the component-level on-orbit with processes and materials that are safe and compatible with the space environment which allows the crew to make the necessary repair.
3. Capability to evaluate and determine that the repaired circuit is safe to return to service.
4. Capability to augment the flight crew with knowledge and skills to diagnose faults and perform repairs without expanding crew size.

This multi-faceted program utilizes a cross-disciplinary approach to examine pre- and post-repair diagnostics and functional test; material and process for repair such as component soldering, conformal coatings removal and replacement; and electronics design for supportability. These areas are investigated by a combination of trade studies, analysis, ground based testing, reduced gravity aircraft testing, and actual spaceflight testing aboard the ISS in multiple experiments. This paper provides an update to this task since previously reported at this meeting in the previous year.[4-5]

II. CLEAR Task Overview

A. Manual Electronics Repair

All repair scenarios for the Constellation Program (CxP) will include some manual repair capability in which the crew can make electronic repairs. Currently, the ISS has a soldering kit aboard which offers a very basic capability and is a logical baseline for future capabilities. The soldering kit and tools available on-orbit are capable of basic repairs (e.g. wire splicing and some limited component-level repair). However, component-level repair has not been actually demonstrated using this equipment aboard ISS. The experience of the US Space Program with repairs is limited to a very few cases (e.g. ARCTIC-1 repair discussed below) and some basic experiments[6]. Before mission planners can expect to have a repair capability, it must be demonstrated in the field (i.e. to raise the technology readiness level, or TRL, to a level six[7]).

In a series of 2 flight experiments, the CLEAR project will demonstrate manual component-level repair using an augmented version of the soldering capability currently on ISS. The first experiment, called SoRGE, uses the soldering kit to investigate the basic materials and processes (M&P) involved with soldering in a microgravity environment using a through-hole configuration. The second experiment, called Component Repair Exp-1, intends to demonstrate all of the physical processes of end-to-end component-level repair of a circuit board. These experiments, which are discussed further below, utilize the Space-station Development Test Objective (SDTO) process to get aboard ISS (ref).

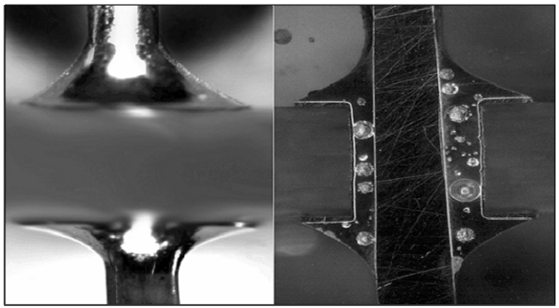

Figure 1: External profile of solder joint (left), and cross section of joint (right) showing internal voids.

1. *Soldering in Reduced Gravity Experiment (SoRGE)*

SoRGE is an experiment which is investigating the formation of solder joints in a microgravity environment (Figure 1). Results from earlier aircraft testing showed that void defects (bubbles /voids trapped within the solder) increased in joints formed in reduced gravity as those formed in normal gravity[8-12]. Joints were formed in various reduced-gravity environments including (nominally) Martian, Lunar, and zero gravity levels[*]. In these tests, the void fraction increased as gravity level was decreased. For joints formed in a nominally zero-gravity environment, the void fraction was 3-times higher than those joints formed in normal gravity. Changes in joint geometry were also observed, with the reduced-gravity joints being more symmetric.

The ISS experiment SoRGE is examining several techniques which may serve to mitigate the formation of voids in the solder joints. This experiment is comprised of a series of small circuit cards, with small electrical components (resistors) attached to the surface (Figure 2). The experiment has several kits, each of which is looking at various solder and flux combinations, to quantify and minimize the amount of void formation in solder joints. Also, this experiment will yield valuable information regarding the physical process of soldering in low-g with a crew-member who received only limited training.

This experiment was brought to the ISS by the Shuttle Atlantis during STS-115 and soldering was accomplished by Astronaut Sunita Williams (Figure 3) during February and May of 2007. Half of the available 12 test kits were completed and returned to Earth aboard STS-118 in August 2007. The samples were returned to GRC in October 2007 and are currently undergoing analysis. The planned analysis consists of a visual examination for solder process quality as well as non-destructive analysis to look at solder joint voiding. The results of this research will help specify the soldering process used in future in-space repairs.

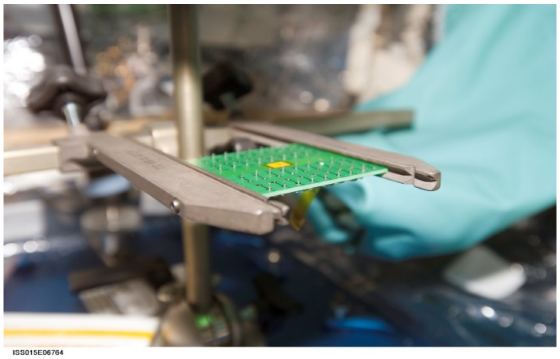

Figure 2: An image of the test card used during the SoRGE experiment.

ISS015E06767

Figure 3: Astronaut Sunita Williams conducting the SoRGE experiment during Expedition 14 aboard the ISS.

---

[*] Brief periods (~25 seconds) of reduced-gravity are experienced aboard these aircraft as they fly parabolic trajectories which are calculated to provide the desired relative acceleration levels.

2. SDTO2: Component Repair Exp-1 (CRE-1)

CRE-1 will demonstrate the physical processes of an end-to-end manual electronics repair in a microgravity environment. The physical processes include:

- Conformal coating removal
- Component removal
- Board cleaning
- Soldering a new component in place
- Reapplying conformal coating

Crew members will work on functional circuit boards designed to mimic those already in use. These board designs use standard circuit components and component spacing. These standard circuit components include through-hole parts, standard-pitch surface mount devices (SMD), and fine pitch SMDs with typical component spacing (Figure 4). The circuit boards also have three thicknesses of silicone room-temperature vulcanizing (RTV) conformal coating: a primed, 4-mil coating; an unprimed 15-mil coating; and no coating, allowing for continued operation should the crew encounter difficulties removing conformal coating. The repairs will be conducted within the Maintenance Work Area (MWA) aboard the ISS (Figure 5). The experiment will utilize the soldering kit available aboard the ISS as well as an augment tool set provided by the CRE-1 experiment. The goal of the tests is to evaluate the feasibility of performing component level repair and evaluate processes so recommendations to procedures, tool selection, crew training, as well as board design may be made. CRE-1 is currently at Kennedy Space Center awaiting a manifest opportunity to fly to the ISS.

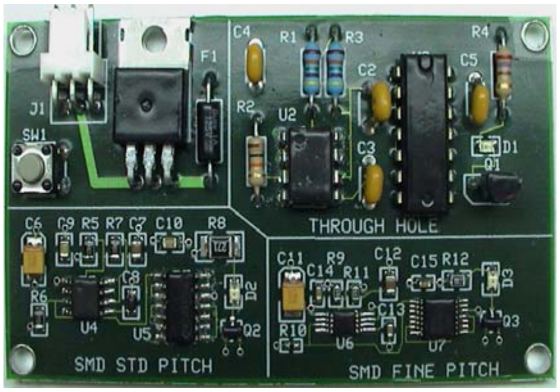

Figure 4: Image of CRE-1 circuit board

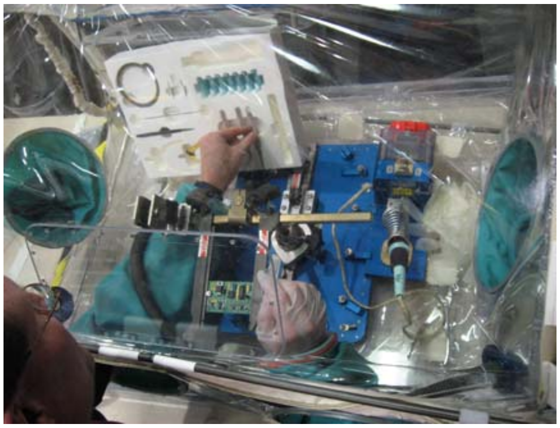

Figure 5: Testing of the CRE-1 experiment in the MWA mock-up at Johnson Space Center. Shown in the image are the auxiliary tools used to conduct manual repair of electronics.

3. Manual Repair Process Recommendation

The primary goal of the manual repair efforts is to develop a series of recommendations to the NASA CxP for processes, materials, tools, and training for crew members to perform manual electronics repairs during space missions. These recommendations will be built from the results of the on-orbit testing, ground based testing on the C-9 reduced gravity aircraft, and work in consultation with the U.S. Navy at the Naval Surface Warfare Center in Crane, IN. Additional work expected to begin in 2008 includes examination of possible conformal coating selection, both in manufacture and after a repair, that would help enable manual repair. It is anticipated that this recommendation will include future development areas needed to refine manual repair.

Analysis of Arctic Freezer Samples

Studying the results of electronics repairs actually performed on orbit will provide an insight into the actual, current capabilities and constraints of crew members performing these repairs. During Expedition-6, Astronaut Don Pettit attempted the repair of ARCTIC-1 (or the Arctic Freezer), a module used for the cold storage of experiment samples. This work included some aspects of electronics repair, including joining wires and connecting wires to component tabs (Figure 6), with the use of the soldering kit on the ISS. Nondestructive analysis and visual inspection of these joints, as well as, similar joints formed in normal gravity for comparison, is on-going and will aid in

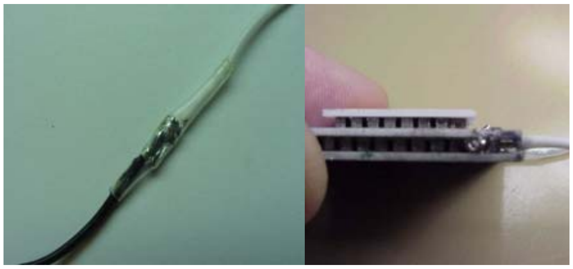

Figure 6: Typical solder joints examined from the repair of ARCTIC-1 freezer aboard the ISS.

evaluating the effectiveness of soldering in reduced gravity, especially in the mitigation of voids within solder joints.

C-9 Test Analysis

In February 2007, a series of solder tests were conducted on the C-9 reduced gravity aircraft which included the examination of various solder and flux combinations, most focusing on the use of no-clean or water-clean fluxes with eutectic solders. This work builds on previous aircraft tests[8-12], and will provide insight into general soldering and void mitigation techniques for reduced gravity operations. The analysis includes discriminating between samples based on the quality of the given in-flight performance (the aircraft parabola) as well as acceptance by a NASA flight qualified technician, based on NASA standards. Acceptable samples are nondestructively analyzed for void formation. Results from this analysis of a subset of these tests are presented in a complimentary paper at this conference[13]. These results will help develop criteria for selecting solder, flux, and techniques to be used for in-flight repair of electronics.

Crew Training Requirements (with U.S. Navy)

Crew training prior to a mission is vital for electronics repair. Crew members are presumed to have little or no prior experience in performing repairs, so training materials must prepare and reinforce the repair process. The team, working with a group at the Naval Surface Warfare Center in Crane, IN, responsible for preparing training materials for the U.S. Navy, will prepare and test crew training courses of 4, 8, and 16 hours, allowing NASA to tailor and choose a course suitable for electronics repairs. These materials are also planned to be available during flight as a refresher course and to prepare a crew member immediately prior to performing a repair. The team, together the U.S. Navy, will propose a tool set tailored to the level of crew training to allow crew members to effectively conduct the repairs they have been trained to perform.

B. Semi-Automated Repair

The previous section discussed hand or manually operated repairs used in the soldering and desoldering process. Manual repair will always provide an important repair capability, but it requires training and periodic practice to maintain proficiency. Manual repair also requires direct crew involvement throughout the repair process. A fully automated process such as in manufacturing requires special fixtures and equipment, along with a great deal of experimenting or system "tuning." For single unit repairs a mix of manual and automated operations is more practical and is most likely to achieve successful repairs within the spacecraft weight and volume constraints. Certain operations, such as wiping away process residues, are simple if performed manually but can be very difficult to accomplish by robotic means. Heating devices to narrow temperature bands and then quickly and precisely placing them demand automated operations. Semi-Automated repairs reduce the demand for high skill while increasing productivity.

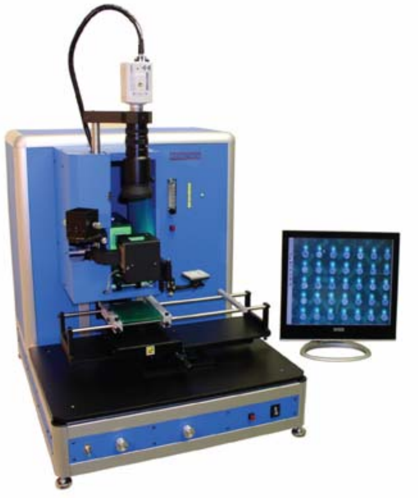

Figure 7: An ATCO AT-707 is typical of a commercial rework station capable of replacing high density integrated circuits. Photo from http://atco-us.com/.

Rework Stations (Figure 7) that melt or "reflow" solder with Hot Gas or Infrared heat evolved to handle complex devices. Such systems are semi-automated where manual operations involve alignment with optical aids but employ automated heating systems and mechanically guided placement. In this way, Semi-Automated rework stations extend repair capabilities to circuits not amenable to manual repair.

Figure 8 is a qualitative representation of how semi-automated technology can extend a repair capability. The vertical axis of Figure 8 qualitative represents how increased PCB layering increases board thermal conductivity. The increased conductivity increases heat transfer away from the solder joint(s) and may exceed the manual soldering iron's capacity. More advanced manual techniques (more advanced soldering tools than available on ISS) may include custom tips and board heaters to preheat the entire board to temperatures just below the reflow solder temperature. However, the high heat loads and long heating cycles require to solder the conductively cooled circuit boards, common in spacecraft, are more likely to be successfully repaired by semi-automatic systems.

The horizontal axis of Figure 8 shows increasing complexity in device packaging and lead count. At the extreme right is the Ball Grid Array (BGA) where lead counts may exceed 1000 and are impossible to solder by hand. Large integrated circuits like BGAs require simultaneous solder or desolder of many pins or solder balls and are best handled by semi-

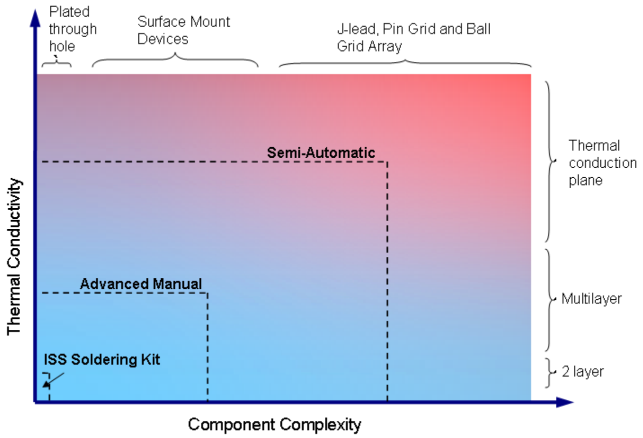

Figure 8: Graphic showing the increased repair capability offered by semi-automated repair technology.

automatic equipment to provide precise parameter control, such as, placement, coordinated motion, temperature ramp and soak profiles, and critical timing.

It is likely that the first operational need for repair capabilities is during long-duration outpost stays on the Moon and especially Mars. However, the ISS is a prime location to evaluate such technology and, because of the retirement of the space-shuttle in 2010, may benefit from a repair capability to help sustain systems with reduced logistical support. While the ISS and outposts share many similarities in terms of the environment, the prime difference is that there is significant gravitational force for the outpost whereas for ISS there is not. The semi-automated system is expected to employ or accommodate a variety of functions that include machine set-up, optical examination, process monitoring, a variety of mechanical repair operations (including soldering and de-soldering), handling and application of a variety of process fluids, and containment of solid debris and volatile products within the tight confines of a spacecraft or habitat. Before investing in specialized equipment, studies need to determine if the processes have any significant reduced gravity dependence, outgas, or other space environment sensitivity. The CLEAR task is in an early evaluation phase examining the general operation and capability of these stations, as well as the benefits and challenges for adapting them for use in space flight.

C. Diagnostics and Functional Test

While the physical repair of electronics in spacecraft and habitats is challenging, diagnosing faults down to the component level represent a bigger challenge. Furthermore, confidence of a successful repair must be accomplished via a functional test of the repaired board and/or subsystem. On the ground, NASA, the military, and industry all have practices, technicians, and equipment in place to perform diagnostics and repairs of electronics. Each group has adapted standard test equipment as well as customized equipment to perform the diagnostics particular to their requirements. None of these cases, though, have the volume, mass, power, and user experience level limitations imposed on them as for a long duration space mission.

Currently, ISS diagnostic and test equipment is limited to a portable Fluke Scope Meter®, a laptop logic analyzer and a limited output power supply and a special test set up to specifically test on-orbit multiplexer/de-multiplexer units. Such hardware is far from a complete diagnostic instrument set suited to test the array of systems including: electrical power, command & data handling, communications & tracking, guidance & navigation, and controls & display systems throughout spacecraft. Even if provided detailed information, it is beyond the most capable crews to fully understand diagnostic measurements of every spacecraft component. The next sections describe the strategy and technology that CLEAR is evaluating for diagnostics and test capability in future manned space missions.

NATIONAL INSTRUMENTS
NI PXI-1045
PXI

Figure 9: A representative National Instruments PXI chassis populated with a variety of instruments from different manufacturers. Photo from http://www.pxisa.org/.

Diagnostics

Repairs of circuit board assembles requires isolating faults to the component level. There is no single technology solution but success lies in focusing on the fundamentals of measurements rather than stacks of instruments. The challenge is selecting equipment and/or developing hardware that can cover the majority of diagnostic needs (as well as functional test discussed below) within the allowable mass and volume constraints of a spacecraft or habitat. The PXI (PCI eXtensions for Instrumentation) based suite of instruments (Figure 9) may be one potential solution. The advantage of such devices is the space saved by combining many PXI-based instruments into one bus. The drawbacks include requirements for instruments to be redesign into card format which is compatible with the bus architecture. Further, bus architecture often becomes obsolete. For example, the PXI architecture is currently being displaced by the new PXI Express.

Another approach would be to use Local Area Network (LAN) technology such as LXI (LAN Extension for Instrumentation). LXI instruments can be used in a coordinated suite of instruments or broken out as independent and portable instruments. High speed LAN based instruments are expected to resist obsolescence much longer. LXI instruments however, are not as compact as PXI. Recent industry trends indicate that a mixed system of LAN and Bus based instruments provide the best solution.

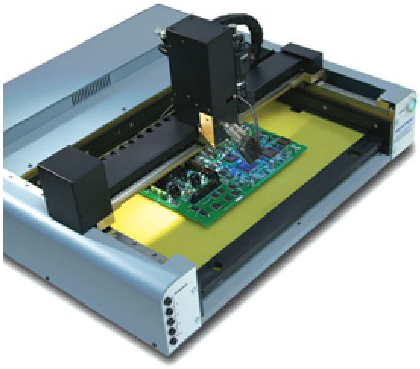

Figure 10: Huntron® ACCESS unit is an automated diagnostic system that employs circuit computer aided design (CAD) data and imaging to help guide the probing process. Photo courtesy of Huntron. Inc.

Diagnostics are often comprised of instruments that are used manually or programmed to automatically make measurements in a prescribed sequence. The instruments usually send stimulus signals and capture responses from the target circuit. For automated diagnosis, the same motion control capability used in repair can provide probing for diagnostics. One promising technology is the Analog Signal Analysis (ASA) technique used by the Huntron® ACCESS instrument to probe circuit nodes with a very low power signal that will not harm the circuit (Figure 10). This signal energizes single nets on the card to determine a characteristic waveform. A net is a common connection where multiple components are connected. This waveform is then compared with a known good board signature. If there is significant difference between the measured waveform and the known good waveform, one or more of the components attached to the net are defective. This approach reduces the number of components required to be replaced and minimizes the operator's skill requirements. However, ASA may not always isolate a fault to individual components, particularly, if they are not directly accessible. Complex Signature Analysis (CSA), being developed by CLEAR, is an alternative approach that relies on characterizing a circuit's self resonant and network resonant behaviors. CSA is expected to detect faulty devices that are inaccessible to ASA techniques. ASA and CSA both provide the ability to diagnose a circuit in a "power OFF" condition. Should ASA/CSA fail to isolate faults using a "known good board" technique, ASA/CSA can still capture measurements that could be further examined by knowledgeable ground based engineering. ASA/CSA operates on circuits in a "Power Off" condition which affords extra safety. However, it is often necessary to run tests on a circuit in a "Power On" condition to isolate functional problems such as software faults.

Functional Test Equipment

Functional testing is used to determine if a circuit is capable of performing its intended function before it is integrated into a system. It is often used to verify software functions that cannot be measured by fundamental diagnostic measurements. The actual functions of an ORU electronic circuit may be simple and repetitive. Most ORUs are part of a larger system and thus functionality may require interaction through multiple external interfaces. Functional test equipment often emulates the external system and operational conditions and includes additional "breakout" instrumentation to monitor interactions. Automatic Test Equipment (ATE) is employed when the number of channels and execution speed exceeds the capability of human operators. Typically, ATE systems are a combination of custom and off-the-shelf test equipment and software, with a software executive that governs the test process.

It is not uncommon for a single avionics box to require multiple racks of test equipment. In their terrestrial form, the weight and volume required for functional testers prohibits their use aboard spacecraft. However, functional test is an important part of any repair process and must be available. The ability to perform functional testing at the board level enables the generation of engineering data during the debug process. It also allows for the functional testing at the board level to minimize the risk of a circuit card damaging the system. Therefore, strategies for functional testing in spacecraft or habitat volumes require significant reduction of both mass and volume of terrestrial systems or newer technology. One such technology is offered by synthetic instruments.

Synthetic Instruments

Synthetic Instruments (SI) refers to an approach that exploits software and reconfigurable hardware to maximize the flexibility of test systems. Synthetic Instruments are implemented on generic hardware, typically, Field

Programmable Gate Arrays, (FPGAs). FPGAs are designed to provide a vast array of logic gates that can be configured to provide distinct data and control functions. Unlike software executed by microprocessors, the "Synthetic Instrument" programmed into the FPGA executes at extremely high speeds and with high levels of parallel processing. The FPGA can be reconfigured, on demand, as a completely new Synthetic Instrument. The latest generation of FPGAs can provide real-time signal processing which was once the domain of Digital Signal Processors. The main advantage of SI is that it allows us synthesize high performance instruments on an "as needed" basis.

The Department of Defense regards SI as a major advance in reducing (a) life cycle costs (b) time to develop and field new or upgraded test equipment, (c) test system logistics footprint, and (d) test systems physical footprint[14]. The strategy behind SI is to allocate any digitized functions to software. Innately analog functions, such as sensors, analog signal devices, and power sources are handled by modules that can be reconfigured electronically to provide wide operating ranges. In addition, to handle the vast variety of connector configurations, SI provides an upfront analog switching matrix that routes signals from a target test circuit to a selected analog instrument module. The CLEAR project is evaluating SI as part of a strategy to provide both diagnostic and functional test capability for a wide range of spacecraft electronics using only a small amount of physical hardware.

Both repair and diagnostics require significant skill and knowledge related to the circuit under test. Therefore, it is anticipated that the crewmember will require significant ground based support to debug issues. Furthermore, many of the process described above can be automatically controlled from the ground in a non-real time fashion. To keep the crew workload to a minimum, the semi-automated diagnostic and repair system should be amenable to tele-operations. Such operations also will allow data from the circuit under test to be available to ground personnel.

D. Tele-Operations: Linking the Crew to Knowledgeable and Skilled Support

In light of limitations on available technician-level skill and designer knowledge of the electronic systems, the key to success is to link the process to knowledgeable and skilled engineering staff though tele-operations. Other tele-robotic experiments focus on real-time control and real-time feed back while other robotic efforts focus on achieving total robot autonomy. Although crew autonomy is the desired goal, a likely strategy for a semi-automated diagnostic and rework station in spacecraft and habitats is to provide timely but not real-time interaction. The preferred mode is to avoid real-time "joystick" interaction with the hardware because the current infrastructure is prone to interruptions and signal delays.

For Lunar operations, the 4 second round trip transmission and system delays make real-time control awkward and even dangerous. The vast range of delay times for Mars makes real-time control impossible. Even the ISS has delays but also frequent "loss of signal" events which makes real-time control unreliable. Avoiding real-time interaction simplifies the communications and interaction and also provides an opportunity to "validate" commands prior to sending them to prevent costly and possible hazardous mistakes. Pre-scripted repair routines for anticipated needs will be developed. A potential solution to avoid the cost of a of support staff on standby, repair depots and manufacturers could support repairs on an "as needed" basis. The use of such a tele-operations capability is best captured by a Semi-Automated Diagnostic and Repair Operations scenario we describe below. This scenario is intended to illustrate how a diagnostic and repair tele-operation might proceed with a repair capability as shown in Figure 11.

Semi-Automated Diagnostic and Repair Operational Scenario

A vehicle health monitoring system reports a fault in a system ORU package. The faulty ORU is removed and replaced with a spare ORU which restores functionality to the system. Subsequently (as crew time permits and criticality requires), the faulty ORU is further diagnosed with a computer connected via an ORU test port. An internal Built-In-Tests (BIT) checks the diagnostic codes on all circuit boards. Ground support observes the diagnostics data via tele-operations. One circuit board fails to respond to BIT initiation. The subject board is removed from the ORU and interconnections were found to be good. Ground support asks the crew to move the board to the Semi-Automated Diagnostic and Repair Station and set up for further diagnostics and possible repair.

The board's failure to execute the BIT implies that the main processor is non-functional due to internal fault or failed supporting component. The ground support engineers examine high-resolution camera images down-linked from workstation but no visible damage is found. The circuit is equipped with a JTAG port and supports "boundary scan techniques[5]". The JTAG Boundary Scan Analyzer finds no problems at the I/O ports but reveals that several

registers are irreparably damaged, possibly due to radiation. Having isolated the component, the repair workstation is set up to remove and replace the device.

The ground crew determines that no prior repair routine exists so they go “offline” to create a repair program while the crewmember resumes other activity. Assisted with information from the vendor, the ground crew loads the circuit’s Computer Aided Design (CAD) data into a Repair Process Modeling Tool that aids in programming robotic operations of the rework station. The circuit’s registration points and exclusion zones are defined to prevent collisions with clamps and some taller board components. The Repair Process Modeling Tool defines motion paths, tool change points, including the component pick & place operations. Reflow heater position, heating profile are calculated using a reflow thermal simulation tool developed as part of the rework station. When the control code script is complete, it is run through a verification tool that simulates the process and shows a 3D animation of the process. Tool collisions discovered in the simulation are corrected and the code is determined to be error free.

On-orbit a “touch-off” of circuit registration points assures the machine motion is calibrated. The ground crew has determined that the conformal coating around the component should be removed manually because jumper wires interfered with mechanical methods. The workstation enclosure circulation filters capture any stray debris as the crewmember strips away the coating.

The control is then switched to automatic mode and the process is initiated. After the reflow heat cycle, a robotic pick & place tool removes the component. A quick manual wipe of the site removes any residue and a solder paste dispenser applies new solder. Another reflow cycle melts the paste while a component pre-heater prepares the new device. The robotic suction tools picks up and positions the new device and holds it until the last reflow heat cycle is complete.

An imaging camera scans the board for completeness and looks for debris. The tool is changed to an Analog Signature Analysis Probe and the preprogrammed probing sequence reveals that the board’s signatures are normal. Subsequent JTAG boundary scan and register checks are normal. Power up BIT tests also return normal results. Finally, the ground team has come up with code to program the SI system available on orbit to do a function test on the card. The board is connected via a cable assembly and the instruments go through a functional checkout of the circuit board with normal results. The board is then re-integrated into the ORU and BIT tests indicate functionality. The final assembly is complete and any configuration information is noted. Since the original ORU was replaced with a spare, this unit now becomes the next serviceable spare until needed. The ground updates any lessons learned and refines the repair program. After further simulations, the repair script is “canned” as a ready-to-run routine for future use.

Impact on the Future of Constellation

Extrapolating a future capability based on Earth based practices is not enough. On Earth, the economy of mass markets, low cost labor, low cost transportation, and very high production rates results in circuits that have short service life and are un-repairable "throw-away" electronics. Further, the design, materials, and processing choices are based on meeting economical production needs and often involve waste, aggressive chemistry and materials that are unsuited for space.

Understanding the behavior of basic materials in low-g and high vacuum and making the effort to fully exploit processes that are innately suited for space will lead to in-situ repairable electronic circuits. The extremely high cost of launching replacement hardware drives us toward electronic designs that provide long service life, but are also repairable, and can be reworked and reconfigured to serve alternate uses.

The spacecraft constraints imposed on the addition of new equipment are formidable. The development of several key capabilities will enable us to repair and rework spacecraft electronics without relying on Earth launched logistics. The CLEAR task is considering the strategy of compressing large test systems to small scale because of the huge cost of redesigning every known instrument into a small form factor. We are seeking alternate ways of diagnosing circuits by exploiting built in features where possible such as the JTAG Boundary Scan, and by looking at potential technology solutions such as Synthetic Instruments. Such concepts can be the first steps for a fabrication capability to help build infrastructure to support future missions.

The tele-operations developed for robotic repair can evolve into a fabrication capability as well. The experience learned from conducting repairs as well as the underlying materials and processes directly translates to operations for manufacturing with in-situ resources. Another possibility is to build additional infrastructure by reworking spent flight hardware for different functional use. This strategy need not wait for Mars – it can be employed and perfected in the Lunar Outpost phase. The near term need not be overlooked as the impact on logistics is already being felt as Space Shuttle support for ISS begins to draw to a close. By delivering capabilities starting with the ISS and then the Lunar Outpost, we can benefit from cost savings and early return on our development investments as well as gain confidence in their capability by the time we send humans to Mars.

Summary

NASA's historical solution to the problem of in-flight electronics repair has been the replacement of sub-units called Orbital Replacement Units. This approach requires significant logistical support through regular re-supply flights. For long-duration space missions, resupply flights are limited. Therefore, NASA is investigating component-level repair of electronics as a potential way to reduce the logistical footprint required to support future missions.

The Component-Level Electronics-Assembly Repair (CLEAR) project under the NASA Supportability program was established to develop and demonstrate the technology necessary to allow crew-member to effectively perform electronic repair down to the component level. CLEAR is looking at ways future exploration crew can, within the constraints of a spacecraft or habitat, (a) diagnose electronic assemblies and identify the faulty components, (b) repair electronics down to the component-level, (c) evaluate the circuit post repair via a functional test, and (d) augment the flight crew with knowledge and skills to diagnose faults and perform repairs without expanding crew size. These areas are investigated by a combination of trade studies, analysis, ground based testing, reduced gravity aircraft testing, and actual spaceflight testing aboard the ISS in multiple experiments. This paper provides an update to this task since previously reported at this meeting in the previous year.

Disclaimer

Certain commercial entities, equipment, or materials may be identified in this document in order to describe an experimental procedure or concept adequately. Such identification is not intended to imply recommendation or endorsement by the National Aeronautics and Space Administration, nor is it intended to imply that the entities, materials, or equipment are necessarily the best available for the purpose.

Acknowledgments

The authors wish to acknowledge Dr. Richard Pettegrew for his valuable technical contribution and leadership in the development of the CLEAR task. Also, the authors wish to thank Mr. Duc Truong of the NASA Glenn Research Center for his work and dedication. This work is funded by the Supportability Project in NASA's Exploration Technology Development Program Office (Mr. Barmac Taleghani, Program Manager, NASA Langley Research Center).

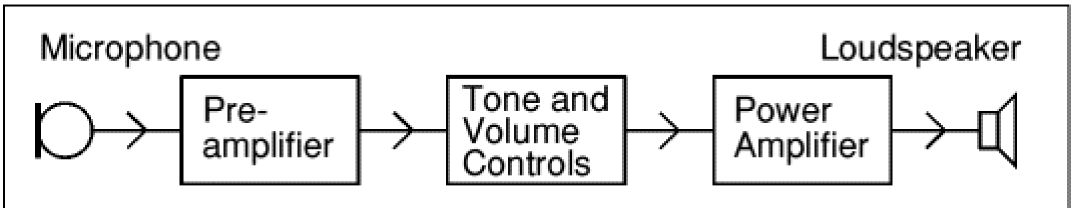
Block Diagrams

Block diagrams are used to understand (and design) complete circuits by breaking them down into smaller sections or blocks. Each block performs a particular function and the block diagram shows how they are connected together. No attempt is made to show the components used within a block, only the inputs and outputs are shown. This way of looking at circuits is called the **systems** approach.

Power supply (or battery) connections are usually not shown on block diagrams.

Audio Amplifier System

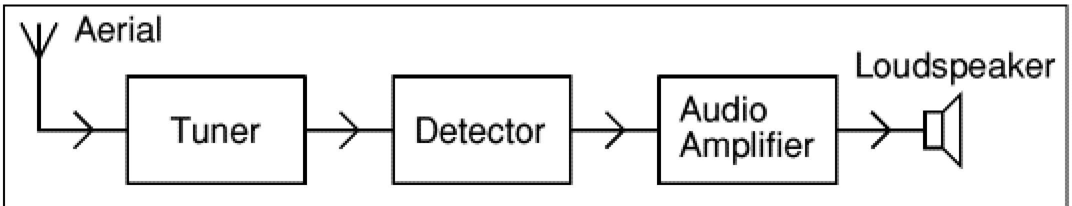


Block Diagram of an Audio Amplifier System

The power supply (not shown) is connected to the pre-amplifier and power amplifier blocks.

- **Microphone** - a transducer which converts sound to voltage.
- **Pre-Amplifier** - amplifies the small audio signal (voltage) from the microphone.
- **Tone and Volume Controls** - adjust the nature of the audio signal.
  The tone control adjusts the balance of high and low frequencies.
  The volume control adjusts the strength of the signal.
- **Power Amplifier** - increases the strength (power) of the audio signal.
- **Loudspeaker** - a transducer which converts the audio signal to sound.

Radio Receiver System

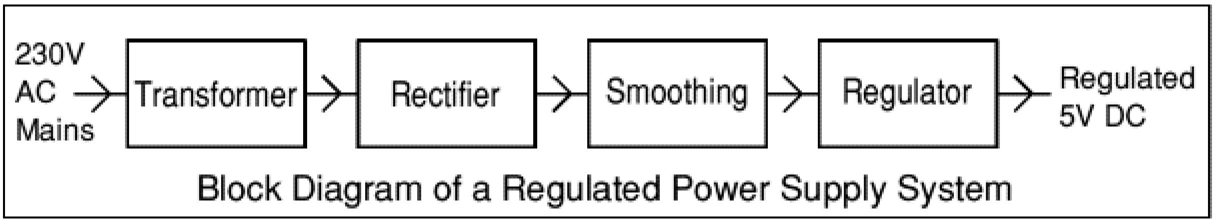


Block Diagram of a Radio Receiver System

The power supply (not shown) is connected to the audio amplifier block.

- **Aerial** - picks up radio signals from many stations.
- **Tuner** - selects the signal from just one radio station.
- **Detector** - extracts the audio signal carried by the radio signal.
- **Audio Amplifier** - increases the strength (power) of the audio signal.
  This could be broken down into the blocks like the Audio Amplifier System shown above.
- **Loudspeaker** - a transducer which converts the audio signal to sound.

Regulated Power Supply System



230V
AC
Mains
Transformer
Rectifier
Smoothing
Regulator
Regulated
5V DC
Block Diagram of a Regulated Power Supply System

- **Transformer** - steps down 230V AC mains to low voltage AC.
- **Rectifier** - converts AC to DC, but the DC output is varying.
- **Smoothing** - smooth the DC from varying greatly to a small ripple.
- **Regulator** - eliminates ripple by setting DC output to a fixed voltage.

Feedback Control System
